parties asked her what had become of that nice quiet old gentleman whom he used to meet every Wednesday evening at her house, and whose absence he had noticed for the last month. "That gentleman, sir," answered Madame, "was my husband; he is dead." Madame De Staël felt to its full extent the evil resulting from the immoral conventionalism adopted by the fashionable world, and she stigmatised it most energetically in *Delphine*, a novel which was published for the first time in 1802. This work produced the greatest sensation when it first came out; it was a revolution in the style of romance-writing. "Delphine," says Madame Necker de Saussure, "is Madame De Staël in her youth." Those fond of studying an author's character through the creations of his fancy, must have felt interested whilst perusing *Delphine;* but besides this, Madame De Staël there endeavoured to defend an idea, which is nothing else but a dangerous paradox. "Men ought to know how to set public opinion at defiance; woman must submit to it." Such is the text selected—a text so attractive, and at the same time so unsound, that it has, since 1802, been the favourite motto of a school in metaphysical literature. If Madame De Staël invented the *femme incomprise*, George Sand may be said to have vulgarised her. The principle which serves as a fundamental axiom to *Delphine* is essentially false. To quote Chénier, "Man ought not to defy public opinion; woman ought not blindly to bend before it. They should both sift it; accept it when it is legitimate; and reject it when it is erroneous. Right and wrong are invariable: the rules of propriety differ, it is true, according to the sexes; but nature does not condemn man to a life of scandal, and woman to a course of hypocrisy. Virtue and reason exist equally for both, and before those eternal limits all conventionalisms must stop. *Delphine*, as a novel, is more interesting from the sketches of character it contains than from the plot itself: M. de Talleyrand is painted to the life under the name of Madame de Vernon.

It is not our intention to give here a detailed account of Madame de Staël's numerous voyages during the revolution and the empire. We find her in 1793 at Coppet in Switzerland, where was her father's estate; she also visited England, and established herself at a house called Juniper Hall at Mickleham, near Richmond. There a colony of French refugees was speedily formed; the pressure of the times drove to foreign countries the most illustrious families of France, and several distinguished personages were the constant companions of Madame de Staël at Richmond. Count de Narbonne, Madame de la Châtre, M. de Talleyrand, General d'Arblay—such are a few names taken at random. Under the most distressing circumstances, the colony managed to keep up their spirits and to weather the storm. Occasionally they were reduced to very ludicrous shifts; we are told that this little party could afford to purchase only one small carriage, which took two persons, and that MM. de Narbonne and De Talleyrand alternately assumed the post of footman as they rode about to see the country, removing the glass from the back of the coach in order to join the conversation of those inside.

It was not without the greatest difficulty that Madame de Staël contrived to escape from Paris during the Reign of Terror. She had given dire offence by the independent way in which she acted, and by the sympathy she openly manifested for persons whom the "sovereign people" had visited with a sentence of proscription. Her letters on Jean Jacques Rousseau contain the following remarkable passage:—"N'éffacez point le sceau de raison et de paix que le destin veut apposer sur votre constitution; et quand l'acord unanime vous permet de compter sur le but que vous voulez atteindre, *prétendez à la gloire de l'obtenir sans l'avoir passé.*" The gifted writer had thus strikingly prophesied, six months before the convocation of the States General, the excesses into which the spirit of demagogueism was speedily to lead the revolution. The national convention, or rather the members of the famous *comité de salut public, did* go beyond the limits of legitimate reform; and they were not likely to deal mercifully with those, above all, who maintained the rights of liberty and protested against the tyranny of the mob. How to preserve her friends, how to harbour them, how to facilitate their escape, was the task Madame de Staël firmly and exclusively undertook, at a time when every attempt of the kind rendered her amenable to the guillotine. She thus saved the life of M. de Talleyrand, M. de Jaucourt, and M. de Lally-Tollendal. M. de Narbonne, ex-minister of war, was one of the persons on whose behalf she devoted herself most energetically. She watched the streets anxiously during one night when the police were hunting for him. His fate, if he were seized, would be instant death, and she knew that the search of her house must discover him. In this critical circumstance, the government agents called at the house of the Swedish embassy to make their dread domiciliary visit; one would think that only nerves of iron could maintain a calm appearance at such a moment. But she assures us that with her the case was otherwise. "We can always," she adds, "master our emotion, however violent it may be, when we feel that its indulgence would expose the life of another." Was there ever a nobler sentence penned?

Prior to the appearance of *Delphine*, Madame de Staël had published a work, which, together with the volumes on Germany to be presently noticed, contains the programme of her æsthetic system. It appeared in 1800, exactly one year previous to the literary *coup d'état* of M. de Châteaubriand. The title is, *On Literature considered in its relation to Social Institutions*."[1] Thus, nearly at the same time, from two opposite points of the horizon, rose two standards more intimately allied with one another than was thought at first; and round them were soon gathered those who had long felt the necessity of a literary revival. M. de Chateaubriand's fame has cast into the shade Madame de Staël's treatise, but the impression produced by the work we are now mentioning was strong and lasting. It was, in truth, a bold undertaking, both from the novelty of the opinions stated, and the frequent allusions to passing events; and Madame de Staël expected to meet with much bitter opposition.

Literature holds the closest and the most essential connection with the virtue, the glory, the liberty, and the happiness of a state; humanity is ruled by a law of perfectibility; and it is this law which, from time to time, has elevated the standard of public morality, together with the criteria of taste. The law of perfectibility is indefinite: guaranteed to the future as it was enjoyed by the past, it must follow the development of the social institutions; and its distinctive character in the present day will be the predominancy of the serious principles over wit, the triumph of the spirit of the north over the literary aspirations of the south. Such is, in a few words, the argument chosen by Madame de Staël for the subject-matter of her two volumes. They are composed of two parts quite distinct, and ought to be judged each by itself. The historical explanations are not generally very correct, nor the quotations apposite; this, of course, impairs more than once the strength of the best arguments. Madame de Staël may be said to have often guessed uncommonly well; but everything is not a matter of guess, and she has repeatedly adduced errors in support of truths. Imperfectly acquainted as she was with ancient literature, she might have been expected to stumble at the name of a Greek philosopher or a Roman poet, but the Paris Aristarchi could not forgive her a few gross mistakes in

[1] *De la Littérature considérée dans ses rapports avec les Institutions Sociales.*

modern lore: they insinuated that she had blundered purposely in order to make good a Utopian system; and when she gave the name of "father of modern poetry" to Ossian—that is, to the notorious Macpherson—no wonder that a hue-and-cry was immediately raised by the public press.

If we consider Madame de Staël's work as a development of the idea of perfectibility, it is open to the severest discussion. There is in it much to blame, much that is questionable; at the same time the author's faith and generous impulses are entitled, on our part, to respect and admiration. Nay, if we believe in Divine revelation, we also acknowledge the principle of perfectibility, although modified and corrected by the influence of the Gospel. Madame de Staël is too dogmatical, but we sincerely admire her fervent hope, her thirst for truth, her thorough contempt and hatred for everything that tends to sever us from immortality, and to bind us to the present moment.

In a literary point of view, the work we are now noticing is a complete manifesto of what the French term *romanticism.* It is not absolutely necessary, says the author, that we should do *better* than our forefathers, but we must do *otherwise;* we must not be *imitators*, we must be *ourselves.* Let us, as regards literature, yield to the inspirations which, after the downfall of the Roman Empire, came upon society; let us make room for the Christian element and the Germanic principle. Madame de Staël may not have suspected the extent of the literary revolution which she so strongly advocated; but her views were correct, and have only been explained and carried out by the Hugo school of French authors. At the time when she wrote, amidst all the anxieties of a revolutionary government, and the din of European warfare, it must have seemed extraordinary to many thinkers, that northern poetry should be considered as the necessary substratum for a new literary construction. Then, the idea of turning melancholy into an æsthetic axiom, appeared ridiculous beyond description. Critics laughed at that poetry which mingled its strains with the roaring of the waves and the moaning of the winds. The wits of the time of the Directoire shrugged up their shoulders when told that melancholy was the true source of inspiration, that authors ought to be gloomy, and that every genuine poet was, more or less, under the influence of despondency. In fact, Madame de Staël's axioms were so unexpectedly announced that they were rejected altogether as traits of sophistry. Chénier, Delille, Fontanes, and many others who enjoyed a large amount of well-deserved reputation for their poetical talent, were, besides, far from melancholy; and what was worse than all, Madame de Staël advocated her gloomy theory just at the moment when France, escaping from the Reign of Terror, was already half-intoxicated with glory and pleasure.

The asperity of the public press against both *Delphine* and the work *On Literature* went beyond the bounds of common politeness. Could the critics have become Dominicans for the nonce, they would assuredly have made an *auto-da-fe* of Madame de Staël and of her productions. Her exile towards the end of 1803, her travels, her long residence at Coppet, the friendship she formed with the most eminent German thinkers, directed her ideas into a new channel, and diverted her attention from the small talk of the Paris *feuilletons.* During the Directoire, when French society was endeavouring to reorganise itself, two *salons* served in Paris as centres where those persons met who had attained some taste for intellectual pleasures and for the amenities of elegant conversation. The celebrated Madame Tallien gathered together in her drawing-room the supporters of the new order of things, the real republicans, the men of Thermidor; around Madame de Staël might be found assembled, in a small but brilliant array, the thinkers, the enthusiasts who aimed at effecting a compromise between monarchy and the principles of 1789. Their ideal was derived from a deep acquaintance with England and English institutions; they thought that liberty could exist most harmoniously in connection with loyalty, a hereditary line of kings, and even a powerful aristocracy. These discussions, these meetings proved of very short duration; the eventful 18th of Brumaire occurred, and it became quite clear that, under the rule of the Consul Buonaparte, no room would be left for discussions of any kind. Compelled to quit France, Madame de Staël immediately went to Germany, studied the language of that country, visited Weimar and Berlin, and became acquainted with Goethe and the Princes of Prussia. At that time she was already collecting materials for the work which a second excursion (1807–8) enabled her to complete. The tidings of M. Necker's illness reached her in the midst of this new society, so suited to her taste, so calculated to draw out her brilliant conversational powers. Easily alarmed on account of one so fondly beloved, Madame de Staël felt a sad presentiment that she had seen her father alive for the last time. She instantly set out for Coppet, with her son and his tutor, August Wilhelm Von Schlegel. In a state of the greatest anxiety she arrived at Zurich, where she was met by Madame Necker de Saussure, who confirmed her worst fears. Her father was already at rest. Her grief was agonizing to witness, her whole perspective of the future seemed suddenly obliterated; life and death, earth and heaven, were equally at war against her; the one compelled her to wander desolate in strange countries, the other snatched from her her father—her first, most faithful, and dearest friend; her last support seemed gone, and hopeless of relief, she resigned herself to the most afflicting despair. Baron de Staël was dead since 1802. Thus severed from those whom she had a right to regard as her natural guardians, she sought in the delights of friendship both the protection she needed and a diversion to the sad thoughts which the state of her country could not fail to excite. Benjamin Constant, Mathieu de Montmorency, Madame Récamier, were then the favourite *habitués* of Coppet; and she watched with increased anxiety over the education of a son and daughter, whose amiable dispositions more than compensated for the bitter disappointments she had found in marriage. After a short stay in Italy, Madame de Staël passed a year in Switzerland. During this interval she was busy in the composition of *Corinne*, and needed little other employment. But as her work drew to a close, she felt an anxious desire of revisiting Paris, partly that she might correct the proof-sheets of the novel with greater care, partly to be near her son, who was then preparing for the polytechnic school under the direction of Wilhelm Schlegel. A police order prohibiting her from coming within 40 leagues of the metropolis, by dint of manœuvring, and thanks to the kindness of the minister Fouché, she obtained leave to reside at half that distance—at Acosta, a country-house belonging to Madame de Castellane. Poor Corinne! she could find nothing enjoyable far from the atmosphere of a *salon;* and that empassioned poetess whom we love to fancy, as Gerard's picture represents her, sitting on Cape Misenum, would have exchanged without a pang the Lake of Geneva for the muddy gutter which runs along the pavement of the Rue du Bac! Buonaparte was determined not to allow her the simple gratification she so ardently longed for. *Corinne ou l'Italie* appeared for the first time in 1807. Being quite foreign to political subjects, it might reasonably have been thought incapable of giving umbrage to the emperor. But its sudden popularity, and the vivid interest in awakened for Madame de Staël throughout Europe, awoke the detestable spirit of jealousy which characterised a sovereign for whose assaults nothing was too noble or too hopeless. On the 9th of April 1807, the very anniversary of her father's death, she received a new sentence of exile. It was now too evident that nothing but the giving up of her independence could satisfy her enemy.

Counting the bitter cost, and sighing to reflect that she disposed, perhaps, of the future of others as well as her own, she proudly resolved to maintain her consistency, and once more, at the bidding of her tyrant, said adieu to all that remained of her once brilliant connections in France. It was impossible, indeed, that she could please the emperor. Her last sentence breathed a spirit of generous enthusiasm which was distasteful to him. He is said to have remarked peevishly, "It is no matter what she writes, let it be politics, history, or romance; it comes to the same thing in the end: after reading her, people do not like me."

Corinne is a wonderful work; whether considered as a description of Italy, or as a work on the fine arts, or as a sort of autobiography, we are equally delighted and surprised. Her characters are drawn with the most consummate power, and the psychological analysis which it evinces is not surpassed by any book professing to lay before us the strife of the passions in the human heart. *Corinne* is the offspring of enthusiasm and of grief; it is no fiction. Madame de Staël was recording her own struggles when she described the hesitation of a woman who cannot decide in her choice between the happiness which springs from the affections, and the emotions to which talent and glory give rise.

We find by glancing at the innumerable memoirs written during the last century, interesting accounts of the coterie over which Voltaire presided at Ferney; a few particulars respecting Madame de Staël's *salon* at Coppet would be still more welcome, if we could procure them. As many as thirty persons were often at a time the guests of the illustrious exile. Benjamin Constant, Schlegel, Bonstetten, Sismondi, M. de Barante, Madame Récamier, M. de Sabran, were among the most assiduous. Zacharias Werner was introduced in 1809; Lord Byron and "Monk" Lewis represent the genius of England in 1816. The days were spent in intellectual enjoyments, discussions on literature, and critical readings; a spirited opposition was maintained against antiquated formulas and despotism of every description. The book on Germany (*de l'Allemagne*) may be considered as the result of this epoch in the life of Madame de Staël. It was written with the manifest intention of protesting against a threefold tyranny. Buonaparte had enslaved France; philosophy withered under the oppression of the materialist school; and literature knew nothing beyond a blind acknowledgment of tradition. Madame de Staël felt how much her adopted country stood in need of some stimulant to awaken it to a consciousness of its powers, and she sent *l'Allemagne* to the press. It was launched, as it were, to defy the violence of the tempest, and to rescue sinking France itself, which, as Madame de Staël believed, had well-nigh lost all its dearly-bought liberties. Convinced that nations should guide and support one another, she sought in the bosom of defeated and humbled Germany the safety of France. There was more patriotism than national pride in the book of Madame de Staël. Buonaparte's police gave it a character which it did not deserve. Despite a persecution quite in accordance with the traditions of military despotism, the spirit of the times, and the general bent of the public mind, insured success to the obnoxious work. Two ideas it contained became popular: the men whom victory had not rendered insensible to freedom, felt that a powerful voice had embodied, in an eloquent address, their hopes and their fears; the panegyric of the descendants of the Teutons appeared in its true light—a proclamation of resistance.

Many a battle was fought in the arena of periodical criticism for or against *l'Allemagne*, and it soon became manifest that Madame de Staël had successfully maintained her own doctrine on literature and the fine arts. Already a decided tendency might be traced throughout the reading public towards something more true to nature than the dull and fastidious imitations of Racine and Corneille; the veil was drawn, and from behind it a glorious landscape burst upon the sight of the astonished gazers; for many a young and ardent mind, *l'Allemagne* was replete with the perfumes and emanations of unknown but fragrant stores. That literature described by Madame de Staël, strange, wild, as it appeared, brought to the imagination pleasing fancies and beautiful ideas. Germany became to France as a long-forgotten sister, who had treasured in her heart, and was ever discerning old family traditions, otherwise lost for ever. Then there came along with her the bewitching prestige of liberty, a literature free from all restraints, whose resources were to be increased a hundred-fold; and the young generation, tired of a classicism which was nothing more than the echo of an echo, thought that, with independence, they had recovered all the earnests of real happiness, whether for good or for evil. Madame de Staël's new work had an immediate influence. It brought to a close the coldness, the enmity which had so long existed between two great people. Many years after, Goethe wrote thus of the book we are now alluding to. "It ought to be considered as a powerful battery which made a wide breach in the sort of wall raised up between the two nations by superannuated prejudices. Thus, beyond the Rhine, we were once more exactly inquired after; and we could not, consequently, fail to acquire great influence throughout the whole western part of Europe."

The principle which Madame de Staël sought to inoculate on her side of the Rhine was *enthusiasm*. But she pursued her plan cleverly, without proclaiming it, without any flourish of trumpet. Considering her country as an invalid, to whom change of air is prescribed as the first remedy, she accompanied the patient on a tour through Germany. In reading her work, one can fancy a well-informed and judicious guide pointing out to her friend the most striking features of a foreign land. There is nothing polemical, no attack upon particular feelings or tastes; calmness and impartiality prevail, on the contrary, throughout all the descriptions. Madame de Staël's purpose is not to preach a crusade on behalf of Germany. She simply states the facts, and leaves her readers to judge. Of the Teutonic race she is a decided champion; yet in spite of her acknowledged predilection, she did not find favour in the sight of all her Trans-Rhenish cities. Many accused her of having disguised the truth, and of being a very superficial judge. It is true that she had not within her reach all the information which should have formed the proper ground-work of her observations. As for society itself, she knew nothing beyond the manners of aristocratic circles and the fashionable world; whereas, amongst the higher orders, cosmopolitism is too prevalent, and the national character is worn away by a constant moral and mental friction with those around.

No one will be astonished at hearing that Madame de Staël's *Memoirs* contain a very unfavourable account of Napoleon Buonaparte. Besides the complete antagonism which must exist between military despotism and intellectual powers of the highest description, the French emperor's behaviour towards the author of *Corinne* had been marked by a want of courtesy doubly inexcusable. When a man is so circumstanced that he can say, *sit pro ratione volantas*, rudeness is the characteristic of petty cowardice. At the same time the evident unfairness stamped upon most of the verdicts pronounced in *Dix Années d'Exil*,[1] is much to be regretted; Madame de Staël would certainly have best considered the interest of her glory had she not stooped to the tone of a common pamphlet writer.

Illusions, however, were beginning to vanish around *Corinne*; her circle of friends lost, one by one, its choicest gems;

[1] Such is the title of Madame de Staël's autobiography.

sufferings, disappointments, persecutions, the weight of years, all told upon her mental energies. For a short time she believed she saw in M. Rocca's attachment to her, and in her marriage with him, the phantom of that happiness which genius had failed to give her; but gradually the brightest pictures of her fancy lost their hues, and she wisely sought in the solid joys of religion both peace here and hope for hereafter. The restoration of the Bourbon family brought her back to France, so completely altered from what she was when she left it, that to those who knew her at both periods of her life, the difference could not but be painful. And yet it was a change for the better; it was a shaking off of "every weight," a preparation for the last struggle. The friendship of persons such as Madame de Duras, M. du Chateaubriand, and Sir James Mackintosh, made up, in some measure, for old ties which the rude hand of death had broken asunder; but she did not lean too much upon those earthly supports; and when, in July 14, 1817, she breathed her last, it was with those firm hopes that alone can light up the passage through the dark valley.

Madame de Staël left two children, who were both removed from this world in the midst of a career of piety and of usefulness. Baron Auguste de Staël died in 1827, at the early age of thirty-seven; he had already evinced talents, energies, and dispositions which caused him to be regarded as a new Duplessis Mornay, or as the Wilberforce of Protestant France. He took a prominent part in the establishment of the Bible Society, of savings-banks, and in the abolition of the slave trade. His *Letters on England*, published in 1825, are full of interesting remarks, though necessarily incomplete, from the fact that the author died before he could finish the second volume. Madame de Staël's daughter had married, in 1816, the Duke de Broglie. Her death, in 1838, was felt throughout France as a public calamity. M. Rocca did not long survive his wife. He went into Provence, to be near a brother whom he loved, and there he succumbed under the pressure of sorrow and disease. (G. M—N.)

STAFFA, an islet among the Hebrides, celebrated for its basaltic rocks and caverns, lies off the west coast of Mull, about 8 miles distant from it. It consists of an uneven tableland of an irregular oval form, about a mile and-a-half in circumference, and the highest point, which is towards the south-west, reaches an elevation of 144 feet above the sea. The base of the island is a ledge of conglomerated trap-rock, above which rise basaltic columns, surmounted by a mass of basalt which has not assumed a columnar form. The lowest part of the island is on the eastern shore, and this is where visitors usually land on Staffa. From this point towards the south the principal objects of interest occur in succession. The first of these is the Clam Shell Cave, one side of which consists of large columns of basalt, carved like the ribs of a ship, or one of the shells from which it has its name, while the other side has, from the projecting ends of columns, a tesselated appearance somewhat resembling a honeycomb. Near this is the islet of Bouchaillie, or the Herdsman, a very beautiful basaltic structure of a conical form, and of great symmetry and regularity. From this place a long colonnade of basaltic pillars extends as far as the entrance of Fingal's Cave, which is the most beautiful and sublime of all the basaltic wonders of Staffa. This cave extends back from its mouth 227 feet; its breadth at the entrance is 42, and at the inner extremity 22 feet. The sides are formed by perpendicular columns of great size, beautifully jointed and arranged in varied groups. The roof is beautifully marked with the ends of pendent columns, and has a deep fissure extending through its whole length parallel to the sides of the cave. The sea never leaves the cavern, and there is a depth of 18 feet at low water. The height of the roof from the mean level of the sea is 66 feet, and the cliffs above rise 30 feet higher. The singular resemblance of this magnificent work of nature to a work of art has called forth the well-known lines of Sir Walter Scott on Fingal's Cave:—

> "Where, as to shame the temples deck'd
> By skill of earthly architect,
> Nature herself, it seemed, would raise
> A minster to her Maker's praise."

The Boat Cave, which lies a little to the west of this one, is smaller, but even more symmetrical in its structure; it is 14 or 15 feet in height above high water, about 12 feet broad, and 150 long. The last cave of any beauty or interest is Mackinnon's, also called the Scart or Cormorants Cave, which approaches the dimensions of Fingal's Cave, but is less regular in its structure. There are various other caves in the island, but none of them so remarkable for size or beauty as those already mentioned. Though Staffa is green and fertile, it is entirely destitute of trees, and there is not a dwelling of any kind, even a hut, on the island.

STAFFORD, the county town of Staffordshire, a municipal and parliamentary borough and market-town of England, on the left bank of the Sow, 123 miles N.W. by W. of London. It was anciently walled, and defended by a castle; the latter, about a mile and a half to the south-west, has been recently rebuilt; but of the walls, which were destroyed by the parliamentary forces in the 17th century, few vestiges remain. The houses are for the most part built of brick and slated, and most of the buildings stand in two main streets, called Green Gate Street and Gaol Gate Street, which extend to the north-west of a bridge spanning the Sow. There are also two squares, in one of which, the Market Square, stands the County Hall, a spacious building of stone, containing court-rooms, an assembly-room, and other handsome apartments. But the finest buildings in Stafford are the Established churches, two of which are parochial and of considerable antiquity, while two others, Christ Church and St Paul's, have been recently built. St Mary's is a large cruciform edifice, with a lofty octagonal tower in the centre. Its architecture is chiefly of the early English style, but some portions have more resemblance to the Norman and the perpendicular. In 1847 the church was repaired and restored at considerable expense. The church of St Chad is of smaller size; it has a Norman chancel, but is partly of modern date. There are other places of worship in the town for Presbyterians, Independents, Methodists, Quakers, Baptists, and Roman Catholics. The educational establishments in Stafford comprise a grammar school of ancient date, much enlarged by Edward VI., National, British, and Ragged schools. The town has also a Mechanics' Institute, a public library, almshouses, an infirmary, two lunatic asylums, and a county jail. Tanning is carried on to some extent in the town and neighbourhood; and the principal articles manufactured in the town are shoes, which are exported in considerable quantities. Markets are held weekly, and there are five annual fairs. The borough is governed by a mayor, 5 aldermen, and 18 councillors, and it returns two members to the House of Commons. Assizes and quarter sessions for the county are held at Stafford. The town seems to have grown up round a castle, which was built here in 913 by Ethelfleda, sister of King Edward the Elder, and at the time of the Norman conquest it was a borough, called by the name of Statford or Stadford. In the civil war of the 17th century, Stafford was occupied by the king's forces, after the capture of Lichfield by their adversaries. An indecisive battle was fought at Hopton Heath, in the vicinity, in 1643, and at a later period the town was taken by the Roundheads, under Sir William Brereton. The castle was also taken shortly after, and at the close of the war was entirely demolished. Stafford was the birth-place of the celebrated Isaac Walton. It com-

municates with London by the Trent Valley and London and North-Western Railways, and has also easy intercourse by railway with Liverpool, Manchester, and other towns in the north. Pop. (1851), 11,829.

STAFFORDSHIRE, an inland county, nearly in the centre, but rather to the W. of England. It is bounded on the S. by Worcestershire and a detached part of Shropshire, W. by the main body of Shropshire, N.W. by Cheshire, N.E. by Derbyshire, E. by a small portion of Leicestershire, and S.E. by Warwickshire. Its greatest length from N. to S.E. is 60 miles, and its greatest breadth 38 miles. The southern boundary is very irregular and much involved with that of Worcestershire. A portion of the latter county, including the important town of Dudley, is entirely insulated by Staffordshire, whilst a portion of Staffordshire, including the Clent Hills, lies within Worcestershire. An effort was recently made by the Right Hon. Sir John Pakington and the Worcestershire magistrates to rectify this irregularity, but it was opposed by the Staffordshire magistrates, on the ground that great expense would be incurred in increasing the county jail at Stafford to provide for the prisoners from Dudley. Staffordshire contains 1250 square miles, or 781,000 statute acres. It is the 18th county in England in superficial extent, and the 6th in population.

Its physical aspect is marked by great variety. It includes within it a part of the great watersheds of England, different portions of it draining into the German Ocean, the Irish Sea, and the Bristol Channel. The main part of the county, however, belongs to the basin of the Trent; a small portion to the W. drains into the Mersey, and a larger strip on the S. into the Severn, which crosses a narrow limb of the county. The N.E. part of the county forms the termination of the Pennine range of mountains, which, stretching southwards from the Cheviot Hills, form the backbone of that part of England. The river Dove, which separates Staffordshire from Derbyshire on the N.E., flows through a valley formed by two spurs of this range, which presents a succession of scenery of exquisite beauty. From the S. or Staffordshire slope of its basin the Dove receives the Manyfold, Hamps, and Churnet. The two former streams disappear underground and flow for some miles in subterranean channels, uniting their streams before they emerge, and fall into the Dove at Ilam. The Dove enters the Trent near Burton. Extending from the basin of the Dove on the N.E. to the N.W. of the county is a continuous range of hills and moorlands of a wild and varied character, sloping gradually towards the Trent, and forming the boundary of its basin to the N. To the E. of this range, which includes the Weavèr Hills, there are eminences rising to the altitude of 1200 or 1500 feet above the level of the sea. They gradually subside towards the W., but are still high enough to give a decided feature to the scenery, which is mainly moorland. To the W. much lower elevations separate the basins of the Trent and Mersey. This line of division is marked by large pools, called meres, and considerable deposits of peat, which are to be found extending to the confines of Shropshire. Aquilate (*aqua lata*, broad water), near Newport, in Shropshire, is one of the largest of these pools.

To the south of the county a range of hills extends from Wolverhampton to Rowley Regis, and forms at once the southern boundary of the coal-field of South Staffordshire, and of the basin of the Trent. Wolverhampton itself is on the apex of this ridge, and its streams drain partly into the Bristol Channel and partly by the Trent into the German Ocean. These hills rise at Rowley to the height of 700 feet. They have been most interestingly described by Hugh Miller in his *First Impressions of England.* They belong to the Silurian system, and are very rich in fossils. From the great extent to which they have been quarried for limestone, they present extensive sections, open to the observation of the geologist. Very pure basalt exists in large masses at Rowley, and is locally known as Rowley Rag. It is used very extensively for paving. "The Silurian islets," as Miller calls the principal eminences in this chain, are precipitous; and two, "The Wren's Nest" and the site of Dudley Castle, are very striking objects.

The basin of the Trent extends from the summit of these hills in the south to the rugged heights which bound it on the north; but near the centre of the county rises an elevated *plateau*, known as Cannock Chase, which extends from the west of Rugeley to the east of the county, rising rather abruptly on all sides, except the east. It forms a striking feature in the scenery, viewed either from the Trent Valley Railway, which it closely approaches, or from the line between Stafford and Wolverhampton, which is on its opposite side. Between this central elevation and the hills to the south of the county, lies the coal-field of South Staffordshire, which drains eastward into the Tame, a river rising to the north-west of Walsall, which town is on the edge of the Chase. The Tame enters Warwickshire near Birmingham, but sweeping north and north-east, re-enters Staffordshire at Tamworth, and falls into the Trent a few miles north of Lichfield.

Between Cannock Chase and the northern range of the Staffordshire Hills the country is generally level. Through this district runs the River Trent, the third river in England for length. It rises in the moorlands near Biddulph, in the north-west of the county, on the borders of Cheshire, flows south by Trentham, south-east by Rugeley, east to the boundary of Derbyshire, when it turns north-east, forming the boundary between the two counties, and enters Derbyshire just below Burton, its length to that point being 50 miles. It only becomes navigable at Burton. Its chief tributaries on the left bank are the Blythe and the Dove, the latter already described. On the right bank is the Sow, with its tributary the Penk, which latter stream drains the country north-west of the southern ridge of hills, terminating west of Wolverhampton. The Tame has already been described.

The new red sandstone is the prevailing geologic formation throughout the county. Gypsum is quarried in Needwood Forest, an elevated tract of land in the north-east, and in the adjacent parts of the valley of the Dove. The basalt at Rowley Regis has been noticed in defining the boundaries of the river basins. Trap-rock, apparently part of a thick vertical greenstone dyke, is found near Walsall.

The coal-fields form, however, the most important mineral feature of the county. The largest is in the south, extending from near Walsall to Rowley, and from Wolverhampton to within a few miles of Birmingham. The south part of this coal-field contains a seam of coal 30 feet thick, of excellent quality. The coal-measures in this basin have an average aggregate thickness of about 40 feet, and the ironstone of about 40 inches. Ironstone is found in strata intervening between the coal-measures in each of the coal-fields.

The Pottery coal-field, in the north-west, is triangular in shape, its greatest length from base to apex being 13 miles, and 8 or 10 miles along the base. East of this is a small insulated basin, called the Cheadle coal-field; and near Tamworth, on the east of the county, the Warwickshire coal-field just enters Staffordshire. Colliery operations are now being energetically conducted near that town. Nearly the whole of the elevated district of Cannock Chase is found to contain valuable beds of coal; and this, hitherto a barren heath, formerly covered with timber, is rapidly becoming intersected by canals and railways, which the mining operations call into existence. Ironstone is also found, but is not yet extracted to any large extent. In

the north of the county, near Froghall, valuable beds of limestone and ironstone are worked, and the minerals conveyed to the ironworks of South Staffordshire. Copper and lead are mined in the north of the county, in the neighbourhood of Oakamoor. Salt-springs occur at Shirleywitch and Weston, to the west of Colwich.

The climate is colder than in other counties in corresponding latitudes, and the fall of rain is large, averaging about 36 inches a year. The highlands, which form part of the great watershed of the county, intercept the vapours from the Atlantic, whilst the quantity of snow which falls upon them tends to reduce the temperature. The arable land forms about four-fifths of the land under cultivation. Clay and heavy loams, gravelly and sandy loams, and light gravel and sand, exist in various proportions. The meadows along the banks of the rivers are very fertile. Great progress has been made within the last few years in the improvement of the breeds of animals and the processes of agriculture. Lord Hatherton, the lord-lieutenant of the county, is a most enterprising and successful agriculturist, and at a very early period adopted steam culture, the use of the reaping machine, and other improvements. His extensive farm adjoining his residence at Teddesley, near Penkridge, is a remarkable illustration of profitable reclamation.

Staffordshire occupies an important position amongst the manufacturing counties of England. The leading branches of industry are the manufacture of iron and hardwares on the South Staffordshire, and of earthenware and iron on the Pottery coal-field. The iron manufacture has been long carried on in the former district, but has been immensely extended since coal was rendered applicable to smelting the ore instead of charcoal, and again since the hot-blast was employed. The supply of the superior qualities of ironstone in the district is now, in consequence of the vast quantities raised, unequal to the demand, and the supply of native stone is largely supplemented by the hematite ore from Cumberland, calcined stone from the Potteries, &c. The opening of the coal-mines on Cannock Chase has greatly increased the supply of fuel. The works for the manufacture of iron extend over the whole of the coal-field. In the commencement of 1860 there were 189 blast furnaces in the district, including a few in East Worcestershire, of which 135 were in and 54 out of operation. The average yield of a furnace is about 120 tons of pig-iron per week, which would give an annual production from the furnaces then in blast of 842,400 tons a year. Very little is exported in the shape of pig-iron. In 1826, there were 109 furnaces in the district, of which 90 were in blast, the annual yield being estimated at 197,280 tons. The produce per furnace has been much increased of late years. The competition of districts where the minerals can be raised at less expense, and which are nearer the seaboard, limits the manufacture of iron in South Staffordshire for export chiefly to the superior kinds. Rails are not now largely made in the district.

Almost every branch of hardware manufacture is carried on in South Staffordshire. Locks are produced to a large extent in Wolverhampton and Willenhall; tin and japan wares in Wolverhampton and Bilston—this being one of the most progressive branches in the district—cast hollow wares at Wolverhampton, West Bromwich, Sedgley, &c.; saddlers' ironmongery and saddlery at Walsall; ironwork for coach-building, and wheels and axles for railways, at Wednesbury; chains and nails at Dudley, and the district to the south; gas-tubes, Wednesbury and Walsall; gun-locks, Wednesbury and Darlaston; and foundries abound in various parts. There is scarcely an article of ironmongery which is not produced in the district. The hardware trades are fully as flourishing as the iron trade. A large proportion of articles of hardware are got up at the houses of the workmen, in many cases the various portions of an article being collected by the factors or merchants from the separate artificers, and put together in their establishments. They are extensively exported to every part of America, Australia, the East Indies, China, the Cape, the Mediterranean, &c.

The other principal manufacturing district is situated on the Pottery coal-field, on the north-west of the county. The manufacture of earthenware in that locality, originally confined to the commoner kind of articles, has been gradually improved, until now not only is the most exquisite china produced there, but new kinds, as encaustic tiles, parian, jasper, majolica, &c., raise the productions of the district to a distinguished position in art-manufactures. The pottery art is greatly indebted for its improvement to the genius and perseverance of Josiah Wedgwood, who founded the town of Etruria, where his descendants still carry on the manufacture. A statue of this benefactor of the Potteries is about to be erected at the railway station, Stoke; and an institute, which is to bear his name, for instruction specially in art and science applicable to the production and ornamentation of the staple manufacture, is shortly to be established in Burslem, his native town. It is worthy of remark, that the workmen engaged in the earthenware manufacture are engaged from year to year, instead of by the week or fortnight, as in other trades. The principal towns are Hanley, Burslem, Stoke, Shelton, Longton, Tunstall, Fenton, Etruria, Dresden, &c.

Within the last few years the iron trade has been rapidly extending in the Pottery district. In January 1860 there were 31 blast furnaces, of which all but 8 were in operation. The Earl Granville is the proprietor of extensive mines and ironworks in the Potteries.

The manufacture of ale and beer at Burton-on-Trent is carried on to a very large and increasing extent, and that town is rapidly rising into great importance. No branch of trade in the county is making more remarkable progress.

At Stafford and Stone the manufacture of shoes is extensively carried on, and hats are made at Newcastle-under-Lyme. Glass-works exist in various parts, and branches of cotton manufacture are prosecuted in some of the rural districts, but several of these manufactories have long been closed. At Leek, in the north-west of the county, silk goods are made to a considerable extent.

Staffordshire is admirably supplied with the means of internal communication. In addition to good roads, there is a perfect network of canals and railways, which the development of its mineral riches, and the progress of its manufactures, have rendered necessary. The Grand Trunk Canal, the work of the distinguished Brindley, connects the navigation of the Trent and Mersey. It extends from the junction of the Derwent with the Trent in Derbyshire, entering the county near Burton to Runcorn Gap, where it joins the Mersey. Of its entire length of 93 miles, about 50 are in Staffordshire. At Harecastle, west of the Potteries, it is carried through two tunnels, one of which is 2926½ yards in length. The Staffordshire and Worcestershire Canal connects the Grand Trunk east of Stafford with the Severn, and thus the communication between the German Ocean, the Irish Sea, and the Bristol Channel is completed. The Birmingham Canal, extending from near that town, traverses the South Staffordshire coal-field, uniting with the Staffordshire and Worcestershire Canal south of Wolverhampton. It is thence extended to Nantwich in Cheshire, forming a direct line of communication for Birmingham and South Staffordshire with the Mersey. From the nature of the district through which the Birmingham Canal passes, it has been extended in every direction by branches. A splendid tunnel, in connection with one of these branches, recently constructed at Netherton near Dudley, pierces the lofty range of hills which intersect the thick coal-basin in that locality. By the Coventry and

Oxford Canal, which joins the Grand Trunk Canal near Alrewas, the latter is connected with the Thames. Other canals in South Staffordshire connect every part of the district with the main lines, and important extensions on Cannock Chase are in progress.

The county is well supplied with railways. The Grand Junction line traverses it from Birmingham to near Crewe, where it enters Cheshire. The Trent Valley, a shorter route from Rugby to Stafford, passes by Tamworth, Lichfield, and Rugeley, south of Cannock Chase; the Stour Valley from Birmingham to Bushbury, a mile north of Wolverhampton, where it unites with the Grand Junction, was formed to obviate the original defect of the latter, which scarcely touches any of the South Staffordshire towns. The South Staffordshire Railway extends from Dudley, crossing Cannock Chase to Barton, a few miles from which it runs into the Midland. A branch from Walsall extends to Cannock, on the summit of the central tableland; and a short line, the Cannock Mineral, opened in the autumn of 1859, connects Cannock with Rugeley, where it unites with the Trent Valley. Other branches from the South Staffordshire line are in progress. The Oxford, Worcester, and Wolverhampton Railway, passing through Dudley, connects the South Staffordshire line with the south of England and London. The North Staffordshire, constructed specially for the convenience of the Pottery district, connects it with the Grand Junction Line at Norton Bridge, near Stafford, with the Trent Valley at Colwich, with the Midland at Burton and Willington, and extends to Macclesfield on the north-east, and thence along the north of the county, in an eastern direction, to Uttoxeter, where it unites with the Midland branch. Besides these, the Great Western Railway traverses the district between Birmingham and Wolverhampton, extending from that town by Shrewsbury to Birkenhead.

The county is divided into five hundreds, each of which is subdivided into north and south. They do not include the city of Lichfield, which is a county of itself. For parliamentary purposes it is divided into North and South Staffordshire, each of which returns two members. The population in 1851 was 608,716, having doubled in forty years. The following are the numbers of the population at each of the decennial periods named:—1801, 254,084; 1811, 308,129; 1821, 361,859; 1831, 425,140; and 1841, 520,867.

The population of the principal towns is as follows:—Wolverhampton, 49,985; Walsall, 25,680; Wednesbury, 11,914; Stafford, 11,829; Newcastle-under-Lyme, 10,569; Leek, 8877; Burton-on-Trent, 7934.

The parliamentary boroughs, with their population in 1851, are as follow:—Wolverhampton, including Bilston, Willenhall, Wednesfield, and Sedgley, 119,748; Stoke-upon-Trent, including the Pottery towns, 84,027; Walsall, 25,680; Stafford, 11,829; Newcastle-under-Lyme, 10,569; Tamworth, 8,655; and Lichfield, 7,012. Except Walsall, which only returns one member, all these boroughs return two each, making 17 members for the whole county.

The rapid collection of large populations on the coal-fields in the north and south of the county, earning high wages, has had its usual effect in occasioning much sensual depravity. This is increased by the influence on the physical aspect of these districts of the mining and manufacturing pursuits. The former cover the surface with the refuse matter raised from the mines; whilst the volumes of smoke emitted by the works darken the whole atmosphere, causing the South Staffordshire district to be locally termed "the Black Country," and destroy vegetation. Hence garden culture, and the enjoyment of natural scenery, are prohibited to the residents; cleanliness is very difficult; and the higher classes usually live at a distance beyond the smoke, thus depriving the working-classes of much of the influence they would otherwise exert over them. In the recollection of many persons, bull-baiting and cock-fighting on Sunday were common in South Staffordshire. Great improvement is, however, manifest. Schools have been extensively established for the artisans and labourers. Their influence is greatly diminished by the temptation which high wages offer to parents to send their children to work at an early age; and prizes, contributed by proprietors of the mines and ironworks in South and North Staffordshire, are given to encourage protracted attendance at school. At an early period the active efforts of the Methodists and Dissenters did much to keep alive religious and moral sentiments; and within the last twenty years the Church of England has made extraordinary exertions to provide for the religious and educational wants of the population. The census of 1851 showed that there were then 863 places of worship within the county, containing 304,292 sittings. Of these, 317 places of worship and 163,856 sittings belonged to the Established Church. The proportion of sittings to population was 50 per cent., of which 26·9 were connected with the Church of England. As an indication of the progress made lately, it may be mentioned that the present Bishop of Lichfield has consecrated 121 new churches since his elevation to the see in 1843, and very much the greater part of these were in Staffordshire. The building of churches in the diocese is assisted by a society; and the present bishop (Lonsdale) has on three several occasions of appealing for its support, headed the subscription list with L.1000. The census of 1851 showed that there were in the county 1318 day schools, attended by 66,187 scholars, of which 44,489 were at public, and 21,698 at private schools.

An efficient police force has for many years been established in the county, Wolverhampton, Walsall, and one or two of the smaller boroughs, having separate forces. The towns of Wolverhampton and Hanley have been incorporated under the Municipal Reform Act of 1835—the former directly after its passing, the latter in 1859. The other municipal boroughs are Stafford, Lichfield, Tamworth, Walsall, and Newcastle-under-Lyme. Most of the towns now possess local boards of health, under the Public Health Act of 1848, or of Commissioners; and paving, lighting, and sewerage are better attended to than they were. In both the south and north coal-fields, the sinking of the ground, and the destruction of buildings, roads, &c., from the mining excavations, is common. South Staffordshire was last year supplied with water by works intercepting streams and springs at Lichfield, whence the water is raised to the summit of Cannock Chase. Wolverhampton is supplied mainly from surface water from the south, and by borings into the red sandstone, the water having to be pumped to the level of the town. There is also a waterwork in North Staffordshire.

In the Roman period Staffordshire was inhabited by the Cornavii. The Roman roads, Watling Street, Ryknield Street, and Via Devana (Chester Road), crossed the county. At Wall (Etocetum) Roman remains are extensively found, and at Rowley Regis and other places. In the Saxon period the county formed a part of Mercia; and Tamworth was the place of residence, and of the death, of the celebrated Ethelfleda. The beautiful cathedral at Lichfield occupies the site of a church erected as early as the seventh century. A part of its south side has been admirably restored in stone within the last fifteen years; and the interior of the choir is now being restored, at a cost of about L.10,000, under the direction of Mr G. G. Scott. Croxden Abbey, in a small valley between Cheadle and Uttoxeter, is a fine old ruin.

STAGNELIUS, Erik Johan. See Scandinavian Literature.

STAHL, Georg Ernst, an eminent German chemist, was born at Anspach, on the 21st of October 1660, and chosen professor of medicine at Halle, when a university

was founded in that city in 1694. The excellency of his lectures while he filled that chair, the importance of his various publications, and his extensive practice, soon raised his reputation to a very great height. He received an invitation to Berlin in 1716, which he accepted, and was made counsellor of state and physician to the king. Stahl is without doubt one of the greatest men of which the annals of medicine can boast: his name marks the commencement of a new and more illustrious era in chemistry. He was the author of the doctrine of *phlogiston*, which, though now completely overturned by the discoveries of Lavoisier and others, was not without its use, as it served to combine the scattered fragments of former chemists into a system, and as it gave rise to more accurate experiments and a more scientific view of the subject, to which many of the subsequent discoveries were owing. This theory maintained its ground for more than half a century, and was received and supported by some of the most eminent men which Europe has produced—a sufficient proof of the ingenuity and the abilities of its author. He was the author also of a theory of medicine, founded upon the notions which he entertained of the absolute dominion of mind over body; in consequence of which he affirmed, that every muscular action is a voluntary act of the mind, whether attended with consciousness or not. This theory he and his followers carried a great deal too far; but the advices, at least, which he gives to attend to the state of the mind of the patient are worthy of the attention of physicians. "Stahl," says Dr Cullen, "has explicitly founded his system on the supposition, that the power of nature, so much talked of, is entirely in the rational soul. He supposes that, upon many occasions, the soul acts independently of the state of the body; and that, without any physical necessity arising from that state, the soul, purely in consequence of its intelligence, perceiving the tendency of noxious powers threatening, or of disorders anyways arising in the system, immediately excites such motions in the body as are suited to obviate the hurtful or pernicious consequences which might otherwise take place. Many of my readers may think it was hardly necessary for me to take notice of a system founded upon so fanciful a hypothesis; but there is often so much seeming appearance of intelligence and design in the operations of the animal economy, that many eminent persons, as Perrault in France, Nichols and Mead in England, Porterfield and Simson in Scotland, and Gaubius in Holland, have very much countenanced the same opinion, and it is therefore certainly entitled to some regard." (Cullen's *First Lines of the Practice of Physic*, vol. i., p. 12.) Stahl died in 1734, in the seventy-fifth year of his age.

His principal works are, *Experimenta et Observationes Chymicæ et Physicæ*, Berlin, 1731, 8vo; *Dissertationes Medicæ*, Halle, 2 vols., 4to; *Theoria Medica vera*, 1737; 4to; *Opusculum Chymico-physico-medicum*, 1740, 4to; *A Treatise on Sulphur, both Inflammable and Fixed*, written in German; *Negotium Otiosum*, Halle, 1720, 4to—it is in this treatise chiefly that he establishes his system concerning the action of the soul upon the body; *Fundamenta Chymiæ Dogmaticæ et Experimentalis*, Nürnberg, 1747, 3 vols., 4to; *A Treatise on Salts*, written in German. Haller, in his *Bibliotheca*, gives 250 works which were either written, edited, or superintended by Stahl.

STAINDROP, a market-town of England, in the county and 16 miles S.S.W. of Durham, in a beautiful valley on a branch of the Tees. It consists of one long street, and contains an old and handsome church, four Dissenting places of worship, and several schools. In the vicinity there are lead-works. Pop. 2447.

STAINES, a market-town of England, in the county of Middlesex, on the left bank of the Thames, 18 miles W. by S. of London. It has a market-house, places of worship belonging to the Established Church, and to Methodists, Independents, Baptists, and Quakers; a bank; several schools; flour-mills; and gas-works. Pop. 2577.

STAIRCASE. See Architecture.

STALEYBRIDGE, a market-town of England, in Lancashire, on both sides of the Tame, 8 miles E. by N. of Manchester, and 185 N.W. by N. of London. It is built on ground which slopes down to each side of the river, and consists of three principal streets, one of which is old and somewhat irregular; while the others are straight and regular, lined, for the most part, with brick-houses two storeys high. As the town is almost entirely modern, and owes its importance chiefly to the cotton manufacture, there are few buildings of much interest or antiquity; the oldest of them being an octagonal church, which occupies a prominent position on a rock overhanging the river. There is also a market-house, which was built in 1832, at a great expense. Besides the Established church, various sects of Methodists, the Independents, Baptists, and Roman Catholics have places of worship here. There are several schools, a mechanics' institute, and a savings bank. The town contains nineteen establishments for spinning cotton-yarn and weaving calicoes, which employ in all about 9500 hands; some of the single factories being very large, and employing from 1000 to 1500. Woollen cloth is also made at Staleybridge, and there are brass and iron foundries, brick-works, collieries, and quarries. Markets are held weekly, and fairs twice a year. Pop. 20,760.

STALIMENE. See Lemnos.

STAMENS. See Botany.

STAMFORD, a parliamentary borough and market-town of England, in the county and 39 miles S. of Lincoln, on a pleasant slope above the Welland, 89 miles N. by W. of London. The river is crossed by an old stone bridge of five, and a modern one of three arches. The town is old and straggling, consisting of houses, substantially built of freestone from the neighbouring quarries, and roofed with slate. There are five parish churches, most of which are old and interesting buildings. All Saints, which was built in 1465, is partly early English and partly perpendicular, and has a fine crocketted spire, and several old monuments. St George's church, rebuilt in 1450, is a plain building, with some portions very ancient; and that of St John the Baptist, which is about the same age, has a fine embattled tower, and some good carving in wood. St Mary's dates as far back as the thirteenth century; and St Michael's has been recently rebuilt on the site of one still older. In the church of St Martin, a fine building in the late perpendicular style, the remains of the great Lord Burleigh lie in the family vault; and a handsome monument has been erected to his memory. Of the Benedictine priory of St Leonards part of the nave is still standing, used now as a barn; and there is also to be seen the west gate of a Carmelite friary to the north-east of the town. Stamford once had, besides these, several other ecclesiastical buildings, of which few or no remains now exist. The grammar-school occupies part of the old church of St Paul, a building in the Norman and early English styles; and near it is a Norman gateway, which anciently belonged to Brasenose College, a monastic school now no longer in existence. The grammar-school, which was founded in 1530, has an endowment of about L.580 annually. Stamford has also a blue-coat school, two free schools, national schools, and an infant school. There are places of worship for independents, Roman Catholics, Wesleyan and Reformed Methodists. All these, as well as the large town-hall, market-house, and jail, are comparatively modern buildings. The charitable institutions of Stamford are very numerous. There are several hospitals for different classes of the poor; alms-houses, establishments for lending money to tradesmen, and for apprenticing poor boys, and several others. A literary and scientific institution was

Stammering.

established here in 1838, with a library, museum, and lecture-room. There are also in Stamford an assembly-room, a theatre, and public baths. The town contains several large breweries, and a manufactory of agricultural implements. Malt is also made to some extent, but on the whole Stamford is not an important manufacturing town. It has an extensive retail trade with the neighbouring country, which is facilitated not only by the connection of the town by railways with all parts of the country, but by its situation on the Welland, which is navigable up to the town for boats and barges. The borough is governed by a mayor, six aldermen, and eighteen councillors, and is represented in Parliament by two members. Stamford is a very old town, and is mentioned in history soon after the departure of the Romans from Britain. The Picts and Scots, who at that time greatly harassed the country by their invasions, were defeated here by the Britons and Saxons in 449. At a later period it was in the possession of the Danes, who lost it in 922 to Edward the Elder; but afterwards recovered it, and remained in possession until 1041, though it was taken from them for a time by Edmund I. in 942. About this time it had risen to be a place of some size, and was a market-town and king's borough. In the twelfth century it was inhabited by many wealthy Jews, who were plundered and maltreated by the Crusaders setting out for the Holy Land. Many of the English sovereigns visited the town, and by some of them parliaments or councils were held here. It was at one time fortified and defended by a castle, but it was much injured by the Lancasterian party, who captured it during the Wars of the Roses, and the castle was demolished by Richard III. In 1572 Lord Burleigh, who was lord of the manor, procured the settlement here of some Flemish Protestant refugees, silk and serge weavers, and thus conferred a great benefit on the town. Pop of the borough (1851) 8933.

STAMMERING is a term which has been loosely employed to denote all kinds of defective utterance; neither is any distinction generally made between the terms stammering and stuttering, but they are used synonymously to designate a difficulty in uttering or in articulating without interruption certain sounds, or an absolute inability to do so. The Greeks designated these affections somewhat indiscriminately by the words—*psellismos*, faltering; *traulismos*, lisping; *asapheia*, indistinctness; *ischnophonia*, feebleness of voice; and *battarismos*, stuttering. Among the Romans a stammerer, or any one having an impediment of speech, was called *balbus;* a lisper, *blæsus;* and Cicero uses the term *hæsitantia linguæ*. The terms stammering and stuttering, properly used, designate kinds, and not degrees of the evil. The same confusion exists in the use of these terms as in the use of the words *articulation* and *pronunciation*, which also have been erroneously regarded as synonymous.

Stammering and *stuttering*, as contra-distinguished, may be regarded—the former as mainly an organic or symptomatic, the latter as chiefly an idiopathic or functional affection. Stammering may be defined as a difficulty in enunciating, or an inability to enunciate certain elementary sounds. This difficulty does not, as is frequently asserted, occur only in the pronunciation of consonants, but extends also to the vowels. Stuttering, on the other hand, consists chiefly in the difficulty fluently to enunciate words and sentences. The great variety of defects which constitute stammering arises naturally from as great a variety of causes; which causes may be either organic or merely functional. Among organic causes may be enumerated harelip, cleft palate, abnormal length of the uvula, inflammation or enlargement of the tonsils (a deficiency or disarrangement of teeth), tumours of the tongue or in the buccal cavity, &c. When the organs are in a normal state, and the person is unable to place them in the proper position for producing the desired effect, the cause is functional. General debility, paralysis and spasms of the tongue, glottis, lips, &c., owing to a general or local affection of the nerves of the vocal organs; bad habit, imitation, &c.; are some of the functional causes of stammering. The cause of the imperfection of the vowel-sounds must be sought in the respiratory organs, the larynx, or the buccal cavity. The sounds may be deficient in timbre, from affection of the vocal ligaments; or the larynx being in a healthy condition, the tone may be altered in the buccal or nasal cavities; while the vowels may be ill formed from misemployment or defective association of the various organs upon which articulation depends. The cause of the defective enunciation of consonants must be sought in the organs of articulation, although it may be found to proceed sometimes from affection or misuse of the respiratory organs or the larynx. The tongue is frequently too large for the buccal cavity, in which case most of the speech-sounds will be affected; while individual muscles often lose their contractility.

Stuttering, as distinguished from stammering, has been described as consisting, in a momentary difficulty, in pronouncing, or inability to pronounce, certain syllables or words. The stoppage of sound may take place at the second or third syllable, but generally occurs at the first. The stutterer usually finds no difficulty in articulating the elementary sounds of which speech is composed (in which respect he differs from the stammerer); but his affection becomes apparent when he attempts to form syllables and words. His greatest difficulty is experienced in the pronunciation of the explosives K, T, P, and their medials G, D, B, or M; because in articulating these elements, the buccal cavity requires to be closed, and immediately reopened for the following vowel. Instead of doing so, the stutterer allows the respective organs to remain in the same position longer than is necessary, and compresses the cavity in trying to force out the sound. The difficulty of the stutterer is much less when the word begins with a vowel. The opening of the glottis, in the transition from the explosive to the vowel, is in fact the chief and most distressing difficulty of the stutterer; and it is this which causes him to repeat the words or syllables until articulation is effected. Stuttering, however, is not confined to the consonants, but may also affect all vowel sounds. It is a remarkable fact, that most stutterers can *sing* without difficulty; the reason being, that in singing, the continuous action of the vocal organs is not so frequently interrupted; and consequently singing is less difficult than speech, in which a constant change is demanded in the position of the vocal organs. The causes of stuttering may be distinguished as predisposing, exciting, and proximate. As belonging to the two former may be enumerated—abnormal irritability of the nervous system; mental emotions; affections of the brain and spinal cord; solitary vices; mimicry and involuntary imitation. The proximate cause of stuttering has been asserted by Drs Müller, Arnott, and others, to be the spasmodic closure of the glottis. Such a theory is not however tenable; the glottis is rarely or ever *per se* at fault, and the cause must be sought for, either in those muscles which regulate the inspiration and expiration of the breath, or in the organs of articulation. If the action were strictly spasmodic, the speaker would be unable to arrest it; whereas all stutterers possess this power. With persons thus affected, expiration is frequently retarded, and all the muscles concerned in vocalization and articulation are thrown into inordinate action. In some cases the tongue may be seen flying about the mouth, and vaguely endeavouring to regulate itself for the articulation of a particular word; while the other organs either sympathise or are in a dormant state. This derangement gradually extends to the larynx and organs of respiration, until the

whole of the vocal organs are influenced, and all voluntary control is lost. When a person thus affected attempts to speak, you see the eyes open and close spasmodically, the face redden, the head jerk backwards and forwards, the veins of the neck swell, the respiratory muscles act spasmodically, the arms and legs even sympathise with the general contortion; while the heart palpitates violently (sometimes intermittently), till, with a violent voluntary effort of the whole muscular system, the word explodes. In less severe cases, the vocal organs are alone affected. In such you may see the lips closing and opening, the under-jaw and tongue working at random; while the air enters the lungs with a croup-like sound, and is immediately expelled again; until at last the stutterer feels that his organs are in the right position, and the word is articulated. In other cases, the facial muscles and all the vocal organs are in a quiescent state, and the ordinary observer could not discover that any effort at articulation was being made; a slight spasm of the eyelid being the only external sign of the great internal struggle. The forms which stuttering assumes are so varied that no two cases are alike. Stutterers may, however, be classed under two heads—the psychical and the physical—a classification which has not often been employed. The psychical or mental stutterer is acted upon by every external influence both mental and physical; while on the physical stutterer external influences have little or no effect. His speech is alike on all occasions, uninfluenced by the places in which, or the persons before whom he is speaking; whereas these circumstances would exercise the greatest possible influence upon the former class. In psychical stuttering the affection is sometimes intermittent, disappearing for various periods of time, and increasing or diminishing according to the mental and physical condition of the sufferer; all pleasurable mental emotions tend to diminish the affection; while those of an opposite character produce a contrary effect. The physical influences liable to increase the stutter are—changeable or damp weather, fatigue, dissipation, tobacco, and alcoholic liquors. These last, however, not unfrequently produce fluency so long as the sufferer is under their influence, but have a corresponding reaction. Cheerful society, healthy mental occupation, athletic sports, and constant observance of the universal law, "To be temperate in all things," are the physical influences which tend to diminish the affection. It may be laid down as a general principle, that everything which tends to lessen the voluntary control increases the stuttering, and *vice versâ*. The statistics respecting the number of persons suffering from impediments of speech are very unsatisfactory. Some writers assume that there is about 1 person in 5000 who stammers; while others believe that there are 2 in 1000. Colombat, who made the former calculation, acknowledged that he only reckoned those who were suffering under a severe impediment. Colombat is possibly right as to the number of bad stammerers, but it is equally true that there are nearly 2 in 1000 who suffer from affections which may be included under the general term *stammering*. The number of severe cases of stammering in the world would thus be 257,200; and the entire number, 2,572,000; thus would give to Great Britain—of the former cases, 5,498; and a total of 54,978. The number of females who stammer is much less than that of males. Some authors maintain that there are only 5 females out of every 100 stammerers. The writer believes that the average is about 10 per cent: his practice has given a proportion of 12½ per cent. The reason why females should stammer less than males is by no means certain.

To the anomalous forms that stammering assumes may probably be traced the variety of remedies that have been employed for its removal. Amongst other remedies proposed by scientific writers are the following:—Colombat employed rhythm to produce harmony between the nervous action and the organs of articulation. Bertrand recommends motions of the fingers and toes, and the introduction of foreign substances into the mouth. Dr Rullier considers that the cause of all stammering must be sought for in the brain, and his remedies correspond. Professor Itard uses a gold or ivory fork about an inch in length, which is to be applied by its convex surface to the alveolar arch of the lower jaw. Dr Serres advises the patient to shake the words out by movements of the arms. Dr M. Hall advises speaking in a chanting voice. Dr Arnott would prefix the vowel *e* to every word, and thus connect words together. Mrs Leigh of New York made her patients put the tongue at the top of the palate. This plan was also adopted by M. Malbouche and by Mr John Broster. Professor Diffenbach performed upon eighty persons the operation of cutting a transverse wedge out of the tongue. Sometimes one of these remedies was in public favour and sometimes another; but all failed to remove stammering on physiological principles. Such a state of public opinion afforded, however, a harvest to quacks and charlatans, each of whom had some secret panacea. One plan was to enforce talking with the teeth closed; another to place bits of India-rubber under the tongue; another advised chanting; another speaking through the nose; another drawling; another the full inflation of the lungs; while another set of professors cut away tonsils, uvula, and portions of the tongue. The Rev. C. Kingsley, in writing of the various systems says:—

> "Meanwhile the true method of cure, or at least its elements, had suggested itself to the late Mr Hunt. He found out by patient comparing of health with unhealth, a fact which seems to have escaped all before him—that the abuse neither of the tongue, nor of any single organ, is the cause of stammering—that the whole malady is so complicated that it is very difficult to perceive what organs are abused at any given moment—quite impossible to discover what organ first went wrong and set the rest wrong. For nature in the perpetual struggle to return to a goal to which she knows not the path, is ever trying to correct one morbid action by another, and to expel vice by vice; ever trying fresh experiments of mis-speaking, and failing, alas! in all: so that the stammer may take very different forms from year to year; and the boy who began to stammer with the lips, may go on to stammer with the tongue, then with the jaw, and last, and worst of all, with the breath; and in after-life try to rid himself of an abuse by trying in alternation all the other three. To these four abuses—of the lips, of the tongue, of the jaw, and of the breath—old Mr Hunt reduced his puzzling mass of morbid phenomena; and I, for one, believe his division to be sound and exhaustive."[1]

From this it will be seen that the great object must be first to discover the true cause of the stammer. To do this with any success, much experience and patient labour are necessary. When the cause has been ascertained, we must return to nature through art, and teach the stammerer to do consciously, what the healthy subject does unconsciously; but as the misuse of organs produces weakness, considerable time is often necessary to restore the vocal apparatus to healthy action. Great attention must likewise be paid to the *economy* of nature, to prevent that waste of nervous energy which generally accompanies psellismus. The art of speaking must be really learned, and the same control gained over the vocal organs as the musician has over his mechanical instrument. The stammerer cannot, however, be treated like a mere machine, for his organs are under the influence of an ever-varying agent—the mind. The physically abnormal condition in psellismus reacts most powerfully on the mind, as is proved by the curious phenomena that most stammerers can read aloud when alone, can talk fluently if in the dark, or if they wear a mask; and can recite or speak in an assumed tone without difficulty. The peculiar disposition of the mind must be studied, and every means used to rouse it into

[1] See *Frazer's Magazine* for July 1859, "The Irrationale of Speech."

Stanhope. vigilant and vigorous control over the vocal apparatus. The same authority before quoted says:—

"Of course the very condition of cure—the conscious use of the organs of speech—makes it depend on the power of self-observation, on the attention, on the determination, on the general intellectual power, in fact, of the patient; and a stupid or volatile lad will give weary work."

The sudden improvement frequently produced on first commencing treatment, induces the belief that the enemy is conquered. A perfect cure, however, can only be effected after much diligent application, and those cases which are quickly cured, are the most liable to relapse. The advice given by Dr J. Mason Warren, the highest authority on this subject in the United States, is most valuable. He says:—

"Seek out a person who has experience in the treatment of impediments of speech. Place him under his care, and if he is benefited do not remove him and think to perfect the cure yourself. Three months is a very short time for him to remain under the superintendence of an instructor; six months is better, and where it is practicable, he should remain a year. If this interferes with other studies, it is of no consequence; he will derive benefits enough to compensate for the loss. The age I should fix upon for this trial should be from eight to twelve. At this period the loss of a year's study may be a gain. If he meets there others who are affected as he is, it is all the better; he will no longer look upon his case as a peculiar one; and if he sees others whose impediments are worse than his, it will give him additional courage.

"Whatever method may be employed for the relief of this affection, no permanent advantage will be gained in the majority of cases unless resolutely persevered in for one or two years."

The writer cannot give his unqualified adherence to the last paragraph; but he believes, with Dr Warren, that the longer the treatment is continued, the more likely is the cure to be perfect and permanent. (J. H—T.)

STANHOPE, Philip Dormer, the fourth *Earl of Chesterfield*, was born at London, on the 22d of September 1694. He was the son of Philip, the third Earl, by his wife, Lady Elizabeth Savile, daughter of George, Marquis of Halifax. At the age of eighteen he was sent to Trinity Hall, Cambridge, where he studied assiduously, and, according to his own account, became an absolute pedant. In 1714 he quitted the university, and travelled on the continent, where a familiarity with good company soon convinced him he was totally mistaken in almost all his notions, and an attentive study of the air, manner, and address of people of fashion soon polished a man whose prominent desire was to please, and who, as it afterwards appeared, valued exterior accomplishments beyond any other human acquirement. While Lord Stanhope, he obtained an early seat in Parliament, and in 1722 succeeded to his father's estate and titles. In 1728 and in 1745 he was appointed ambassador extraordinary and plenipotentiary to Holland. This high character he supported with the greatest dignity, serving his own country, and gaining the esteem of the States-General. Upon his return from Holland, he was sent as lord-lieutenant to Ireland, and, during his administration there, gave general satisfaction to all parties. He left Dublin in 1746, and in October succeeded the Earl of Harrington as secretary of state, in which post he officiated until February 6, 1748. In 1752, being seized with a deafness which incapacitated him for the pleasures of society, he from that time led a private and retired life, amusing himself with books and his pen, in particular, he engaged largely as a contributor to a periodical called *The World*, in which his contributions have a distinguished degree of excellence. He died on the 24th of March 1773, leaving a character for wit and abilities that had few equals. He distinguished himself by his eloquence in parliament on many important occasions, of which we have a characteristic instance of his own relating. He was an active promoter of the bill for altering the style, and on this occasion, as he himself writes in one of his letters to his son, he made so eloquent a speech in the house that every one was pleased, and said he had made the whole very clear to them, "when," says he, "God knows, I had not even attempted it. I could just as soon have talked Celtic or Sclavonian to them as astronomy, and they would have understood me full as well." Lord Macclesfield, who was considered as a great mathematician, and who had a principal hand in framing the bill, spoke afterwards, with all the clearness that a thorough knowledge of the subject could dictate, but not having a flow of words equal to Lord Chesterfield, the latter gained the applause which was more justly due to the former. He left no issue by his lady, Melusina de Schulemburg, Countess of Walsingham, but he had a natural son, Philip Stanhope, Esq., whose education was for many years a close object of his attention, and who was afterwards envoy-extraordinary at the court of Dresden, but died before him. The high character which Lord Chesterfield supported during life received no small injury soon after his death, from a fuller display of it by his own hand. After Lord Chesterfield's death, Mr Stanhope's widow published a series of letters, written by the father to the son, filled with instructions suitable to the different gradations of the young man's life to whom they were addressed. These letters contain many fine observations on mankind and rules of conduct, but it is observable that he lays a greater stress on exterior accomplishments and address than on intellectual qualifications and sincerity, and allows a much greater latitude to fashionable pleasures than good morals will justify. Lord Mahon, now Earl Stanhope, who is the last and the most correct editor that Chesterfield's works have received (5 vols. 1853), says regarding his character—"The defects of Chesterfield were neither slight nor few, and the more his contemporaries excused them, lost as they were in the lustre of his fame, the less should they be passed over by posterity. A want of generosity, dissimulation carried beyond justifiable bounds, a passion for deep play, and a contempt for abstract science, whenever of no practical or immediate use, may, I think, not unjustly be ranked among his errors." These *Letters to his Son* appeared in 1774, in 2 vols. 4to. This publication was followed by a collection of his *Miscellaneous Works*, 1777, 2 vols. 4to. A third volume was added in 1778.

Stanhope, *Charles*, third Earl, born in 1753, was the eldest son of Philip, the second Earl, a man equally remarkable for his mathematical talents, and his liberal political opinions. The subject of this notice succeeded to the peerage in 1786. By his first marriage he became the brother-in-law of Pitt, and on the mother's side he was closely allied to the Scottish Earls of Haddington. By this marriage he had three daughters, one of them Lady Hester Stanhope, who gained so great a notoriety by retiring to the Syrian deserts and fixing her residence at Djoun, among the mountains of Lebanon, where she died in 1839. This eccentric but public-spirited and most inventive man, while he divided his attention among a variety of inquiries, sufficient to have prevented excellence in any, had the rare merit of excelling in several most important pursuits, while in more than one he has bequeathed to the world discoveries that have proved most extensively useful. In politics he was a decided Whig, an assertor of religious toleration, and of non-intervention in the internal affairs of foreign states. Sometimes, however, he carried out the principles of his party with a boldness which other minds scrupled to follow, and in the latter years of his parliamentary life, Earl Stanhope used to be called "the minority of one." His political works were a refutation of Price's scheme of the *Sinking Fund*, an answer to Burke's *Reflections on the French Revolution*, and an *Essay on Juries*. But his inventions in mechanical science are those by which he has secured the gratitude of posterity. They are too

Stanhope.

many to be here so much as completely enumerated. The principal of them, the Stanhope press, has been described in the article PRINTING, where notice has also been taken of his exertions for improving the process of stereotype printing. He was an early student of Franklin's theory of electricity, to which he contributed several valuable observations. Another of his most useful inventions was one for improving the locks of canals, and more curious ones were his two calculating machines, one of which performed addition and subtraction, the other multiplication and division. He died in 1816.

STANHOPE, *George*, an eminent divine of the Church of England, was born at Hartshorn, in Derbyshire, in the year 1660. His father was rector of that parish, vicar of St Margaret's at Leicester, and chaplain to the Earls of Chesterfield and Clare. His grandfather, Dr George Stanhope, was chaplain to James I. and Charles I., had the chancellorship of York, where he was also a canon residentiary, held a prebend, and was rector of Weldrake, in that county. For his loyalty he was driven from his home with eleven children, and died in 1664. The son was sent to school, first at Uppingham, in Rutland, then at Leicester; he was afterwards removed to Eton, and thence chosen to King's College, in Cambridge, in the place of W. Cleaver. He took the degree of A.B. in 1681 and of A.M. in 1685, was elected one of the syndics for the University of Cambridge, in the business of Alban Francis, 1687, minister of Quoi, near Cambridge, and vice-proctor, 1688. He was that year preferred to the rectory of Tring, in Hertfordshire, which after some time he quitted. In 1689 he was presented to the vicarage of Lewisham, in Kent, by Lord Dartmouth, to whom he had been chaplain, as well as tutor to his son. He was also appointed chaplain to King William and Queen Mary, and continued to enjoy that honour under Queen Anne. He commenced D.D. July 5, 1697, performing all the exercises required to that degree publicly and with great applause. He was made vicar of Deptford in 1703, succeeded Dr Hooper as dean of Canterbury the same year, and was thrice chosen prolocutor of the lower house of convocation. His uncommon diligence and industry, assisted by his excellent parts, enriched him with a large stock of polite, solid, and useful learning. His discourses from the pulpit were equally pleasing and profitable, a beautiful intermixture of the clearest reasoning with the purest diction, attended with all the graces of a just elocution. In him were happily united the good Christian, the solid divine, and the fine gentleman. His conversation was polite and delicate, grave without preciseness, facetious without levity. His piety was real and rational, his charity great and universal, fruitful in acts of mercy and in all good works. He died March 18, 1728, aged sixty-eight years, and was buried in the chancel of the church at Lewisham. The dean was twice married, first to Olivia Cotton, by whom he had one son and four daughters. His second lady, who was sister to Sir Charles Wager, survived him, dying October 1, 1738, aged about fifty-four. One of the dean's daughters was married to a son of Bishop Burnet. Stanhope's writings, which are considered as a treasure of piety and devotion, are—*A Paraphrase and Comment upon the Epistles and Gospels*, 1705, 4 vols., 8vo; *Sermons at Boyle's Lectures*, 1706, 4to; *Fifteen Sermons*, 1700, 8vo; *Twelve Sermons on Several Occasions*, 1727, 8vo; *A Translation of Thomas à Kempis*, 1696, 8vo; *Epictetus's Morals, with Simplicius's Comment, and the Life of Epictetus*, 1700, 8vo; *Parson's Christian Directory*, 1716, 8vo; *Pious Breathings*, from the works of St Augustine, with select contemplations from St Anselm and St Bernard; *Rochefoucault's Maxims*, 1706, 8vo; *A Funeral Sermon on Mr Richard Sare, bookseller*, 1724, two editions, 4to; *Twenty Sermons*, published singly between the years 1692 and 1724; *Private Prayers for every Day in the Week, and for the several Parts of each Day*, translated from the Greek Devotions of Bishop Andrews, with Additions, 1730. In his translations it is well known Dr Stanhope did not confine himself to a strict and literal version; he took the liberty of paraphrasing, explaining, and improving upon his author.

Stanislas Leszczynski.

STANISLAS LESZCZYNSKI, or LESZINSKI, King of Poland, was born at Lemberg, the capital of Red Russia, on the 20th of October 1677. His father was a Polish nobleman, distinguished by his rank and the important offices which he held, but still more by his firmness and courage. In 1704 Stanislas was sent ambassador by the Assembly of Warsaw to Charles XII. of Sweden, who had conquered Poland. He was at that time twenty-seven years old, was general of Great Poland, and had been ambassador-extraordinary to the Grand Signior in 1699. Charles was so delighted with the frankness and sincerity of his deportment, and with the firmness and sweetness which appeared in his countenance, that he offered him the crown of Poland, and ordered him to be crowned at Warsaw in 1705. He accompanied Charles into Saxony, where a treaty was concluded with King Augustus in 1705 by which that prince resigned the crown and acknowledged Stanislas King of Poland. The new monarch remained in Saxony with Charles till 1707, when they returned into Poland and attacked the Russians, who were obliged to evacuate that kingdom in 1708. But Charles being defeated by Peter the Great in 1709, Augustus returned into Poland, and being assisted by a Russian army, obliged Stanislas to retire first into Sweden and afterwards into Turkey. Soon after, he took up his residence at Weissenburg, a town in Alsace. Augustus despatched Sum, his envoy, to France to complain of this, but the Duke of Orleans, who was then regent, returned this answer:—"Tell your king that France has always been the asylum of unhappy princes." Stanislas lived in obscurity till 1725, when Louis XV. espoused the Princess Mary, his daughter. Upon the death of King Augustus in 1733 he returned to Poland, in hopes of remounting the throne of that kingdom. A large party declared for him, but his competitor, the young Elector of Saxony, being supported by the Emperor Charles VI. and the Empress of Russia, was declared king, though the majority was against him. Dantzig, to which Stanislas had retired, was quickly taken, and with great difficulty the unfortunate prince made his escape in disguise, after hearing that the Russians had set a price upon his head. In 1736, when peace was concluded between the Emperor and France, it was agreed that Stanislas should abdicate the throne, but that he should be acknowledged King of Poland and Grand Duke of Lithuania, and continue to bear these titles during life; that all his effects and those of the Queen, his spouse, should be restored; that an amnesty should be declared in Poland for all that was past, and that every person should be restored to his possessions, rights, and privileges; that the Elector of Saxony should be acknowledged King of Poland by all the powers who acceded to the treaty; that Stanislas should be put in peaceable possession of the duchies of Lorraine and Bar, but that immediately after his death those duchies should be united for ever to the crown of France. In Lorraine, Stanislas succeeded a race of princes who were beloved and regretted, and his subjects found their ancient sovereigns revived in him. He then tasted the pleasure which he had so long desired, the pleasure of making men happy. He assisted his new subjects; he embellished Nancy and Luneville; he formed useful establishments; he founded colleges, and built hospitals. He was engaged in these noble employments, when an accident occasioned his death. His night-gown caught fire, and burned him so severely before it could be extinguished, that he was seized

with a fever, and died the 23d of February 1766. He was a protector of the arts and sciences. He wrote several works of philosophy, politics, and morality, which were collected and published at Paris in 1763, in 4 vols. 8vo., under the title of *Œuvres du Philosophe Bienfaisant.* An octavo volume, ornamented with engravings, was published in 1825, under the title of *Œuvres choisies de Stanislas, Roi de Pologne, Duc de Lorraine et de Bar*, to which an historical notice was prefixed by Madame de Saint-Ouen.

STANISLAWOW, or Stanislau, a town of the Austrian Empire, in Galicia, capital of a circle, on the Bistritza, 71 miles S.S.E. of Lemberg. It is strongly fortified, and contains a castle, now used as a military hospital, three handsome churches, a gymnasium, normal seminary, and other schools. Here also is a column, erected in 1838 in honour of the late Emperor Francis. Stanislawow is the seat of public offices and courts of law; it is generally well built, and has an active trade in the produce of the surrounding country. Pop. (1851) 10,864.

STANLEY, Thomas, a very learned writer, was the son of Sir Thomas Stanley of Laytonstone in Essex, and Cumberlow in Hertfordshire, by his second wife Mary, the daughter of Sir William Hammond of St Alban's Court. He was descended from a natural son of Edward earl of Derby. He was born in the year 1625, and received a domestic education under the tuition of William the son of Edward Fairfax, the well-known translator of Tasso. In 1639, he became a fellow-commoner of Pembroke Hall, Cambridge, where he distinguished himself by his progress in classical learning. After having travelled on the continent, he resided for some time in the Middle Temple. Here he lived on terms of particular intimacy with his cousin Edward, afterwards Sir Edward Sherburne, who cultivated similar studies, and who dedicated a volume of poems to this learned kinsman. Stanley published *Poems and Translations* in 1649, 8vo. They were reprinted, with additions, in 1651. But his principal work was his *History of Philosophy, containing the Lives, Opinions, Actions, and Discourses of the Philosophers of every Sect.* Of the original edition, printed in folio, the first part appeared in 1655, and the third in 1660. The work is dedicated to his uncle-in-law, Sir John Marsham, author of the *Canon Chronicus*, who first suggested the undertaking. There are four editions of the History, the last and best being that of 1743, 4to. The author has displayed solid as well as extensive erudition, but his valuable materials are not disposed to the best advantage. The reputation of his work extended to the continent; and a Latin translation of it by Olearius was published at Leipzig, in quarto, in the year 1711. The part relating to the history of Oriental philosophy had been translated into the same language by Le Clerc, and published at Amsterdam in 1690, with a dedication to Bishop Burnet. This version Le Clerc afterwards inserted in the second volume of his *Opera Philosophica.* Stanley next prepared his elaborate and valuable edition of Æschylus, Lond., 1633, fol. Some copies of the same impression bear the date of 1664. This edition, which includes the fragments and the Greek scholia, and is accompanied with a commentary and a Latin version, was of great importance when it first appeared; but since the death of the learned editor, so much has been effected by Schütz, Wellauer, Dindorf, and Scholefield, that it has lost a great portion of its original value. It was thought expedient to reprint Stanley's edition, with the commentary, corrected and enlarged from his papers preserved in the university library at Cambridge. The charge of this edition was committed to a very competent scholar, Samuel Butler, afterwards promoted to the bishopric of Lichfield; who, with the addition of his own annotations, published it at Cambridge in the year 1809, in 4 vols. 4to, and in 8 vols. 8vo. Some notes on Demosthenes, ascribed to Stanley, have recently been published in the ninth volume of Dobson's *Oratores Attici.* He died at his lodgings in Suffolk Street, in the parish of St Martin's-in-the-Fields, on the 12th of April 1678. He had married Dorothy, the daughter and co-heiress of Sir James Enyon of Flower in Northamptonshire, Bart. He had a son, who bore his own name, and, like himself, was educated at Pembroke Hall. At a very early age, he published *Aelian's Various Histories, translated into English*, Lond., 1665, 8vo. A memoir of Stanley will be found prefixed to the edition of his *Poems*, published in 1814–15, by Sir Egerton Brydges.

STANNARY COURTS (Lat. *Stannum*, tin), are legal institutions in Devonshire and Cornwall, for the administration of justice among the tinners. They are held before the lord-warden and his substitutes, by a privilege granted to the workers in the tin-mines, to sue and be sued only in their own courts, that they may not be drawn from their business by attending their lawsuits in other courts.

STANOVOI, or Yablonoi Mountains, a chain in Siberia, extending for about 3000 miles in a direction for the most part N.E. from the Altai range, parallel to the shores of the sea of Ochotsk, as far as Behring Strait. This chain sends out numerous smaller branches, but it is more remarkable for length than for altitude. South of 55. N. Lat., the mountains are densely wooded; from that point as far north as 63., they gradually become more and more bare, and beyond the latter point they are quite covered with snow. Many considerable rivers take their rise in the Stanovoi Mountains.

STARAJA RUSSA, a town of European Russia, in the government and 40 miles S. of Novgorod, on the south side of Lake Ilmen. It is generally ill built, but has several churches and other edifices. Here there are celebrated salt-works, and an active trade in linseed. Pop. 8044.

STARCH. See Chemistry and Food.

STAR-CHAMBER, Court of (*Camera Stellata*), a famous, or rather infamous, English tribunal, said to have derived its name from the room in which it sat, the old council-chamber of the palace of Westminster, because the roof was at first garnished with gilded *stars.* This was a court of very ancient origin, but new-modelled by statutes 3 Henry VII., c. 1, and 21 Henry VIII., c. 20, consisting of divers lords spiritual and temporal, being privy councillors, together with two judges of the courts of common law, without the intervention of any jury. Their jurisdiction extended legally over riots, perjury, misbehaviour of sheriffs, and other notorious misdemeanours, contrary to the laws of the land. Yet this was afterwards, as Lord Clarendon informs us, stretched "to the asserting of all proclamations and orders of state; to the vindicating of illegal commissions and grants of monopolies; holding for honourable that which pleased, and for just that which profited; and becoming both a court of law to determine civil rights, and a court of revenue to enrich the treasury: the council-table by proclamation enjoining to the people that which was not enjoined by the laws, and prohibiting that which was not prohibited; and the star-chamber, which consisted of the same persons in different rooms, censuring the breach and disobedience to those proclamations by very great fines, imprisonments, and corporal severities: so that any disrespect to any acts of state, or to the persons of statesmen, was in no time more penal, and the foundations of right never more in danger to be destroyed." For these reasons, it was finally abolished by statute 16 Car. I., c. 10, to the general joy of the whole nation.

STARGARD, a town of the Prussian monarchy, Pomerania, in the government and 21 miles E.S.E. of Stettin, on the navigable river Ihna. It was anciently the chief town of Farther Pomerania (*Hinterpommern*), and is still surrounded by ancient walls and watch-towers, and entered by three gates. The town has 4 churches, one of which,

that of St Mary, a Gothic building of the 14th and 15th centuries, is remarkable for its richly adorned exterior, and for the majestic proportions of the interior. The town-hall, which dates from the 16th century, is also a fine building. Stargard has a gymnasium and several other schools, various hospitals, and an orphan asylum. Woollen and linen cloth, hosiery, hats, &c., are extensively manufactured here, and an active trade is carried on. Pop. 13,107.

STARGARD, a town of Prussia, on the Ferse, in the government, and 29 miles S., of Danzig. It has a town-hall, Protestant and Roman Catholic churches, a school, and an hospital. Tanning, brewing, and distilling, are carried on here. Pop. 4875.

STARK, WILLIAM, a physician of Scottish descent, was born at Manchester in the month of July 1740. He was sent to the University of Glasgow, where, under the tuition of Dr Smith and Dr Black, with other eminent masters, he learned the rudiments of science, and acquired the mathematical accuracy, logical precision, and contempt of hypotheses, with which he prosecuted all his future studies. Having chosen physic for his profession, he removed from the University of Glasgow to that of Edinburgh, where he was soon distinguished, and honoured with the friendship of the late Dr Cullen. Having finished his studies at Edinburgh, though he took there no degree, Mr Stark, in the year 1765, went to London, and devoted himself entirely to the study of physic and the elements of surgery; and looking upon anatomy as one of the principal pillars of both these arts, he endeavoured to complete with Dr Hunter what he had begun with Dr Monro; and under these two eminent teachers he appears to have acquired a high degree of anatomical knowledge. He likewise entered himself, about this time, a pupil at St George's Hospital; and with what industry he prosecuted this plan, with what success his labours were crowned, may be seen in a series of *Clinical and Anatomical Observations*, which were made by him during his attendance at the hospital, and were published after his death by his friend Dr Carmichael Smyth.

In the year 1767 he went to Leyden, where he took the degree of M.D., publishing an inaugural dissertation on dysentery. On his return to London, he recommenced his studies at the hospital; and when Dr Black was called to the chemical chair in Edinburgh, Dr Stark was solicited, by several members of the University of Glasgow, to stand as a candidate for their professorship of the theory and practice of physic. This, however, he declined, being influenced by the advice of his English friends, who wished to detain him in London, and having likewise some prospect of an appointment in the hospital. In 1769 he commenced a series of experiments on diet, which he was encouraged to undertake by Sir John Pringle and Dr Franklin, whose friendship he enjoyed, and from whom he received many hints respecting both the plan and its execution. These experiments, or rather the imprudent zeal with which he prosecuted them, proved, in the opinion of his friends, fatal to himself; for he began them on the 12th of July 1769 in perfect health and vigour, and from that day, though his health varied, it was seldom if ever good, till the 23d of February 1770, when he died after suffering much uneasiness.

STARODUB, a town of European Russia, on the Babinza, in the government and 100 miles N.E. of Tchernigov. It is surrounded by earthen ramparts, and contains a cathedral, a monastery, an extensive copper-work, a bell-foundry, and tanneries; and it has a considerable trade with the Baltic and Black Sea. Pop. 9500.

STATEN ISLAND. See NEW YORK.

STATICS

Is that branch of mechanical science which treats of the laws of equilibrium or repose; it is divided into three distinct sections, according as it may refer to solid, to fluid, or to gaseous matter. Hydrostatics and Aërostatics have already been treated of under their proper heads; and in the present article we shall confine our attention to the equilibrium of solid bodies, or to Geostatics, as this section may, with propriety, be termed.

If we could place a body in space so as that nothing might obstruct its motion, it would move on the application of the slightest pressure, and could then only be kept at rest by the application of antagonistic pressures, so that the doctrines of statics must relate to the manner in which pressures applied to a solid body keep that body at rest, or, as we say, in which they balance each other.

Our idea of pressure is obtained directly from the experience of resistance to muscular effort; and as our knowledge of the very existence of resistance is experimental, so our acquaintance with the laws of resistance must also be derived from experience, and cannot possibly be the result of mere intellectual ratiocination: the attempt to make statics a branch of pure logic must, in the very nature of things, be a vain one.

When a piece of solid matter is entirely detached from all other solid bodies, it, except in certain very peculiar circumstances, moves and continues to move until it come in contact with some other solid body, and all the repose of which we have any actual cognisance, exists among solid bodies in contact with each other.

On attempting to displace a body which is at rest, we experience three distinct kinds of resistance:—in the first place, on trying to lift it, we experience an opposition, as it were, in the object itself, and if we succeed in raising it we still feel that it tends to go down again; to this well-known and yet very wonderful quality, the name *weight* is given, and we recognise in it that very tendency in virtue of which the object, when let go, descends until it meet an obstacle. In the second place, on attempting to push the object against the body on which it is resting, we find that that body resists our utmost endeavours which never succeed unless by its displacement or by its fracture; this kind of resistance may, for the convenience of language, be called *direct*. And in the third place, on trying to push the object along the surface on which it is resting, we experience a resistance, not insuperable as before, but varying according to the nature of the surfaces and to other circumstances; this kind of resistance is commonly called *friction*, but as this word implies motion, it would be more accurate to use the expression *resistance to friction* or *lateral resistance*. When the surfaces are smooth and the substances hard, the friction is comparatively small, and, as is well-known, becomes less when grease or oil is applied.

EQUILIBRIUM OF TWO PRESSURES.

If we place an object O upon a smooth flat surface, and push it gently by means of a stick BA, we find that it remains at rest, unless the intensity of the pressure be sufficient to overcome the friction. If

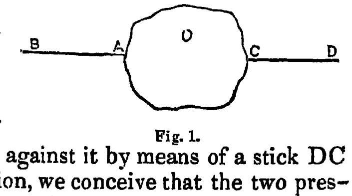

Fig. 1.

now another person press against it by means of a stick DC so as to prevent the motion, we conceive that the two pressures are of like intensity, or differ from each other only by

Equilibrium of Two Pressures.

the friction, while everyday experience shows that their directions must be exactly opposed to each other. The object O seems to be the means of communication between the two pressing bodies, and if the two sticks were applied end to end with pressures equally intense, there would also be equilibrium. so that we very readily admit the general proposition, "*Two pressures equal in intensity and opposite in direction balance each other.*"

When the object O is hard, we do not readily perceive that any change is made upon it by the pressures at A and C, but if a soft body, such as a cork or a bit of elastic gum, be subjected to such pressures, a visible change is made in its form; this change increases as the pressures are augmented, so that it becomes a kind of index of the intensity of the pressure, and careful experiments show, that though often imperceptible in extent, analogous changes take place in even the hardest substances. When the pressure is removed, the body resumes its original shape more or less accurately, and with greater or less rapidity according to the nature of the material. With some subtances, as lead, a permanent change of form results if the pressure be considerable; with others, as vulcanised caoutchouc, a considerable time elapses; while with the generality of what are called hard substances, the resumption of form is complete and almost instantaneous. The communication of pressure, then, from the point A to the point C, implies important and complicated changes in the form and position of the parts of the intervening body.

We have not, however, completely examined this experiment; for if one person press against the end B of the stick BA, while another presses against the end D of DC, the object O is almost invariably found to turn round: the slightest error in the direction of either of the rods is followed by a dislocation of the arrangement. The same thing takes place if two parties attempt to make trial of their strength by pushing the buttons of their foils against each other, and it is only by laying the rods between guides that we can prevent this inconvenience.

If we make two holes in the object O, one at A and the other at C, and having passed a cord through each, pull at the ends B and D of these cords, the object no longer gets displaced; but, on the contrary, the threads AB and CD always come into one straight line. The two pressures are still opposite in direction and equal in intensity.

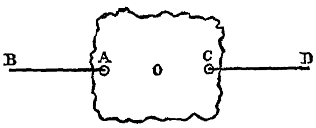

Fig. 2.

These two modes of conducting this fundamental experiment furnish excellent examples of *unstable* and *stable* equilibrium, the contrast between them is instructive in another way. It appears at first sight, that there are two modes of urging a body in a given direction, one by pushing, the other by pulling; but a closer examination of the matter shows that pulling or *traction* is, in reality, pushing or *pressure*. No body can influence another body to move (setting aside gravitation and such influences as magnetic or electric attractions and repulsions), except by pressing upon it. We cannot draw an object to us by stretching out the hand unto it and withdrawing the arm again; no: the hand must be reached to and beyond some integral part of the object, the fingers must be bent round, and *pressure* must be applied to the further surface; we must take hold of it. Even when, as in the case of pulling a rope or seizing the end of a stick, we do not reach to a surface opposed to the direction of the intended effort, we grasp the object in the hand so as to occasion friction, and thus our ultimate resort is still to pressure. The perception of this truth leads to the use of hooks, eyes, loops, rings, ties, &c., which are all contrived for the very purpose of reaching beyond and pressing upon the further surface.

Equilibrium of Two Pressures.

Vices and forceps, again, are constructed for pulling by friction; their jaws are pressed against the lateral surfaces of the object, and the friction thus occasioned offers resistance to the pulls.

Traction occasions complicated changes in the internal part of the bodies subjected to it. Thus, if a pin A driven firmly into the block B be drawn towards E by means of the hook CDE, the parts of the pin near C are compressed, but of the parts near the lower end *a* some are compressed and some are distended. The hook at C is compressed, the parts D on the one side of the line of traction are partly distended and partly bent, while the parts E in the line of strain seem to be merely distended; so that in this little arrangement we have compression, lateral flexure, and distension combined, and this combination is to be found in every case of traction.

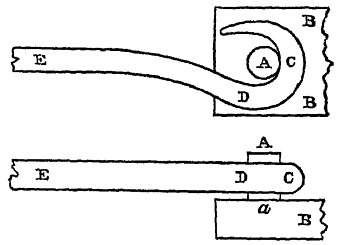

Fig. 3.

When we pull by means of a chain, each link is strained, on the whole lengthened, and communicates its tension to the next, so that we have a series of examples of the equilibrium of two opposing pressures. So, when a rope is used, we imagine that each part is distended, and communicates the pressure to the adjoining part; but as we, in truth, know very little of the internal constitution of matter, this idea rather furnishes us with a convenient mode of speech, than with an explanation of the matter; it clearly points to the well known fact that the length of the cord does not, unless its weight has to be considered, in any way influence the transmission of pressure from the one end to the other.

It is apparent that we cannot strain a rope by pulling at the one end unless the other end be held fast; and therefore, when two men pull at opposite ends of a rope, the rope is not strained by the exertions of two men, but only by the exertion of one man, and he the weaker of the two. This is very obvious, yet we have examples of its misapprehension. Thus, Otto von Guericke, when exhibiting publicly his famous experiment of the hemispheres, yoked eight horses to the one and eight horses to the other cup, in order to pull them asunder, thinking that he thus employed the strength of sixteen horses, whereas, had he fastened one of the hemispheres to the adjacent tree, the eight horses yoked to the other cup would have pulled quite as effectively as when pulling against the other teem.

The change which pressure causes in the form of a solid is well seen when the strain acts transversely. Thus, if a wire AB (fig. 4) be bent into the form of a screw, a slight pressure applied to the end is accompanied by a perceptible alteration in the length of the spiral. By using a thin wire with large and numerous convolutions, any degree of delicacy may be obtained in this kind of spring, so that we can construct a convenient indicator of pressure. Tension gauges of this kind are in common use; the spiral spring being generally inclosed in a tube, and the divisions to indicate the quantity of compression or distension are marked either along the side of the tube or on a style protruding from one end.

We are not entitled to assume, nor, indeed, is it strictly true, that the intensity of the pressure applied is proportional to the lengthening or shortening of the spiral spring, yet such spring gauges can be made truly to indicate the pressures, and they are the most convenient instruments for examining experimentally the laws of equilibrium. The unit of pressure is usually

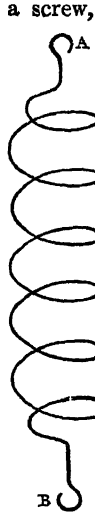

Fig. 4.

taken as the weight of some known heavy body, such as a pound, an ounce, or a grain; and this will answer sufficiently well our present purpose, although it be a fact that gravitation is not quite the same all over the world.

Let then a weight, say of one pound, be hung from the hook of a spring-balance, and let the protrusion of the style be marked: remove now the pound, substitute for it a mass somewhat heavier, and by paring or filing adjust it so as to bring the index exactly to the same mark, and you have another pound weight; in this way we may prepare as many weights as may be required. Hang on now two, three, four, and so on of these weights at once, marking the indication corresponding to each, and you have the spring-balance graduated to show pressures of one, two, three, etc., pounds. Having prepared several of such pressure gauges, we are ready to make experiments on the manner in which pressures balance each other.

On hooking two of these gauges together, directly or by the intervention of a cord, we obtain at once a confirmation of the law already stated, that two pressures balance each other when they are equal in intensity and opposite in direction.

EQUILIBRIUM OF THREE PRESSURES.

In order to examine the simplest case of the equilibrium of three pressures, we may knot three threads together, and attach the loose ends of these to the hooks of three pressure-gauges. On stretching the threads of this little arrangement, the first thing which offers itself to our notice is, that, sensibly, they are always in one plane; and we are convinced that, when three pressures acting on one point balance each other, this is always the case. Let (fig. 5) PA, PB, PC represent the three threads knotted together at P; in PA and PB take any points a and b, then if we join these by a fine line, as a silk fibre, the continuation of CP always cuts it; this is in accordance with the well-known property of plane surfaces. A very slight examination of a few cases shows us that the continuation of the direction of one of the pressures always passes between the other two, and also that the greater pressure has the lesser angle opposite to it. If the distances Pa, Pb be measured off proportional to the intensities of the pressures, it is found *invariably* that the continuation of the third line CP divides the line joining a and b into two equal parts. Any observer may convince himself of the truth of this law by bringing a strained system of three threads over a sheet of paper, by noting the arrangement and by making the appropriate delineation.

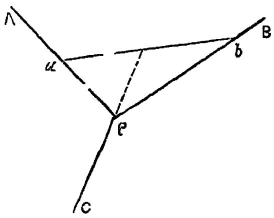

Fig. 5.

In order to be a general law, this statement must apply as well to the two pressures PB and PC as to PA and PB, wherefore if Pc be measured proportional to the tension of PC, bc should be bisected by the continuation of AP, and ca by the continuation of BP; and this is in accordance with the truth that the three lines which join the corners of any trigon with the middles of the opposite sides all meet in one point. Having produced the line CPf until fg be equal to Pf, join ag and bg, then it can easily be shown that ag is equal to Pb, bg to Pa, and Pg to Pc, so that *the intensities of three pressures which balance at a point are proportional to the three sides of a trigon drawn parallel to the three directions of the pressures:* thus the tensions of the cords PA, PB, PC are proportional to Pa, ag, gP. Again, since the sides of a trigon are proportional to the sines of their opposite angles, and since the sine of an angle is equal to the sine of its supplement, it follows that, *of three pressures which balance each other at a point, the intensities are proportional to the sines of the opposite angles.* The same truth may be stated yet in another way. The two pressures Pa and Pb may be regarded as balancing or resisting the third pressure Pc; but a pressure represented by Pg would alone resist Pc, so that we may, as it were, regard the single pressure represented by Pg as equivalent to the two Pa and Pb; the pressure represented by Pg is called the *resultant* of Pa and Pb; and thus, *if the two sides of a rhomboid represent in direction and in intensity two pressures acting on a point, the diagonal of the rhomboid represents the resultant of those pressures.*

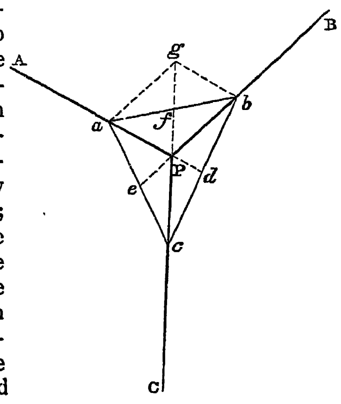

Fig. 6.

This theorem, in whichever way we may prefer to state it, is the foundation of all mechanical science. Various attempts have been made to show that it ought, necessarily, to be true, or, in other words, to deduce our knowledge of it from some fancied intuitive perception of what should be; but the authors of all such attempts proceed by assuming, stated in one form of words, the very law which, disguised in another form, they wish to establish. Experience, and experience alone, tells us that this law *is*, but *why it is*, is utterly beyond our comprehension.

If three pressures, not acting on one point, balance each other, they must act through the intervention of some solid body, and must produce strains in the parts of that body; for we have no example of pressures applied to one being resisted by other pressures applied to another and disconnected object. Let us then suppose that three points, Q, R, S, are connected by three slender rods, QR, RS, SQ, and let us endeavour to trace the effects of three pressures, QA, RB, SC, acting on these points and balancing each other.

In this arrangement, putting out of view the weights of the tie-rods, the point Q is kept in equilibrium by three pressures—one QA, one the strain on QR, and one the strain on QS; so, according to the previously observed

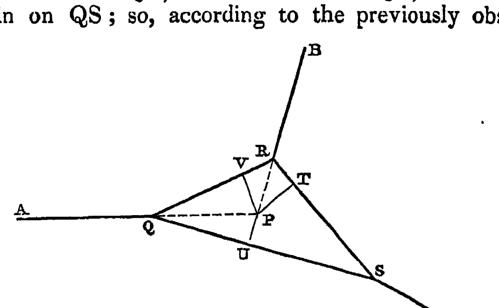

Fig. 7.

law, the direction of QA must be in the plane QRS, and as the same may be said of RB, SC, it seems that, in such an arrangement as this, the directions of the three pressures must lie in one plane. Let us produce AQ and BR to meet in P, and draw the perpendiculars PT, PU, PV to the lines RS, SQ, QR. Then since PU is the sine of the angle AQS to the radius QP, while PV is the sine of AQR to the same radius, it follows that the strain on QR is to the strain on QS as PU is to PV, or denoting strain by a superscribed line,

$$\overline{QR} : \overline{QS} :: PU : PV.$$

Equilibrium of Three Pressures.

In the same way, by considering the three strains balancing at the point R, we find that

$$\overline{RS} : \overline{QR} : : PV : PT ;$$

wherefore by compounding the ratios we obtain

$$\overline{RS} : \overline{QS} : : PU : PT.$$

Now this is what would ensue if the direction of the third pressure CS were to pass through P ; and thus we conclude that *when three pressures acting on three points connected by tie-rods balance each other, their directions must all tend to one point;* and farther, it is very easy to show that the intensities of these pressures must be just as if they had acted directly on that point.

This proposition, which we have easily deduced from our first law in the case of a linear frame QRS, is also true of pressures applied to any three points in a solid body; but without having recourse to farther experiments, we are unable to show that it is so.

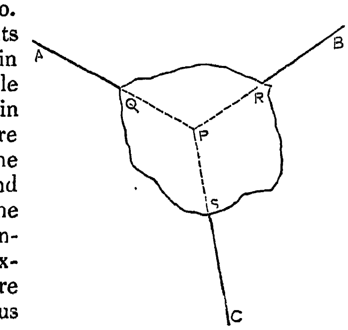

Fig. 8.

If, for example, the points Q, R, S be taken in a thin flat plate, we are unable to trace the manner in which the strains are transmitted from the one point to the other, and are thus without the means of pursuing the investigation. A few experiments, however, are enough to convince us that the three directions, AQ, BR, CS, converge to one point, and that the intensities of the pressures bear to each other the very same ratios that they would have had if the strings had been attached to that point.

If the plate have a forked form, as shown in fig. 9, the tendency is to lengthen the arms QR and RS, and to open the angle QRS, so that we have a cross or angular strain upon the arms of this, which is called a *bent lever*. On making trials with such a form as this, we find, as before, that the three pressures balance just as if they had been attached directly to their point of common intersection; and thus we may accept it as a general law, that *when three pressures balance each other, their directions meet in one point, and are in one plane, and their intensities are proportional to the sides of a trigon drawn parallel to them.*

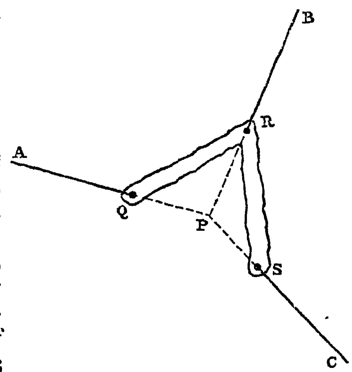

Fig. 9.

From this law it follows that the resultant of two pressures is always less than their sum. If the pressure $\overline{QA}$ were made nearly equal to the sum of the other two $\overline{RB}$, $\overline{SC}$, the trigon formed with its sides proportional to these three would have the angle opposite to the representative of $\overline{QA}$ very obtuse, so that its supplement BPC would be a small angle, and the point P would necessarily be situated considerably beyond Q, in the direction QA, as shown in fig. 10. If the pressure $\overline{QA}$ were gradually augmented, so as to become almost equal to the sum of the others, P would move off to a very great distance, and the lines QA, RB, SC, would be nearly parallel; so that in the limiting case, when we may suppose these lines to have become absolutely parallel, the middle pressure must be equal to the sum of the other two. From Q let fall the perpendiculars QT, QU upon the directions of the pressures RB, SC; then, since these are proportional to the sines of the angles QPB, QPC, they must also be proportional to the intensities of the pressures $\overline{SC}$, $\overline{RB}$; and as this proportion, viz., $\overline{SC} : \overline{RB} :: QT : QU$, holds true of every case up to the very limit of parallelism, we must conclude that it is true of parallel pressures also.

Equilibrium of Four Pressures.

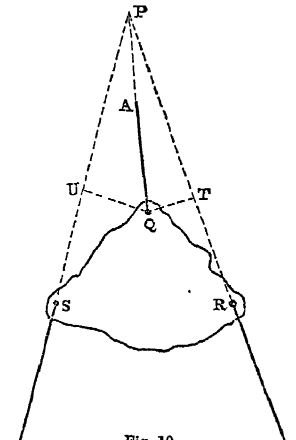

Fig. 10.

This brings us to the very well known doctrine of the lever. When a rigid body RQS, of any form whatever, is made to rest at one point, as Q, against an obstacle, and has pressures applied to it at two other points, it is called a *lever*, the resisting point being called the *fulcrum*, and the distances, as QR, QS, of the other two points from the fulcrum, being called the *arms* of the lever.

When the three points Q, R, S are in one straight line, the lever is said to be straight; and in that case, if the pressures SC, RB be parallel, the perpendiculars QU and QT are proportional to QS and QR; hence, when a straight lever is kept in equilibrium by weights hung on at its two extremities, these weights must be inversely proportional to the lengths of the arms; and when these lengths are equal, the weights also must be equal to each other.

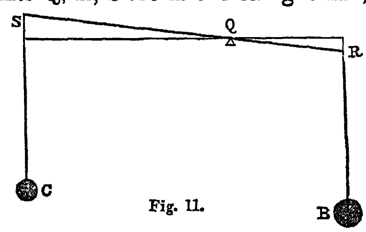

Fig. 11.

This proposition concerning the equilibrium of three pressures applied to three points in a solid body, contains the essential principles of *balances*, *steelyards*, and other weighing machines; but it must be remarked, that such an equilibrium is hardly to be obtained in practice, even though it were desirable. The balance is always made to rest on the two ends of a knife edge, and thus there are at least four pressures acting on four points. (See the article BALANCE in Vol. IV.)

EQUILIBRIUM OF FOUR PRESSURES.

When four pressures, acting in the directions PA, PB, PC, PD, balance each other, we may seek to investigate their relations by finding the resultants of two of them, as $\overline{PA}$, $\overline{PB}$, which we shall suppose to be $\overline{PG}$, and by then considering the equilibrium to subsist among the three, $\overline{PG}$, $\overline{PC}$, $\overline{PD}$; but in following such a course we would be assuming that because $\overline{PA}$, $\overline{PB}$ would be resisted by a pressure

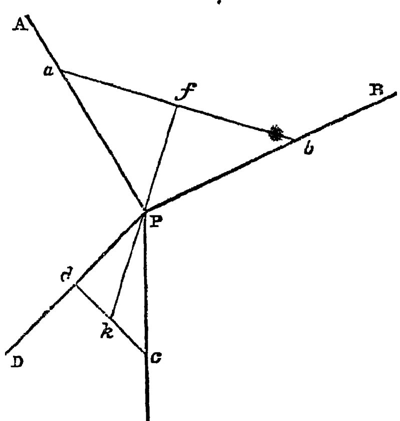

Fig. 12.

Equilibrium of several Pressures.

equal and opposite to $\overline{PG}$, the pressure $\overline{PG}$ may, in all cases, be substituted for them. This, however, we cannot demonstrate logically; it is a mere surmise, and cannot be admitted as an established truth, until it shall have received a substantial confirmation.

On tying together four cords, and straining them by help of pressure-gauges, we observe, on varying the directions of the pulls, that they no longer necessarily lie all in one plane; and we readily notice that the continuation of any one of the directions passes within the solid angle or corner formed by the other three. If we now measure along PA and PB distances, Pa, Pb, proportional to the tensions, join the points a, b, by a fine thread, and mark f the middle of $a\,b$, we find, on bringing the eye into the plane of the two other cords PC, PD, that f is in that plane. Thus, the line Pf must be the intersection of the two planes APB, CPD. Similarly, if this be really a law, on measuring Pc, Pd proportional to the respective strains, and joining $c\,d$, the middle, k of that line must be in the plane APB, so that Pk must be the intersection of the same two planes, and must therefore be a continuation on fP. In the same way, the line joining the middles of $a\,d$ and $b\,c$ ought to pass through P, as also that joining the middles of $a\,c$ and $b\,d$. Now it is a well known property of the tetrahedron, that the straight lines joining the middles of the opposite sides meet in one point, and bisect each other, so that this statical law, which we have observed, is not inconsistent with the truths of geometry.

The double of $\overline{Pf}$ represents in direction, and in intensity, the resultant of $\overline{PA}$ and $\overline{PB}$, and also represents a pressure which alone would resist $\overline{PC}$ and $\overline{PD}$, so that we have our surmise confirmed, and may safely conclude that, so far at least as statical effect is concerned, the resultant of two pressures may be substituted for them.

Having taken any point p in space, draw $p\,a$ parallel and equal to Pa of fig. 12, and $a\,g$ parallel and equal to Pb, then it is evident that $p\,g$, if joined, would be parallel and equal to the double of $\overline{Pf}$; it would, therefore, represent the resultant of $\overline{PA}$ and $\overline{PB}$. Draw now $g\,e$ parallel and equal to Pc, and it is obvious that $e\,p$ is also parallel and equal to Pd, so that we have this general law, that *when four pressures acting on one point are represented in direction and in intensity by four connected lines taken in order, they balance each other;* and this proposition is true whether the connected lines $p\,a$, $a\,g$, $g\,e$, $e\,p$, be or be not all situated in one plane.

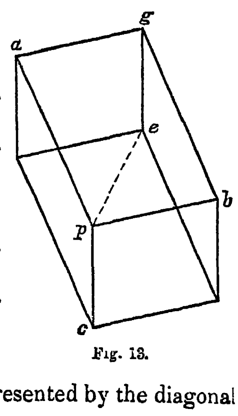

Fig. 13.

The pressure represented by $p\,e$ may be regarded as the resultant of two represented by $p\,g$, $g\,e$; but $p\,g$ itself represents the resultant of $p\,a$, $a\,g$; so that $p\,e$ may be regarded as the resultant of the three pressures $p\,a$, $a\,g$, $g\,e$. Complete now the rhomb or parallelopiped, of which $p\,a$, $p\,b$, $p\,c$ are three concurring sides, and we see that, of three pressures, $\overline{PA}$, $\overline{PB}$, $\overline{PC}$, represented by those lines, the resultant, viz., the opposite of $\overline{PD}$, is represented by the diagonal $p\,e$ of the solid.

EQUILIBRIUM OF SEVERAL PRESSURES.

These observations on the equilibrium of four pressures applied to one point, may be extended to that of any number; and we have this general law, that if there be any number of lines connected in the manner of the sides of a polygon, but not necessarily in one plane, pressures represented in intensity and in direction by these lines, taken in order, will balance each other when they all act on one point. The equilibrium of many pressures is, however, best investigated by help of the

Decomposition and Recomposition of Pressures.

DECOMPOSITION AND RECOMPOSITION OF PRESSURES.

We have seen that the resultant of two pressures may be substituted for those pressures, and so, conversely, we may put, instead of a single pressure, any two or more pressures of which it would be the resultant: this substitution is called, though with a little impropriety of language, the decomposition of the pressure. As, for the purpose of indicating the relative positions of points, we use the method of co-ordinates, so we employ, with great advantage, the same method in examining the conditions of equilibrium of a system of pressures. We decompose each pressure into three acting in the directions of the axes of co-ordinates, and thus carry on our investigations more readily.

For the convenience of description let us refer the positions of the points of a system to three planes—one horizontal; one vertical, passing from east to west; and one also vertical, and passing from north to south. Let us measure x northwards, y eastwards, and z upwards. The direction in which a pressure acts may be indicated by what astronomers call its zenith distance, that is the angle which it makes with the vertical line z, and its azimuth or bearing, that is the angle which its projection upon the horizontal plane makes with the north line x.

In the first place, we may regard the actual pressure p as the resultant of two imaginary pressures—one, which we shall denote by $p(h)$, horizontally in the direction of the projection, and the other $p(z)$ towards the zenith; and, in the second place, we may consider $p(h)$ as the resultant of $p(x)$ towards the north, and $p(y)$ towards the east. The values of these, expressed in trigonometric language, are—

$$\left.\begin{array}{l} p(x)=p\times\text{sin zen. dist.}\times\text{cos bearing} \\ p(y)=p\times\text{sin zen. dist.}\times\text{sin bearing} \\ p(z)=p\times\text{cos zen. dist.} \end{array}\right\} \quad . \quad . \quad (1.)$$

By making this decomposition for each one of the pressures acting on a point, and taking the sums of all those acting in each direction, we obtain the three elements of the resultant, viz.:—

$$\Sigma p(x)\,;\ \Sigma p(y)\,;\ \Sigma p(z)\,;$$

from which we can compute the bearing, the zenith distance, and the intensity of the resultant; and, if these pressures keep each other in check, we must have

$$\Sigma p(x)=0\,;\ \Sigma p(y)=0\,;\ \Sigma p(z)=0 \quad . \quad . \quad . \quad . \quad (2.)$$

three equations which contain the conditions of equilibrium.

When the system under examination contains several points acted on by various pressures, the above equations must hold good of each separate point, as, otherwise, that point could not be at rest.

FLEXIBLE POLYGON.

When a number of points are connected by a succession of ties which bind each one to only two others, the polygon thus formed is flexible whenever the number of the points exceeds three. Let ABCDEF (fig. 14) be such a polygon acted on by pressures Aa, Bb, . . . Ff, the directions of which may or may not be all in one plane; and let $\overline{AB}$, $\overline{BC}$, &c., represent the tensions on the various parts of the cord; then, since the point A is kept in equilibrium by the three tensions $\overline{Aa}$, $\overline{AB}$, $\overline{AF}$, the direction and intensity of $\overline{Aa}$ could be discovered if the tensions $\overline{AB}$, $\overline{AF}$ were known; and hence the problem, " to find those pressures in virtue of which the parts of a flexible polygon may be

Flexible Polygon.

strained with prescribed strains and kept in given positions," admits of a very easy solution.

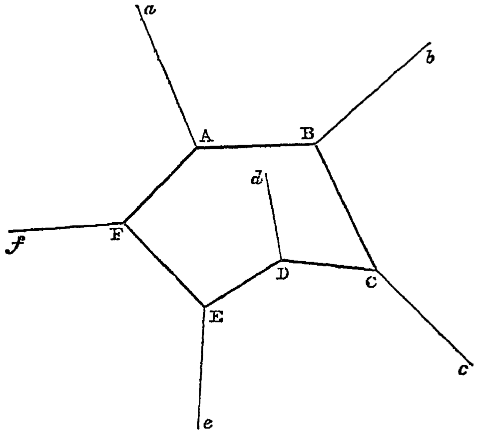

Fig. 14.

If we decompose each of these strains in the directions x, y, z, we have for the point A,

$$\overline{Aa}\,(x)+\overline{AB}\,(x)+\overline{AF}\,(x)=0\,;$$

and again, for the point B,

$$\overline{Bb}\,(x)+\overline{BA}\,(x)+\overline{BC}\,(x)=0\,;$$

and so on for every other point in the series. Adding all these equations together, and observing that since $\overline{BA}$ and $\overline{AB}$, being representatives of the tension on the cord AB, are equal and opposite to each, $\overline{BA}\,(x)+\overline{AB}\,x$ is zero, we have

$$\overline{Aa}\,(x)+\overline{Bb}\,(x)+\&c.=0\,;$$

and similarly,

$$\overline{Aa}\,(y)+\overline{Bb}\,(y)+\&c.=0$$
$$\overline{Aa}\,(z)+\overline{Bb}\,(z)+\&c.=0\,;$$

wherefore, the extraneous pressures would, applied to one point, produce equilibrium.

The same kind of demonstration may be applied to any system whatever, and we have this general proposition, that "*the extraneous pressures which, when acting on any system, keep it in equilibrium, would balance each other if they acted on one point.* The converse of this proposition is not true.

The most interesting case of a flexible polygon is that of a chain fixed at its two extremities, and carrying weights attached to it at intervals along its length. As the theory of this kind of polygon forms the foundation of the doctrine of chain-bridges, and of arches in general, it deserves our particular attention.

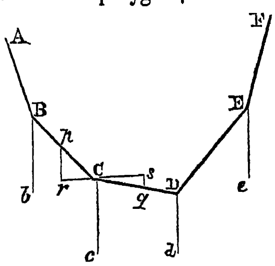

Fig. 15.

Let ABCDEF (fig. 15) represent a chord to which are attached strings Bb, Cc, Dd, &c., carrying weights; and let us examine the conditions of its equilibrium. Since the three tensions $\overline{BA}$, $\overline{BC}$, $\overline{Bb}$ balance each other at B, we have

$$\overline{BA} : \overline{BC} :: \sin bBC : \sin bBA :: \text{cse}\, bBA : \text{cse}\, bBC\,;$$

and again, on account of the equilibrium at C,

$$\overline{CB} : \overline{CD} :: \text{cse}\, cCB : \text{cse}\, cCD\,;$$

wherefore, compounding these ratios we have, since the angle cCB is the supplement of bBC,

$$\overline{BA} : \overline{CD} :: \text{cse}\, bBA : \text{cse}\, cCD\,;$$

and, as this reasoning can be continued, it follows that, in every such suspended chain, the tensions at the various parts are proportional to the cosecants of their inclinations to the vertical line, or the secants of their inclinations to the horizon.

Suspension Bridges.

Let the distance Cp be measured along cB to represent the intensity of the strain on BC, and similarly Cq along CD; also, having drawn a horizontal line through C, draw the vertical lines pr, qs to meet it: then the strain Cp may be decomposed into cr, rp; and the strain Cq into Cs, Sq. The two horizontal strains, Cr, Cs, are equal to and balance each other; while the difference between the two vertical strains, rp, sq, must be equal to that caused by the weight hung on at c. Hence, if h denote the horizontal strain,

$$\left.\begin{array}{l}\overline{BA}=h.\text{sec incl.AB};\ \overline{CB}=h.\text{ sec incl. BC}\\ \text{weight at C}=h(\text{tan incl.AB}-\text{tan incl.BC}).\end{array}\right\} \quad (3.)$$

wherefore the weights hung on any part of such a chain are equal to the horizontal tension multiplied by the difference between the tangents of the inclinations at its two extremities.

These are the well known principles which regulate the construction of bridges; they are most distinctly seen in the case of suspension-bridges, but they are not less essentially connected with stone-arches.

SUSPENSION-BRIDGES.

The essential parts of a suspension-bridge are—*first*, the chain attached to two well secured supports; *second*, the suspending-rods; and, *third*, the roadway. In general, the weight of the roadway far exceeds that of the other parts; so that, in a first examination of the matter, we may take it alone into consideration, and

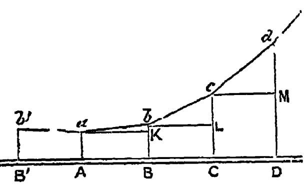

Fig. 16.

suppose that the weights of the chain and of the suspending-rods are so small as not to be worth notice. Let, then, B'ABCD, &c., represent the roadway of a chain-bridge suspended, at equal intervals B'A, AB, BC, &c., by rods B'b', Aa, Bb, Cc, &c., from the chain $b'abcd$; and let us suppose that a is the lowest point of the chain, the parts ab' and ab being equally inclined to the horizon.

Put h to represent the horizontal tension, r the weight of one foot of the road-way, and a the distance between the vertical roads, ar being thus the weight supported by each rod. Then, since the links ab' and ab are equally inclined, the tangent of the inclination must be $\frac{ar}{2h}$. Draw aK parallel to the horizon, and we must have

$$a\text{K} : \text{K}b :: 2h : ar, \text{ whence } \text{K}b=\frac{a^2r}{2h}.$$

Passing to the point b, at which again there is an equilibrium of three pressures, and drawing the horizontal line bL we have

$$\tan \text{L}bc-\tan \text{K}ab=\frac{ar}{h}, \text{ but}$$

$$\tan \text{K}ab=\frac{ar}{2h}\,; \text{ wherefore,}$$

$$\tan \text{L}bc \qquad =\frac{3ar}{2h}\,; \text{ and}$$

$$\text{L}c=a\tan \text{L}bc=\frac{3a^2r}{2h}.$$

Proceeding in this way, we easily show that the distances Kb, Lc, Md, &c., must be as the successive odd numbers, 1, 3, 5, &c., and therefore the rises above the lowest point a, must, at b, c, d, &c., be as the successive square numbers 1, 4, 9, and so on; wherefore, the length Nn of a rod situated at n intervals from aA, would be given by the equation

$$\mathrm{N}n = \mathrm{A}a + \frac{n^2a^2r}{2h};$$

and thus it seems that the chain $b'abcb$ must be inscribed in a parabola.

If, however, we take into account the weights of the links of the chain, and the varying lengths and weights of the suspending-rods, we must obtain a form differing perceptibly from the parabola. Putting c for the weight of one foot of the chain, where it is horizontal, and i for the inclination at any other part, the strain there is h sec. i, and, therefore, as the chain ought to be thickened to bear the greater strain, the weight of one foot of it should be c sec. i, and consequently the weight of that portion of the chain which is vertically over one foot of the roadway must be c, sec. i^2, and thus, exclusive of the suspending-rods, the whole weight above a foot of the roadway is

$$r + c \sec i^2, \text{ or } r + c + c \tan i^2.$$

The suspending-rods, having to carry equal weights all along, must be of uniform strength; and hence their own weights are proportional to their lengths, so that the weight of the suspending-rods may be assumed as proportional to the area AadD of the elevation of the arch. Let, then, x be the horizontal distance measured along AH, z the ordinate Pp, reckoned from the horizontal line passing through a, and let s be the weight of the suspending-rods, corresponding to one square foot of side-area: then the weight above a minute element, dx, of the horizontal line is

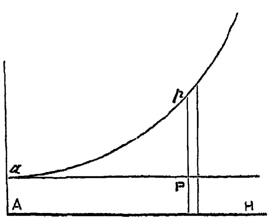

Fig. 17.

$$dw = (r + c + c \tan i^2 + sz)\, dx;$$

and this, according to the law already explained, is equal to the differential of the tangent of the inclination, multiplied by the horizontal strain; wherefore

$$h \,.\, d \tan i = (r + c + c \tan i^2 + sz)\, dx$$

expresses the condition of the equilibrium in chain-bridges when none of the accidents of their formation is neglected.

The complete integration of this expression cannot be obtained in finite formulæ, but we can develop the value of the ordinate z in a series containing the even powers of x; thus, if we put

$$z = \mathrm{A}x^2 + \mathrm{B}x^4 + cx^6 + \mathrm{D}x^8 + \mathrm{E}x^{10} + \&c.;$$

and if, for shortness sake we make

$$\alpha = \frac{2cr + c^2}{h}, \text{ we have}$$

$$\mathrm{A} = \frac{r + c}{2h};\ \alpha = 4\mathrm{A}c;$$

$$\mathrm{B} = \mathrm{A}\frac{\alpha + s}{3\,.\,4\,.\,h};\ \mathrm{C} = \mathrm{B}\frac{4\alpha + s}{5\,.\,6\,.\,h};$$

$$\mathrm{D} = \mathrm{B}\frac{34\alpha^2 + 20\alpha s + s^2}{5\,.\,6\,.\,7\,.\,8\,h^2};$$

$$\mathrm{E} = \mathrm{B}\frac{496\alpha^3 + 474\alpha^2 s + 84\alpha s^2 + s^3}{5\,.\,6\,.\,7\,.\,8\,.\,9\,.\,10h^3}, \&c.$$

In all practical cases, the fractions $\frac{\alpha}{h}$ and $\frac{s}{h}$ are small, so that the coefficients B, C, D, &c., decrease rapidly in value, and for all the wants of the engineer, the above terms are amply sufficient.

The question, "What is the extreme limit to which a chain-bridge can be thrown?" is an interesting one, particularly in reference to proposals which have, from time to time, been made for throwing such bridges across our estuaries, across even the Bosphorus, or the Dardanelles. In order to answer this question definitely, we may remark that an unloaded chain, no part of which is thicker than the strain upon it requires, must be capable of spanning the utmost stretch which the material will allow. Let us, then, suppose a chain having its horizontal tension h as great as is compatible with the thickness of c pounds per foot at the lowest part, to be thickened towards each end in such a way as in every part to be just able to bear the strain; then c sec. i will be the weight per linear foot at any point in the curve, and the condition of equilibrium will be expressed by the differential equation

$$h \,.\, d \tan i = c \,.\, \sec i^2 \,.\, dx,$$

from which we at once obtain

$$i = \frac{cx}{h};$$

so that in this, which may be called the *catenary of regulated strength*, the inclination of the curve at the point p is proportional to the horizontal ordinate aP, and becomes 90°, when $x = \frac{\pi h}{2c}$; and thus the utmost horizontal stretch of such a chain is

$$2\mathrm{X} = \frac{h}{c} \times 3{\cdot}1415926,$$

and even to attain this the vertical height would need to be infinite. By putting for $\frac{h}{c}$ the *modulus of strength*, or the length of itself which a uniform chain can support, we would have the absolute limit of span for any given material.

The form of the *catenary of regulated strength* is given by the equations

$$z = \frac{h}{c} \,.\, \text{nep. log sec } \frac{cx}{h},$$

$$l = \frac{h}{c} \,.\, \text{nep. log tan } \left(\frac{\pi}{4} + \frac{cx}{2h}\right),$$

in which l is the length of the curve reckoned from the lowest point a to the top of the ordinate z.

When the chain is of uniform thickness all along, the form which it assumes is called the *catenary*. This curve, although of no great importance in regard to chain-bridges, has a close connection with the theory of equilibrated arches, and possesses besides certain very remarkable geometrical properties. The same notation remaining, its equation of condition is

$$h \,.\, d \tan i = c \sec i;$$

whence we obtain, on integrating,

$$z = \frac{h}{c} \times \frac{1}{2}\left\{e^{\frac{cx}{h}} + e^{-\frac{cx}{h}}\right\} - \frac{h}{c},$$

$$l = \frac{h}{c} \times \frac{1}{2}\left\{e^{\frac{cx}{h}} - e^{-\frac{cx}{h}}\right\}$$

e being the basis of the Neperian system of logarithms. The utmost horizontal distance which can be spanned by a chain of uniform thickness is 1·3254838, or about $\frac{4}{3}$ths of its modulus of strength.

The theory of stone-arches is almost a counterpart of that of chain-bridges; the difference consisting principally in this, that the load on the stone-arch is the quantity of material included between the surface of the roadway and

Equilibrium of parallel Pressures.

the lower face of the arch-stones. Let AR (figure 18) represent the line of road over a bridge, apq the arch-stones; then the load upon the part ap of the *intrados* is the quantity of material included in the figure aA Pp. When the entire space is filled up and the arrangements made suitable to this condition, the arch is said to be *equilibrated.* The roadway is commonly almost level; but, in the general investigation, we shall suppose it sloped at an angle α to the horizon. The point a, as before, being made the origin of rectangular co-ordinates, we have

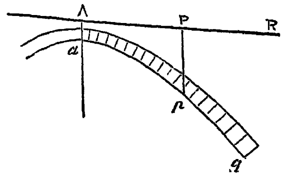

Fig. 18.

$$Pp = Aa - x \tan \alpha + z$$

or putting v for the distance Aa, and u for Pp,

$$u = v - x \tan \alpha + z,$$

and the condition of equilibrium is

$$hd \tan i = k \frac{d^2u}{dx} = u\,dx;$$

wherefore, if a be taken at that point of the curve where it is parallel to the roadway, we have, on integrating,

$$u = \frac{v}{2} \left\{ e^{\frac{x}{\sqrt{h}}} + e^{-\frac{x}{\sqrt{h}}} \right\}$$

which is the equation of a modified catenary.

It may be remarked, that the chords of this curve drawn parallel to the roadway are bisected by the vertical axis Aa; and that, contrary to what has been supposed, the case of bridges with oblique roadways differs in no essential point from that of bridges with the roadway horizontal.

EQUILIBRIUM OF PARALLEL PRESSURES.

Parallel pressures can only balance each other by the intervention of some solid body, which may form a connection between the points to which the various pressures are applied. The simplest mode of viewing the subject is to imagine the points to be connected by straight rods, the lengths of which would, geometrically, determine the relative positions of the parts, and to investigate at each point of attachment the distribution of the pressures. But this method is inapplicable when all the points of attachment are situated in one plane; in such a case, we should have to assume some accessory points out of the plane so as to communicate firmness to the system.

If, in some plane which passes entirely to one side of the system of connected points, three points not in one straight line be chosen, the distances of any point in the system from these three arbitrary points will determine its position, and we may thus regard the rigidity of the system as obtained by means of inextensible rods connecting each point in it with each one of the three assumed points. Let, then, A, B, C (figure 19), be the three arbitrarily assumed points, and P one of the points in the system to which the pressure $\overline{Pp}$ is applied. These being connected by slender rods, the pressure $\overline{Pp}$ is resisted by the tensions of PA, BP, CP. In order to obtain the values of these tensions, let the direction Pp be continued, to meet the plane ABC in p, and through p lead planes parallel to BPC, CPA, APB; these, with the planes to which they are parallel, include a rhomb, of which Pp is the diagonal, so that if, for the moment, Pp be taken to represent the intensity of the pressure $\overline{Pp}$, the sides of that rhomb would represent the strains $\overline{AP}$, $\overline{BP}$, $\overline{CP}$. To avoid confusion, this rhomb is not drawn in the figure, but only the plane passing through p parallel to BPC is shown, cutting PA in α; Pα in this case represents the tension $\overline{PA}$.

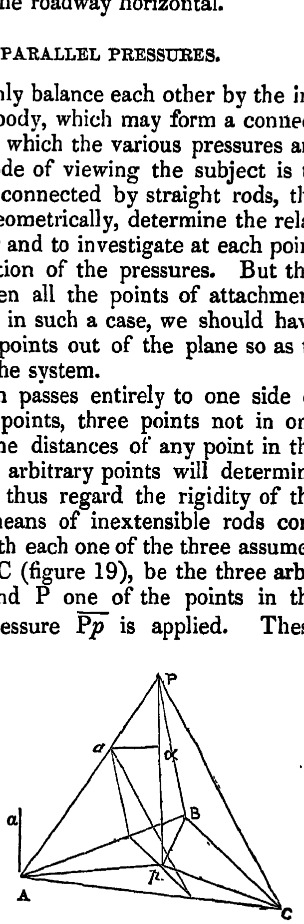

Fig. 19.

The rod PA conveys this strain to the point A, which is acted on by three pressures $\overline{PA}$, $\overline{AB}$, $\overline{AC}$; and these not being in one plane, cannot be in equilibrium; a fourth pressure must therefore aid in establishing the balance. Through α draw $a\alpha$ parallel to Ap; the pressure Pa acting at A may be decomposed into two, one parallel and proportional to $a\alpha$, another parallel and proportional to Pa. That part represented by $a\alpha$ being exerted in the direction pA is resisted by the tensions of the rods AB, AC; and the other part represented by Pa, exerted in the direction of a line drawn through A parallel to Pp, must be resisted by the other pressures, to which the system is subjected.

Since Pp : Pa :: PA : Pα, and since the altitudes of the trigons BAC, BpC are evidently in the same ratio, we have—

$\overline{Pp} : \overline{P\alpha}$ :: ABC : BpC; and similarly
$\overline{Pp} : \overline{P\beta}$ :: ABC : CpA,
$\overline{Pp} : \overline{P\gamma}$ :: ABC : ApB,

so that the pressure $\overline{Pp}$ is distributed among the points A, B, C in shares proportional to the areas of the opposite trigons BpC, CpA, ApB.

If the same process be followed for each pressure, we obtain, on summing up all the shares which are resisted at each of the points A, B, C,

$$\Sigma\,\overline{P\alpha} = 0;\ \Sigma\,\overline{P\beta} = 0;\ \Sigma\,\overline{P\gamma} = 0.$$

Since each pressure $\overline{Pp}$ is equal to the sum of the three $\overline{P\alpha}$, $\overline{P\beta}$, $\overline{P\gamma}$, it follows, from the addition of the above equations, that the sum $\Sigma\,\overline{Pp}$ of all the parallel pressures must be zero; or, in other words, that the sum of those which act in the one direction must be equal to the sum of those which oppose them.

The trigons BAC and BPC having a common base BC, are proportional to their altitudes, and these altitudes again are proportional to the distances of the lines Aα' and $\overline{Pp}$ from BC, wherefore the tendency which the pressure $\overline{Pp}$ has to turn the system round BC as an axis, is just equal to that which $\overline{A\alpha'}$ would have, and thus the expression, $\Sigma\,\overline{A\alpha'} = 0$ or $\Sigma\,\overline{P\alpha} = 0$, may be interpreted as signifying that the tendencies of the several pressures to turn the system round any assumed axis BC must amount to zero; and it is easy to see that if, while $\Sigma\,\overline{Pp}$ the sum of the pressures themselves is zero, the sum of the tendencies round any two axes having different azimuths round the direction Pp be also zeroes, the system must be in equilibrium.

The above reasoning can, in strictness, only apply to a network or skeleton of straight rods connecting the points to which the pressures are applied; and seeing that we know nothing, and are not likely ever to know anything of the manner in which pressure is conveyed from one point to another of a solid body, it is only by inference that we can extend the doctrine to the general case of points anyhow connected. Experience, however, abundantly testifies that this law of equilibrium is universal.

This course of reasoning leads us to the remarkable conclusion that the pressure $\overline{Pp}$ exerts the same influence, so far as the ultimate resistances are concerned, at whatever point in the line of its direction it may act; but it is to be noticed, that the strains internal to the system of connecting-rods are altered by every change in the position of the point of attachment.

Centre of Gravity.

CENTRE OF GRAVITY.

Gravitation affords the best example of parallel pressures; each part of a body tends downwards, or has weight, and thus the mere resting of any object whatever upon a support implies the equilibrium of a multitude of conflicting pressures.

In order to examine this important subject minutely, let us consider the case of two material points, A and B, connected by a rigid straight rod AB.

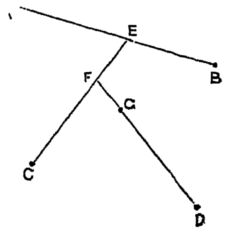

Fig. 20.

If AB be divided at E, so that $EB : EA :: \bar{A} : \bar{B}$ a pressure of $-(\bar{A}+\bar{B})$ applied at E would resist the two strains $\bar{A}$ and $\bar{B}$, and this in whatever position the rod AEB may be placed. E, in that case, is called *the centre of gravity* of the two weights A and B.

If we put x_A, x_B, x_E to represent the distances of A, B, E, from some assumed plane surface, we have—

$$(\bar{A}+\bar{B})\, x_E = \bar{A}x_A + \bar{B}x_B.$$

Suppose now that there is a third point C, the weight of which is $\bar{C}$, join CE and divide it at F, so that $CF : FE :: \bar{A}+\bar{B} : \bar{C}$; then a pressure $-(\bar{A}+\bar{B}+\bar{C})$ applied at the point F would resist $\bar{A}+\bar{B}$ applied at E, and $\bar{C}$ applied at C, that is, it would resist the three pressures $\bar{A}$, $\bar{B}$, $\bar{C}$, applied at the points A, B, C.

Taking a fourth point D, which may or may not be in the same plane with A, B, C, join DF, and divide DF in the ratio of $\bar{A}+\bar{B}+\bar{C} : \bar{D}$; the pressure $-(\bar{A}+\bar{B}+\bar{C}+\bar{D})$ acting at G would balance the weights $\bar{A}$, $\bar{B}$, $\bar{C}$, $\bar{D}$, placed at the several points A, B, C, D. In this case G is called the *centre of gravity* of the four weights $\bar{A}$, $\bar{B}$, $\bar{C}$, $\bar{D}$; and in reference to any plane,

$$(\bar{A}+\bar{B}+\bar{C}+\bar{D})\, x_G = \bar{A}x_A + \bar{B}x_B + \bar{C}x_C + \bar{D}x_D.$$

As this line of argument can be continued to any extent, it follows, generally, that if x, y, z be the co-ordinates referred to three planes, the position of the centre of gravity G of any number of heavy *points* A, B, C, &c., is given by the equations—

$$x_G = \frac{\Sigma\, \bar{A}x_A}{\Sigma\, \bar{A}};\quad y_G - \frac{\Sigma\, \bar{A}y_A}{\Sigma\, \bar{A}};\quad z_G = \frac{\Sigma\, \bar{A}z_A}{\Sigma\, \bar{A}}.$$

These formulæ, however, only apply to discrete points: in order to make them applicable to concrete matter we must extend the calculations to the infinity of infinitely minute parts of which we may conceive solid matter to be composed. For the purposes of this inquiry, we regard a solid body as composed of a multitude of slices, which may be rendered so numerous and so thin, that each one may, so to speak, be regarded as a mere surface. Such surfaces, again, we divide into elongated sections, which, when made excessively narrow, are almost lines; and these lines we again divide into multitudes of parts, which, from their smallness, we call points. The ideas of physical points, lines, surfaces, thus differ essentially from those which the geometer designates by the same names; and it is also to be noticed that this ideal decomposition of a solid body into an infinity of infinitely minute particles, does not show either the infinite divisibility of matter, or any other fact concerning its physical constitution.

The centre of gravity of a uniform physical straight line is, clearly, at its middle. This becomes evident when we consider it as composed of equal parts symmetrically arranged from either end.

Fig. 21.

The centre of gravity of each pair of such particles is at the middle point, wherefore that middle point is the centre of gravity of the whole. But this mode of reasoning will not apply in more complex cases. Representing by w the whole weight of the thin rod AB, and by l its length, let us divide the whole length into a great number p of equal parts, of which Pp may represent one; the weight of this part Pp must be $\frac{w}{p}$, and the tendency of this weight to turn the rod round A as a fulcrum must be more than if an equal weight were hung on at P, and less than if it were suspended at p; hence, if the number of parts in AP be n, and therefore AP itself $\frac{nl}{p}$, the effect of Pp in turning the rod round A is more than $\frac{nwl}{pp}$, and less than $\frac{(n+1)\, wl}{pp}$. As the same may be said of each of the other parts Pp, it follows that the tendency of the whole weight to turn the rod round A as a fulcrum is more than $(0+1+2+3 \ldots\ldots \overline{p-1})\, \frac{wl}{pp}$ and less than $(1+2+3+ \ldots\ldots p)\, \frac{wl}{pp}$; or, summing these series of natural numbers, more than $\frac{p}{p}\, \frac{p-1}{2p}\, wl$, but less than $\frac{p}{p}\, \frac{p+1}{2p}\, wl$; these limits may be otherwise written $\left(1-\frac{1}{p}\right) \frac{wl}{2}$ and $\left(1+\frac{1}{p}\right) \frac{wl}{2}$. By taking the number p enormously large, the value of the fraction $\frac{1}{p}$ is made insignificant, and each of the limits approaches to $\frac{1}{2}\, wl$, which thus takes the place of the sum $\Sigma\, \bar{A}x_A$ of the general formula. Dividing this by w, we find for the distance of the centre of gravity G from the end A, the value $AG = \frac{1}{2}\, l$; that is, G is in the middle of AB. The ordinary operation of integrating is, virtually, this process in disguise. Thus, if we put $AP = x$, $Pp = dx$, the weight of Pp is $\frac{wdx}{l}$, and its effect in turning the lever round A (or its *moment* as it is called) $\frac{wxdx}{l}$; the integral of this, viz., $\frac{w}{l}\, \frac{1}{2}\, x^2$, represents the *moment of* AP, which, on putting l for x becomes $\frac{1}{2}\, wl$ for the *moment* of the whole rod as before.

The position of the centre of gravity of a uniform flat trigonal surface may be found by an extension of the same method.

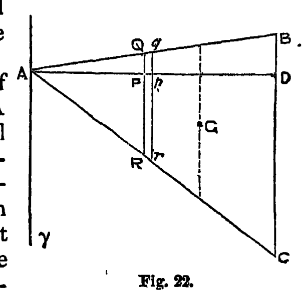

Fig. 22.

Let w be the weight of the trigon ABC; through A draw an axis Aγ parallel to BC, and suppose the surface to be divided into trapezoids by lines QR, qr drawn also parallel to BC. Put l for the length of the perpendicular AD, and suppose it divided into p equal parts n of which go to AP; then the weight of the trigon AQR is $\frac{n^2}{p^2}w$, while that

of Aqr is $\frac{(n+1)^2}{p^2} w$, so that the weight of the trapezoid QRrq is $\frac{2n+1}{pp} w$. The moment of this in reference to the axis Aγ is more than $\frac{n}{p} \frac{2n+1}{pp} wl$, and less than $\frac{n+1}{p} \frac{2n+1}{pp} wl$; it is therefore between $(2n^2+n) \frac{wl}{p^3}$ and $(2n^2+3n+1) \frac{wl}{p^3}$. Giving to p all values from 0 to $p-1$ successively, and summing, we find that the *moment* of the whole surface is between

$$\{2\,(0^2+1^2+\ldots\ldots \overline{p-1}^{\,2})+(0+1+\ldots\ldots \overline{p-1})\} \frac{wl}{p^3} \text{ and}$$

$$\{2\,(0^2+1^2+\ldots\ldots \overline{p-1}^{\,2})+3\,(0+1+\ldots\ldots \overline{p-1})+p\} \frac{wl}{p^3},$$

or, summing these series, between

$$\left(\frac{2}{3}-\frac{1}{2p}-\frac{1}{6p^2}\right) wl \text{ and } \left(\frac{2}{3}+\frac{1}{2p}-\frac{1}{6p^2}\right) wl.$$

Wherefore, on supposing p to be an enormously large number, the true value of the moment of the whole trigon is $\frac{2}{3} wl$, and the distance of the centre of gravity from the axis Aγ is two-thirds of the altitude AD. Now the centre of gravity must also be at the distance of two-thirds of the altitude drawn from C to AB: wherefore, it is the intersection of the lines which join the corners with the middles of the opposite sides. The centre of gravity of the surface of a trigon coincides with that of three equal weights placed at its three corners.

Similarly it may be shown that the centre of gravity of a tetrahedron or triangular pyramid, is the intersection of the four lines which join the four corners with the centres of gravity of the opposite faces, and therefore coincides with that of four equal weights placed at the four corners.

Since all polygons may be decomposed into trigons, and all polyhedrons into tetrahedrons, we can easily find the centre of gravity of any rectilineal figure, or of any flat-faced solid, by imagining the weight of each of the component parts accumulated at its centre of gravity, and then finding the centre of gravity of these points. In the cases of surfaces bounded by curved lines, or of solids bounded by curved surfaces, the nature of the curve necessarily enters as an element of the computation. One or two examples may suffice to explain the procedure.

Let it be required to find the centre of gravity of a parabolic segment CAD.

Draw any chord QR parallel to CD, bisect CD in B, QR in P, and join BP, producing it to A; then, according to the property of the parabola, the line Aγ drawn parallel to CD is a tangent to the curve; all chords parallel to CD are bisected by AB, and their lengths are in ratios subduplicate of the distances intercepted from A. Hence, if we put, as before, w for the whole weight or area, l for AB, x for AP, dx for Pp, also b for CD, and α for the angle ABD, we have QR $= bl^{-\frac{1}{2}} x^{\frac{1}{2}}$; wherefore the area of the surface comprised between the proximate ordinates QR and qr is $bl^{-\frac{1}{2}} \sin \alpha \,.\, x^{\frac{1}{2}}\, dx$, and its moment round the axis Aγ is this, multiplied by $x \sin \alpha$ or $dm = bl^{-\frac{1}{2}} \sin \alpha^2 \,.\, x^{\frac{3}{2}}\, dx$. On integrating these expressions, we find for the area

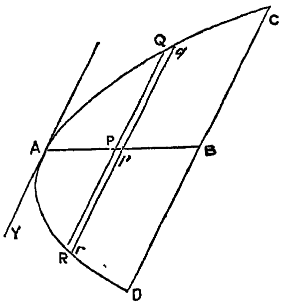

Fig. 23.

QAR, $\frac{2}{3} bl^{-\frac{1}{2}} \sin \alpha x$; and for its moment $\frac{2}{5} bl^{-\frac{1}{2}} \sin \alpha^2 . x^{\frac{5}{2}}$; so that, making x equal to the whole length l, we have $w = \frac{2}{3} bl \sin \alpha$, while the whole moment is $\frac{2}{5} bl^2 \sin \alpha^2$; and therefore the distance of the centre of gravity from the tangent Aγ is $\frac{3}{5} l \sin \alpha$: wherefore, if AG be made three-fifth parts of AB, the centre of gravity must lie in the ordinate drawn through G; but, as all these ordinates are bisected, their centres of gravity must be in AB, wherefore G itself is the centre of gravity of the parabolic segment.

As an example from among solids, we may take the segment of a sphere. Let OA $= r$ be the radius of a sphere, and let it be proposed to find the centre of gravity of the segment having AP $= x$ for its altitude. Making Pp $= dx$ and leading planes PQ, pq perpendicular to AO, the solid comprised between these two planes is the differential of the solidity, or dw, but the area of the circle described by PQ is π . PQ^2, or π . AP . PB $= \pi\,(2rx - x^2)$, wherefore $dw = \pi\,(2rx - x^2)\,dx$, and the moment of this is $dm = \pi\,(2rx^2 - x^3)\,dx$ round an axis passing through A. Integrating these we have $w = \pi \left(rx^2 - \frac{1}{3} x^3\right)$, $m = \pi \left(\frac{2}{3} rx^3 - \frac{1}{4} x^4\right)$; wherefore the distance of the centre of gravity from A is $\frac{x}{4} \frac{8r-3x}{3r-x}$, and its distance from P is $\frac{x}{4} \frac{4r-x}{3r-x}$. On making $x = r$ we find that the distance of the centre of gravity of a hemisphere from the vertex is $\frac{5}{8} r$, and from the centre $\frac{3}{8} r$.

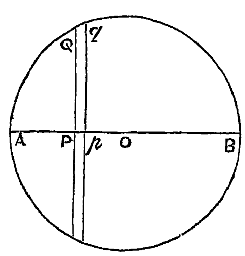

Fig. 24.

When a solid body is suspended by a thread, it takes such a position that its centre of gravity lies in the direction of the thread: hence, if we suspend an object first from one point and then from another, noting the direction each time, the intersection of these two directions will give us the position of the centre of gravity.

If, when a body is laid upon a flat surface, the vertical line drawn through the centre of gravity pass within the convex polygon formed by joining the points at which it touches, it rests securely. Any attempt to overturn it is accompanied by a rise in the position of the centre of gravity, and as soon as the disturbing influence ceases, the body returns to its former site. But if the under surface of the object be curved, the slightest influence causes a displacement: if the arrangement be such that the centre of gravity tend to rise, as is the case with a spherical segment laid on a flat surface, the tendency is to return again to the first position; in such a case the equilibrium is said to be *stable;* if, as in the case of a complete sphere or cylinder, the centre of gravity describe a horizontal line, the equilibrium is *indifferent;* and if, as when the centre of gravity lies above the centre of curvature, that point tend to come lower, the body falls still farther, and the equilibrium is said to be *unstable.*

In all statical computations we may proceed as if the whole weight of a body were concentrated at its centre of gravity; but whenever we have to consider *motion* this hypothesis must be abandoned, because the motion of the

General Condition of Equilibrium.

centre of gravity does not represent the whole motion of a body.

GENERAL CONDITION OF EQUILIBRIUM.

The equilibrium of a number of pressures, acting in various directions upon a solid body, may be investigated by decomposing each pressure into three, acting severally in directions parallel to the axes of co-ordinates x, y, z, and considering that each set of components should, separately, be in equilibrium.

VIRTUAL VELOCITIES.

The whole doctrines of statics are summed up in one general proposition, from which we can most readily obtain the solution of any particular case. To this proposition the name, *law of virtual velocities*, has unfortunately been given: in its statical aspect it has nothing to do with velocity. As a thorough comprehension of its import almost amounts to a complete knowledge of this department of science, we shall endeavour to lay it clearly before the reader.

Let us suppose that the point P is kept in equilibrium by three ropes PA, PB, PC, stretched each from a considerable distance. This being the case, let us imagine that, by some agent exterior to the system, the point P has been displaced to p, the ropes now taking up the positions pa, pb, pc. By this derangement some of the ropes may have been pulled forwards, some may have been let backwards. Let us suppose that three thin, straight wires are thrust, at right angles, one through each of the ropes, so as to form a trigon EDF; then, since this trigon is evidently similar to any trigon formed by drawing lines parallel to the directions of the three ropes, each of its sides may be taken to represent the strain on the rope to which it is perpendicular; that is, EF may represent the tension of PA, FD the tension of PB, and DE the tension of PC. With the derangement of the system the trigon EDF is displaced, being brought into the position edf, such that the lines Dd, Ee, Ff are parallel and equal to Pp. The distance between EF and ef, measured perpendicularly, is, obviously, the distance by which the rope PA has been pulled forward; so the distance between FD and fd shows by how much the rope PB has been let backwards, and so of the third rope PC. The area of the rhomboid EFfe thus represents the product of the tension of the rope PA by the distance through which that tension has been overcome; that is, the quantity of *work* which has been gained upon it. In the same way the area FDdf represents the quantity of *work* lost by the letting down of the rope PB, and DdeE the *work* lost by letting down the rope PC. Now, if, from the pentagon EFfde we take away the trigon edf, there remains the rhomboid EFfe; while if, from the same pentagon, we take away EDF, the two rhomboids FDdf, DdeE remains; wherefore the gain of *work* on the rope PA is exactly equal to the sum of the two losses on PB and PC: on the whole, then, there is neither gain nor loss.

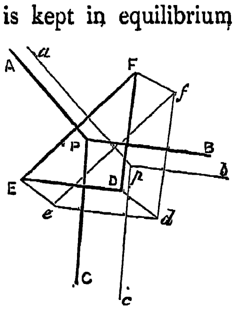

Fig. 25.

Virtual Velocities.

The same kind of reasoning can be applied to all combinations of pressures, and thus we obtain the following general law, that "if any system of pressures in equilibrium be slightly disturbed, there is neither gain nor loss of *work* by the disturbance."

Strictly speaking, this proposition is only true of infinitesimally small disturbances, and this circumstance is intended to be pointed out by the use of the word *virtual* in the title, *law of virtual velocities*, which is given to this theorem.

Using the word *work* to mean the product of a pressure by the distance through which that pressure has been overcome, and representing it in general by the letter w, let us suppose that by the performance of a certain quantity of work some system has been brought into its actual position, as represented by the co-ordinates x, y, z. If now the system be subjected to a definite change, represented by the symbols δx, δy, δz of finite or actual differences, the quantities of work gained or lost on the several strains may be deduced from purely geometrical considerations, and, according to Taylor's well-known theorem, the change in the quantity of work is given by the expression—

$$\begin{aligned}\delta w = {} & \frac{dw}{dx}\frac{\delta x}{1} + \frac{dw}{dy}\frac{\delta y}{1} + \frac{dw}{dz}\frac{\delta z}{1} \\ & + \frac{d^2w}{dx}\frac{\delta x^2}{1\,.\,2} + \frac{d^2w}{dx\,.\,dy}\frac{\delta x}{1}\frac{\delta y}{1} + \frac{d^2w}{dx\,.\,dz}\frac{\delta x}{1}\frac{\delta z}{1} \\ & + \frac{d^2w}{dy^2}\frac{\delta y^2}{1.2} + \frac{\delta^2 w}{\delta y\,.\,\delta z}\frac{\delta y}{1}\frac{\delta z}{1} + \frac{d^2w}{dz^2}\frac{\delta z^2}{1\,.\,2} + \&c.\end{aligned}$$

Now, the law enunciated above refers only to the first differential co-efficients; that is to say, for mere equilibrium we must have $\frac{\delta w}{\delta x}$, $\frac{\delta w}{\delta y}$, $\frac{\delta w}{\delta z}$ each zero; and these conditions must hold good in reference to every separate point of the system.

The values of the second derivatives determine whether the equilibrium be *stable*, *indifferent*, or *instable*. When these derivatives have positive values the equilibrium is *stable;* it required the application of actual *work* to change the position of the system; and when the extraneous pressures cease to act, the system again returns to the position of equilibrium. When the higher derivatives also are zeroes, the equilibrium is indifferent; and, when the second derivatives are negative, the system, if once disturbed from the position of equilibrium, will tend to go still farther from that position.

This theorem, besides being of great value as enabling us readily to investigate the strains in any structure, is important as throwing a clear light upon the general action of machines as transmitters of force. As the machine contains in itself no source of power, it can only convey force, it cannot augment it: thus, although a crane enable one man to raise at once a load which he could only have lifted piece-meal, it does not enable him to do more *work* than he could have done in the same time with the load divided to suit his strength, it only enables him to perform the work more conveniently; nay, on account of the friction of the parts, it even reduces slightly the actual amount of work done. This consideration at once dispels all those dreams about perpetual motions which have emptied the purses of so many schemers, and, at times, even ruined their intellects. (E. S.)

STATISTICS is a term derived from the German word *Staat*, a state or body of men existing together in social union. It was first introduced (at least in its present sense)[1] in 1749 by Professor Achenwall of Göttingen, who has the credit of being the founder of the science. He was the first that attempted to estimate the power and character of a state at a given time, by a systematic examination of its social condition, its progress in civilization, and its natural resources; and to determine the nature and force of those various circumstances in the history and condition of a people that go to form their character.

Statistics, therefore, concerns itself with man as existing in society, and its province comprises everything that bears upon his condition. "As all things on earth were given to man for his use, and all things in creation were so ordained as to contribute to his advantage and comfort, and as whatever affects man individually affects also man in a state of society, it follows that statistics enter more or less into every branch of science, and form that part of each which immediately connects it with human interests." (*Journal of the London Statistical Society*, vol. i.) It is difficult to define the limits of a science embracing so wide a field, and comprehending so great a variety of subjects. Its main object, however, is the collection and arrangement of facts, from which a knowledge may be attained of the nature and power of those laws on which the character, condition, and happiness of man depend.

Man in this world is subject to certain fixed laws, which form his character and determine his condition, and in proportion as these are understood and acted upon will his happiness be increased and his progress in civilisation accelerated. These are, however, so various, and act and react upon each other in so many different ways, that it is difficult or impossible to trace their workings in individual cases, and hence it is only by taking bodies of men in similar circumstances that we can arrive at a satisfactory knowledge of them, and estimate their effects. The laws themselves are as certain, fixed, and complete, as those of astronomy. We cannot indeed predict the history of society like that of the celestial appearances for thousands of years to come; but this arises not from any uncertainty in the laws themselves, but from the data to which these laws are to be applied. The data in astronomy are as certain as the laws themselves: "The circumstances, on the contrary, which influence the condition and progress of society are innumerable and perpetually changing; and though they all change in obedience to causes, and therefore to laws, the multitude of causes is so great as to defy our limited powers of calculation." But while it may be impossible to attain an amount of knowledge necessary for prediction, "there is nothing chimerical in the hope that general laws . . . . really admit of being ascertained," sufficient to enable us, "in any given condition of social affairs, ... to understand by what causes it had, in any and every particular, been made what it was; whether it was tending to any and what changes; what effects each feature of its existing state was likely to produce in the future; and by what means any of those effects might be prevented, modified, or accelerated, or a different class of effects superinduced." (*See* J. Stuart Mill's *Logic*, b. vi., c. 6, § 2.)

We cannot, however, by *à priori* reasoning discover the laws which regulate the complex fabric of human society; we must proceed by induction from well-ascertained facts, and hence the value of that science that more particularly concerns itself with the collection and arrangement of facts, by which alone these can be ascertained. Statistics, then, is that important branch of social science which collects, arranges, and compares the facts from which the politician may ascertain those principles in accordance with which governments may best promote the wellbeing and happiness of their subjects, and the political economist those laws that regulate the production and distribution of wealth. But while the statist collects materials for the politician and political economist, he must from them learn in what manner and in what directions to pursue his investigations; how to arrange his facts so as to bring out the truths which they are calculated to convey; what to collect as valuable, and what to reject as worthless. Facts collected in ignorance of the manner in which they are to be applied, or of the principles which they tend to illustrate, are in most cases of little value. Hence it is that we so frequently find facts collected that convey no useful information, or arranged in such a way as that they tend only to mislead.

But while the statist furnishes the politician and political economist with facts on which to found their reasonings, and from which to draw their conclusions, he, on the other hand, avails himself largely of the labours of the historian and geographer. Indeed, statistics is that science that takes up and shows the practical bearings of the facts of history and geography upon the condition of man. Thus, while history narrates the long series of occurrences that are to be found in the annals of a country, statistics only deals with those of them that may have contributed to form the character and fix the political and social condition of the people. The historian, too, usually travels over an extended period, while the statist brings his facts to bear upon a particular time. Hence, in the words of Professor Schlözer, the pupil and successor of Achenwall, "Statistics is history at a stand; history is statistics in a state of progression." With geography the science of statistics is even more intimately connected, for the physical characteristics of a country are a chief element in determining the condition of the inhabitants. The heat, cold, moisture, &c., of the climate affect their health and energies; while the climate is influenced by the position and physical features of the country,—its mountains, valleys, plains, lakes, marshes, vegetable productions, and state of cultivation. The climate, position, elevation, and nature of the surface and soil determine the animal and vegetable productions, which in their turn impart a distinctive character to the people, and direct their labours. A fertile and plain country draws their attention to the peaceful pursuits of husbandry and pasturage; a mountainous, rugged, and barren country, abounding in wild animals, renders them active, hardy, and fearless, and leads them to seek subsistence in the chase; while in the vicinity of seas and rivers abounding in fish, piscatory pursuits are fostered. Harbours and navigable rivers incline them to commerce, which increases as the want of foreign products is felt, as the country affords them articles of exchange, and as the means of internal communication are favourable; while mineral wealth draws their attention to mining and the working of metals. Hence, while geography describes the position and physical conditions of a country, its mountains, rivers, climate, productions, &c., statistics treats of the political importance of these, and of their bearings upon the condition of the inhabitants at a given time. As the statist looks for direction to the politician and political economist, not less ought the geographer and historian to learn from him how to prosecute their researches, so as to bring into due prominence those circumstances that tend chiefly to stamp the character of a people; for in reality their labours are of value as they can be brought practically to bear upon the conditions of social life.

But indeed every science that bears upon the condition of man enters more or less into statistics; and on the other hand derives valuable aid from it. Law, medicine, che-

[1] The noun *Statista*, signifying a statesman, and the adjective *Statisticus*, occur about three-quarters of a century earlier in *Thesaurus Rerumpublicarum*, by Ph. Andreas Oldenburger, Geneva, 1675.

mistry, botany, zoology, geology, meteorology, ethnology, technology, and anthropology, all contribute facts that are of value in statistics. Its character, however, is distinct from all of them; for while, for example, the jurist studies the laws of a country systematically, according to their nature, or the subjects with which they deal; the statist views them only and judges of them as they affect the social system. We shall, however, perhaps, best illustrate the importance and practical bearings of the science by noticing some of the principal subjects that come within its sphere. As whatever affects the condition of man in society forms a part of statistics, it follows that a statistical account of a country ought to include an exposition of all those circumstances in the physical characteristics of the country, or in the social condition of the people that influence their character, minister to their subsistence, add to their power, or tend to increase their happiness. "*Statistik eines Landes und Volkes ist der Inbegriff seiner Staatsmerkwürdigkeiten*" (Achenwall.) A statistical account of a country therefore includes—Under

Physical Features—An account of its position, extent, and natural divisions; its boundaries; the extent and character of its coast; the height, form, and direction of its mountains; the extent and elevation of its plains; the character of its valleys; the length, direction, size, and velocity of its rivers; the nature and extent of its lakes and marshes; its springs.

Climate—The variations of temperature; fall of rain; direction of the prevailing winds; atmospheric pressure.

Geology—The geological formations of the country; its various mineral resources; character of the soil.

Botany and Zoology—The number and distribution of the various species of animals and plants, with their uses as ministering to the necessities or comforts of the people, as supplying them with materials for labour, or as furnishing them with articles of trade.

Agriculture—The extent of cultivated land, heaths, forests, pastures, &c.; the progress of agriculture; modes of cultivation; agricultural implements; fertility of the soil; the different kinds of crops; their amount, and the proportion they bear to the wants of the people; the number of the various kinds of cattle, and their uses in agriculture or domestic economy.

Mining—The number, character, and productiveness of the mines; the quantities and values of the different ores raised; the progress of mining, and modes of carrying on operations.

Fisheries—The various kinds of sea and river fisheries; their importance, and the means and manner of prosecuting them.

Manufactures—Their progress and present state; the different branches of manufacture; their principal seats; their importance, as contributing to the wealth of the country, or as affording employment and the means of subsistence to the people; the amount and value of the labour expended upon them; the machinery employed; how far the raw materials are home produced or imported; how far the manufactured articles are necessaries or luxuries, are for home consumption or for exportation.

Commerce—The amount of the exports and imports; the quantities and values of the principal articles; the principal ports; the countries with which trade is chiefly carried on, and the principal articles sent to or brought from each; by whom, or under what flags the trade is principally carried on; how far the imports are necessaries or luxuries; how far for direct consumption, for manufacture, or for exportation; how far the exports on raw or manufactured goods, are the natural production of the country or imported or manufactured. It includes, also, an account of the nature, amount, &c., of the internal or coasting trade.

Facilities for Commerce—The amount of shipping belonging to the country; amount of sailing and steam vessels; the state of the harbours; the length of the navigable rivers and canals; the nature and length of the roads and railways; nature of conveyances.

Population—The number at different periods; races; rate of increase; emigration and immigration; proportion of births and deaths; the proportion of the sexes, and marriage relations; the different ages of the population; the average duration of life, and how affected by locality, climate, occupation, or mode of life; the nature and prevalence of certain diseases; the proportion of the population to the production, wealth, and consumption of the country.

Social Condition—The general character, disposition, and habits of the people; their manners and customs; their progress in civilization; the different classes of society; their numbers and relations to one another; the social condition, and intellectual and moral culture of each; houses; the distribution of wealth and power; the occupations of the people; the proportion of capital to labour; skilled and unskilled labour; wages; prices of provisions; amount of chief articles of consumption; national vices; pauperism.

Language and Literature—Character and growth of the language; different dialects; affinity with other languages:—Literature, its character, state, and progress; the branches in which most distinguished; names of principal authors; different classes of publications; literary associations; public libraries; restrictions on literature.

Science and Art—State and progress of; branches in which principally distinguished; institutions for the promotion of, as scientific associations, academies, museums, picture galleries, &c.

Government—Its nature, form, and progress; the legislative, judicial, and executive functions, in whom vested, and how carried out; the character of its laws; the political divisions of the country; how far and in what way the different classes are represented; public works, and other means adopted by government for the encouragement of industry and commerce, or for promoting the social and intellectual progress of the people.

Religion—Its character, condition, and progress; its connection with the state; the various sects; toleration; number of churches and extent of accommodation; the various classes of the clergy; their emoluments; the amount and sources of the church revenues, as provided by the state, by voluntary contributions, &c.

Education—The number and character of the various seminaries of education; their efficiency; how supported; fees; the number of teachers; their incomes; number and ages of scholars, and their proportion to population, within the same ages; how far the state controls or interferes with education.

Crime—State of crime; different classes of offences; the social condition of offenders, age, sex, education, &c.; number of convictions; proportion of convictions to committals; the different kinds of punishment; means for the punishment or prevention of crime, prisons, reformatories, police, &c.

Defence—The natural defences of the country; its fortresses; the amount and efficiency of the army and navy.

Finance—Amount of national debt, its character and growth; the various sources of revenue; the gross and net amount received from each; the proportion of income to expenditure; the various branches of expenditure.

Taxation—Amount of; its character as direct or indirect; its branches; articles on which imposed; how levied; expenses of collection; how far protective or retaliatory; effects on industry or commerce; recent alterations and effects of.

Money, &c.—The weights, measures, and moneys of the country, and their equivalents; banks and banking system, &c.

Antiquities—The different classes of antiquities; their character and age; their state of preservation, &c.

Authorities—The various sources of information, at least so far as not previously referred to, in order to afford the means of judging what degree of reliance can be placed upon the various statements.

Information on these various points, so far as applicable to any particular state is necessary, in order to a comprehensive knowledge of it—in order to understand its present position, to trace the various circumstances by which it has been brought about, and to acquire some knowledge of the action and reaction that is constantly taking place among its various elements. How few the means are that we yet possess of drawing up a complete statistical account of any country it is scarcely necessary to say. Those who have occasion to search for such information know how meagre are the materials and how unreliable the sources. On many points, the governments of the various countries can alone be looked to for information; and they possess numerous facilities for carrying out such investigations. In our own country, a statistical department has been connected with the Board of Trade since 1832, and has collected and published many valuable facts relating to our own and other countries. We are still, however, in this respect far behind several of the continental states. Lord Stanley, in his opening address before section F (Economical Science and Statistics) of the British Association in 1856, forcibly points out the importance to the government of statistical facts, and thus alludes to the necessity of establishing a special department of government, charged with the annual publication of statistical facts relative to our national affairs. "Statistics," said he, "are the function of the state, in a

sense in which no other science is so. . . . We have statistics enough presented to Parliament every session, but they are, in the great majority of cases, called for by individuals. They are drawn out to suit the particular purpose of those who move for them: they are accordingly deficient in unity, and often of no use beyond the moment. Now I speak from some personal observation, when I say, that at a cost hardly greater than that of those desultory, fragmentary, isolated returns (which have in addition the inconvenience, coming as they do at unexpected times, and without any regularity, of throwing a sudden increase of work on particular offices), it would be possible to present to the nation such a yearly *resumé* of administrative statistics, as should, to a very great degree, supersede the present system (if system it can be called) of moving for returns as and when they are wanted. I have said, that I think a statistical department desirable instead of a statistical branch in every department; because the former method gives better security for unity of plan, and because the work will be best done by those whose sole and undivided business it is." In 1833 the statistical section of the British Association for the advancement of science was formed; and in 1834, the London Statistical Society was founded, both of which have done much in the way of collecting and collating important statistical information, and of diffusing a knowledge of the principles and value of the science.

There are indeed some who seek to confine this science exclusively to an exposition of the state of a country or people, at a particular time, and to such circumstances in their condition as may be reduced to numerical calculation and exhibited in tables. But this is to deprive the science of all that is most interesting and instructive, and to render it of little practical value. Numbers are undoubtedly a most important part of statistics. They are that which gives precision and accuracy to the science, and without which it would be little else than a mass of generalities and uncertainties. Figures, however, of themselves unaccompanied by any explanation of the nature of the subject upon which they bear, and especially without any account of the causes that may have influenced them, or the circumstances by which they were attended, can lead only to false conclusions, or to no conclusion at all. Figures are the mere dry bones of statistics, which require to be systematically arranged and explained, and the principles which they illustrate pointed out before they can be of real value. In the same way, to know merely the population, productions, or trade of a country or place at a given time, is of comparatively little value, unless we possess also the same facts for different periods, in order to compare them, and to know how far, and in what particulars, progress or decline has taken place. It is from comparing similar facts of the same country for different times, or of different countries at the same time, and noting the difference of circumstances in each, that the statist arrives at a knowledge of those principles that are constantly at work in society; and hence to confine his operations to mere figures, or to a particular time, would be to deprive them of their chief value. Indeed, nothing has tended more to bring the science into general disrepute than the attempt thus to limit the sphere of its operations. It is by being thus restricted that statistics has been so frequently made the means of promulgating or upholding gross errors. When every one is left to explain or arrange figures in his own way, there is scarcely a theory however wild, or an error however palpable, to which an ignorant or designing person may not by means of them give an air of truth; and thus occasion has been given for the saying, that "anything may be proved by figures." The confidence, too, with which they are handled, and the appearance of accuracy which they bear, lead to their being received without a due amount of examination. Hence statistics is a favourite mode of argument with certain classes of speakers and writers, as it is generally found to carry conviction in proportion as their hearers or readers are ignorant of the principles of the science, or are unable to test their assertions by the rules of sound criticism. Indeed, there is nothing about which one ought to be more sceptical than the great mass of what are called statistical facts, however accurate and imposing they may appear. Statistics, like every other science, has its principles which require to be known, and in accordance with which its facts are to be expounded. It concerns itself chiefly with the accumulation and comparison of facts, and does not admit of any kind of speculation. The statist must, therefore, not only be a man in whose judgment and honesty we can confide, but he must also come to the consideration of his subject with a mind void of preconceived theories, otherwise he may be led, even unconsciously, into a partial or deceptive exposition of the facts.

The statist has, first of all, to ascertain what reliance can be placed upon the facts or figures which are to form the basis of inquiry—from what sources they have been obtained, and how or for what purpose they have been collected. Figures collected for a specific purpose may often be of little or no value for one of a different nature, as details may have been omitted, and distinctions neglected to be made, which would materially affect the result. Even when these are collected with the utmost possible care, and under the most favourable circumstances, they may be of such a nature as that the parties applied to for information may have a direct interest in concealing the truth; and even where such temptations do not ex st, ignorance of the exact nature of the information required, or objections to inquiries of a personal or inquisitorial nature, may lead many to make false or misleading statements. It would be easy to illustrate this by referring to official or parliamentary documents of our own country; and when we find such errors among ourselves, with all our appliances for collecting information, and all our efforts to ensure accuracy, what can we expect of countries and times less civilized? There is no more frequent cause of error than that of taking as complete what is only a partial statement of facts. Where a traveller or historian is the source of information, the statist has to ascertain his character for accuracy or impartiality, the means he had of obtaining information, and the point of view from which he looks at the subject.

Having ascertained what degree of reliance can be placed upon the facts themselves, or made allowance for deficiencies, the next duty of the statist is to arrange them so as to find out what inferences may be legitimately drawn from them. By a careful analysis and comparison of the facts he attempts to ascertain the nature and force of the various laws that have been acting upon them. It is to be borne in mind, that in society no effect can have only one cause, neither can one cause have only one effect. Every one of the social phenomena is the result not of one only, but of a multitude of causes. "Whatever affects in an appreciable degree any one element of the social state, affects through it all the other elements. . . . . There is no social phenomenon which is not more or less influenced by every other part of the condition of the same society, and therefore by every cause which is influencing any other of the contemporaneous social phenomena" (Mill's *Logic*). Every effect, therefore, in the social system is produced by a complexity of circumstances, and "amounts precisely to the sum of the effects of the circumstances taken singly" (Ibid). Hence it is, that as we cannot know all the circumstances that may have been at work in producing a certain result, statistics cannot be considered as an exact science, but rather as a science of probabilities. But while we cannot know all the causes, there are yet in every case certain of them that have been more immediately concerned in bringing about the result, and it is to these that the statist

principally directs his attention. Having, for instance, ascertained the average duration of life in a country at a particular time, he arranges the figures by which that result has been obtained, according to the circumstances that tend more immediately to shorten or prolong life, and thus ascertains how far each of them affects the general result. While the statist thus deals with those causes that have been more immediately influencing a particular result, an important principle comes into operation to give precision and accuracy to his calculations—namely, that the influence of minor disturbing causes diminishes, as the area of his investigations increases, until, if the basis be sufficiently extended, he is justified in disregarding them altogether. Thus, while the number of deaths in a country from any special cause may, in a given year, be much modified or aggravated by other causes, yet by taking the number of the deaths from that cause over a number of years, or over different countries, the disturbing causes will counteract or neutralise each other. It is upon this principle that insurance companies are established. In dealing with great numbers, the average duration of life can be calculated with a surprising degree of precision. An insurance company having only a small number of members, might be ruined in a short time by a few deaths.

It is, however, in the comparison of facts of a similar nature, either of different countries at the same time, or of the same country at different times, that the statist requires to exercise the greatest judgment, and manifest the greatest care. In comparing, for example, the state of crime in this country at present with that of a previous period, there are many things that have to be taken into account besides the proportion of criminals to population. Crime may now have assumed a much lighter character, the means of detection may be greater, lesser offences may have been brought into the penal code, the meaning of terms may have changed, the temptations or facilities to crime may have increased—all these, and many other circumstances, have to be taken into account before the two periods can be properly compared, or their facts correctly reasoned upon. Much more have circumstances like these to be carefully investigated in comparing the state of crime in different countries. In comparing the crime of different towns, the ages of the population is often an important element, for in some towns, as where manufactures are largely carried on, there is always a preponderance of persons at those ages at which the tendency to crime is greatest. In towns, too, the inducements to crime are always greater than in rural districts. It is by comparing the state of crime in the same or different countries under various circumstances that the statist is enabled to discover and estimate the force of the various causes that tend to its production, and at the same time to ascertain the best means of repressing it,—of intimidating, punishing, or reforming criminals. As the astronomer, by finding a discrepancy between his calculations and observations, is led to conclude the existence of some yet undiscovered disturbing cause, so the statist, if, in comparing facts of a similar nature, and after making allowance for difference of circumstances, he finds a marked discrepancy still to exist, may readily infer that there are other causes at work in the one case or the other, of which he is yet ignorant.

Among the errors that reasoners upon statistics frequently fall into, is the attributing of a social fact to one only of its many antecedents or producing causes, without any process of elimination or comparison of instances. It is only by considering, as far as possible, all causes which conjunctly influence a given effect, and compounding their laws with one another, that we can infer the nature and force of the determining circumstances. It is by tracing a certain effect to its various producing causes, or a certain cause down through its numerous effects, that a correct knowledge of the social phenomena can be obtained. The confounding of cause and effect, and the considering of two circumstances as cause and effect which are both the result of common causes, are also frequent sources of error. To estimate the production, &c., of a country from that of a small portion of it is always a very uncertain mode of proceeding, and has frequently led to very grave errors. For while on a large scale minor disturbing causes tend to neutralize each other, on a small scale some of them are always to be found in excess, and thus greatly affect the result when many times multiplied. As every cause in the body social acts and is acted upon by numerous others, many persons err in drawing conclusions from one state of society, and applying them to others in which many of the elements are not the same. Social science, like mechanics, has to deal with conflicting forces,—with causes counteracting or modifying one another. In mechanics, we continually find two or more moving forces producing, not motion but rest, or motion in a different direction from that which would have been produced by either of the generating forces acting separately. Hence it is that the same cause is found to act very differently in different states of society, even to the extent of being beneficial to some and highly injurious to others; and hence, too, the error of "all who found their theories of politics upon what is called abstract right, that is to say, upon universal precepts." (Mill's *Logic*.) It is rarely safe to introduce great or sudden changes into a state, for however beneficial the measure may be in itself, the number of opposing elements with which it will have to contend may deprive it of all utility, if not render it absolutely injurious; whereas small changes, or changes gradually introduced, may meet with a number of favouring circumstances, which will accelerate and increase their beneficial effects. (D. K.)

STATIUS, P. PAPINIUS, a poet and grammarian, who between the age of 13 and 19 was six times crowned as a successful candidate in the Greek poetic games at Naples. Dodwell conjectures that he was born A.D. 39, and died A.D. 86. On the strength of his reputation he went to Rome, where he arrived during the civil wars between Vitellus and Vespasian. Soon after his arrival, the Capitol was reduced to ashes; and seeing in this disaster a fine opportunity for artistic effect, he composed a poem, which was published almost before the cinders had ceased to smoke. This poem excited the admiration of the great men of the day, and, above all, of the emperor himself. Statius opened a school to teach Greek literature to the young nobles, and he also instructed the Salii and other priests in various branches of their duty with equal severity and success. In spite, however, of his literary labours, he seems to have left his son very little other patrimony beside the half-dozen faded chaplets of pine and laurel which he had won in the Neapolitan contests. The story that Domitian made him a tutor, and presented him with a golden crown, only rests on the authority of Maturantius, and may be a mere mistaken inference from the language of the *Epicedion in patrem*. All his works, even the famous poem on the Capitol, have perished, and he would probably have been forgotten but for the reputation of his son.

STATIUS, *P. Papinius*, the son of the above, was probably born about A.D. 61, and at a very early age he excited by his precocious talents the admiration of his father's patrons. It was a miserable school for a young and clever boy, and we trace the flatterer and protégé in all his works. Before his father's death he won a crown at the Neapolitan games, and was thrice victor in the Alban Quinquatria. During Domitian's reign he and Martial were the accredited poets of the imperial court. At that time poems were first made known by public recitation; a pernicious custom, which had been disliked and discouraged by Horace, but which had increased under the injudicious approval of Ovid, and the practice and patronage of Nero and Domitian. A most bril-

liant and lively picture of these public readings is given by M. Nisard in his *Etudes sur les Poëtes de la Decadence*, from particulars gleaned out of the writings of Pliny, Martial, and Seneca. Statius was the most fashionable reciter of the day; and even Juvenal, who reckons "the poets spouting in the dog-days" among the curses of Rome, speaks with enthusiasm of the delight which was felt in the city when Statius had promised to read some fresh Sylva or new book of the *Thebaid*.

At length, however, even his popularity began to wane. He was defeated in the quinquennial games, and this induced him to put in execution his long-cherished design of retiring to Naples, his native city, and bidding a final adieu to the noisy but fickle plaudits of a niggardly and tasteless crowd. He hoped at Naples to enjoy, in a poverty which would be less galling when it ceased to be contrasted with so much grandeur, that domestic life for which he was eminently adapted, and of which he was deeply fond. Statius was a man of a quiet and amiable disposition; and in his private capacity, apart from the degrading accidents of his time and position, demands our honest admiration. While yet a youth, he had married a freed-woman, Claudia, to whom he was faithfully and tenderly attached. What became of Statius is unknown; he probably died in privacy at Naples, and Dodwell conjecturally places his death in the year A.D. 96. We have been unable to discover any authority whatever for the absurd stories that he was a Christian, or that he was stabbed by the emperor with an iron style.

We can only judge of the character of Statius from his own works. One or two of them are very creditable to his personal feelings; and if there are many which show him in the contemptible light of a parasite, a gossip, and a flatterer, we must remember Bacon's warning respecting the difference between *vitia temporis* and *vitia horminis.* But we must not deny that Statius sinks deeper still. We find him lending the ornaments of his ingenuity to the grossest excesses, and the vilest passions of patrician and imperial crime. What can we say of a poet who throws all the force of his charming versification into the *Consolatio ad Flavium*, and the apotheosis of a eunuch's hair? No purity or simplicity of private life can wholly atone for baseness such as this. Yet the *Coma Earini* is the theme of emulous raptures on the part of Martial and Statius, the two recognized poets-laureate of Domitian's court; and it is far from improbable that the necessity of rivalry in the celebration of such subjects led to that jealousy for his brother poet which critics have traced in the writings[1] of the epigrammatist. Both by his envious silence and his malicious sneers, Martial shows his intolerance of "a brother near the throne."

Statius belongs to that period of declining literature in which the poets sink into mere learned versifiers. In such an age, art not only predominates over inspiration, but has entirely superseded it, and for "the sensibilities of the heart are substituted the susceptibilities of the ear." Statius and his contemporaries ("et tous ces garçon-là," as Scaliger somewhat contemptuously called them) "have taste, learning, and ingenuity, but not one spark of the true Promethean fire. They desired to be poets—they fancied themselves poets; but they rarely rise above the level of rhetoricians who wrote in rythm. Statius teaches us nothing, is good for nothing, has no influence in the education of humanity; he sings of the tresses of a eunuch and the dead lion of an emperor, and yet he was endowed, and that in an eminent degree, with those qualities which, at certain privileged epochs, reveal to the poet truths of eternal interest, and suggest to him the utterance which renders them immortal."[2]

The works of Statius are—

1. The *Sylvæ*, five books of poems in various metres, and in commemoration, for the most part, of the trifling subjects of the day. Statius seems to have thought very lightly of these in comparison with his epics; and yet his claim to poetic laurels rests almost solely on these brochures, and not on his more ambitious works. Niebuhr's judgment of them was very favourable; and many of them (particularly those in which he touches on his own private affairs) are sufficiently sincere to be regarded as very interesting and agreeable compositions. They are well deserving of an attentive perusal.

2. The *Thebais*, in 12 books, each of which occupied a year in elaborating, and which were frequently recited previous to their publication. They were completed before A.D. 90, as we infer from various allusions[3] in the *Sylvæ*, and from the prose proems in which Statius dedicated them to his various acquaintances. It was on this work that Statius mainly founded his hope of poetic immortality.

3. The *Achilleid*, which is left in a fragmentary condition, and the completion of which was perhaps abandoned when the poet retired to Naples. He twice alludes to it in his *Sylvæ*.

The chief editions of Statius are—

The *Editio Princeps* of the *Sylvæ*, about 1470, 4to. The *Editio Princeps* of the *Thebaid* and *Achilleid*, folio, about the same date. Markland, Lond., 1728; Sillig, Dresden, 1827; Lemaire, Paris, 1830. Parts of Statius have been turned into English verse by Pope, Stephens, Lewis, and Howard. (F. W. F.)

STAUNTON, SIR GEORGE LEONARD, was descended from an old English family, and was born in Galway, Ireland, on the 19th of April 1737. Having gone to Montpelier, in the south of France, for his health, he studied medicine there, and on his return to London in 1760 commenced writing for periodicals. On setting out for the West Indies in 1762, Dr Johnson, whose acquaintance he had formed during his short stay in London, wrote him a kind letter, which may still be seen in Boswell's *Life*. He settled in the West Indies, where he practiced as a physician, and amassed a considerable fortune from his profession and from official situations. Investing this money in estates in the island of Granada, he returned to England in 1770. In 1772 he again went to Granada, where he was chosen attorney-general, and made the acquaintance of Lord Macartney, who became governor of that island in 1774. Staunton lost his property by the capture of Granada by the French, and he returned to England with the governor of the island in 1779. He accompanied Lord Macartney to Madras in 1781, and for his distinguished services while in India he received a pension of L.500 per annum from the East India Company, was created a baronet, and received the honorary degree of LL.D. from the University of Oxford. Sir George again accompanied Lord Macartney to China in 1792, as secretary and minister-plenipotentiary, and wrote a very interesting account of China and the Chinese on his return to London. He died in London, January 14, 1801, and was buried in Westminster Abbey.

STAVANGER, a seaport of Norway, in the diocese of Christiansand, in the Bůleke Fiord, an inlet of the German Ocean, 100 miles S. of Bergen. It is built on the N.E. side of a promontory, in the fiord, and commands a fine view towards the mountains in the E. and N.E. The principal building is the cathedral, which was built in 1013, and is, with the exception of that of Drontheim, the most perfect specimen of mediæval architecture in Norway. Stavanger has also several schools, an hospital, and a poor-house. There are here shipbuilding yards, distilleries, &c., but the inhabitants depend chiefly on the herring fishery. The harbour is good, and sheltered by a small island. Timber is exported to a considerable extent. Pop. (1855) 11,717.

STAVROPOL, a town of Russia, capital of a circle of the same name, in the province of Caucasus, stands on a hill near the Taschly, 59 miles W.N.W. of Alexandrov, and about 260 S.W. of Astrachan. It is fortified, and has several churches, a gymnasium, and manufactories of soap and leather. Pop. 7000.

STEAM.

Considerations regarding Steam.

CHAP. I.—CONSIDERATIONS OF A GENERAL NATURE REGARDING THE PROPERTIES, PHENOMENA, AND APPLICATIONS OF STEAM.

STEAM is the name given in our language to the visible, moist vapour which arises from all bodies which contain juices easily expelled from them by heats not sufficient for their combustion. Thus we say, the steam of boiling water, of malt, of a tan-bed. It is distinguished from smoke by its not having been produced by combustion, by not containing any soot, and by its being condensible by cold into water, oil, inflammable spirits, or liquids composed of these. We see it rise in great abundance from bodies when they are heated, forming a white cloud, which diffuses itself and disappears at no very great distance from the body from which it was produced. In this case the surrounding air is found loaded with the water or moisture which seems to have produced it; and the steam seems to be completely soluble in air, composing, while thus united, a transparent elastic fluid. But in order to its appearance in the form of an *opaque white* cloud, the mixture with or dissemination in air seems necessary. If a tea-kettle boils violently, so that the steam is formed at the spout in great abundance, it may be observed that the visible cloud is not formed at the very mouth of the spout, but at a small distance before it, and that the vapour is perfectly invisible at its first emission. This is rendered still more evident by fitting to the spout of the tea-kettle a glass-pipe of any length, and of as large a diameter as we please. The steam is produced as copiously as without this pipe, but the vapour is transparent and colourless throughout the whole of the pipe; nay, if this pipe communicate with a glass vessel terminating in another pipe, and if the vessel be kept sufficiently hot, the steam will be as abundantly produced at the mouth of this second pipe as before, and the vessel will remain quite transparent. The visibility, therefore, of the matter which constitutes the steam is an accidental circumstance, and appears to require its dissemination in the air; and we know that one perfectly transparent body, when minutely divided and diffused among the parts of another transparent body, but not dissolved in it, makes a mass which is visible. Thus oil beaten up with water makes a white *opaque* mass.

When steam is produced, the water gradually wastes in the tea-kettle, and will soon be totally expended if we continue it on the fire. It is reasonable, therefore, to suppose that this steam is nothing but water, changed by heat into an ærial or elastic form. If so, we should expect that the privation of this heat would leave it in the form of water again. Accordingly, this is fully verified by experiment; for if the pipe fitted to the tea-kettle be surrounded with ice, or any cold substance, no steam will issue, but water will continually trickle from it in drops; and if the process be conducted with the proper precautions, the water which we thus obtain from the pipe will be found equal in quantity to that which disappears from the tea-kettle. Steam is therefore the matter of water converted by heat into an elastic vapour.

We are most familiar with steam when in the act of rising violently from heated water in the process of ebullition. The history of steam at this crisis is highly instructive, and its phenomena may be studied with advantage by examining it in a glass vessel placed over a strong lamp. When heat is first applied, a rapid circulation of the fluid ensues. The water on the bottom, being first heated and expanded, becoming lighter than the rest, rises to the top, and is replaced by the current of colder water descending, to receive in its turn a further accession of heat. By and by small globules of steam, formed on the bottom and surrounded by a film of water, are observed adhering to the glass; as the heat increases they enlarge; in a short time several of them unite, form a bubble larger than the others, and, detaching themselves from the glass, rise upwards in the fluid. But they never reach the surface; they encounter currents of water still comparatively cold, and descending to receive from the bottom their supply of heat, and encountering them, the bubbles are robbed of their heat, shrivel up into their original bulk, and are lost among the other particles of water In a short time the mass of the water becomes more uniformly heated; the bubbles, becoming larger and more frequent, are condensed with a loud crackling noise, and at last, when the heat of the whole mass reaches 212°, the bubbles from the bottom rise without condensation through the water, swell and unite with others as they rise, and burst out upon the air in a copious volume of steam, of the same heat as the water from which they are formed, and pushing aside the air, make room for themselves. In this process, by continuing the application of heat, the whole of the water may be "boiled away" or converted into steam.

The singular sounds produced from a vessel of water exposed to heat previously to boiling, have attracted attention; the water is then vulgarly said to be simmering or singing, and, when this takes place, it is because the vessel is boiling at one place and comparatively cold at another. This noise is most distinctly heard when the fire or flame applied is small and its heat intense, when the vessel is large and the water deep; for in that case the entrance of the caloric will take place more rapidly than the circulation can convey it to the remote particles of fluid, and so bubbles of steam will form rapidly at one place and be rapidly condensed at another; the degree of velocity with which such bubbles succeed will determine the pitch of the singing tone. We have observed this phenomenon in greatest perfection when we have attached a slender pipe to a close boiler producing steam, and carried its open mouth, of the diameter of $\frac{1}{8}$ or $\frac{3}{16}$ths of an inch, down below the surface of cold water in a glass jar. When the mouth of the steam-pipe is held just below the surface of the water, the steam issues with great rapidity in small bubbles, producing an acute tone; and, on the other hand, when the pipe is held at a considerable depth, the concussions become more violent and louder, their intervals of succession greater, the tone is lowered, and finally, the shocks become detached, and so violent as to shake the glass and surrounding objects with much force. On this subject Professor Robison observes that a violent and remarkable phenomenon appears if we suddenly plunge a lump of red-hot iron into a vessel of cold water, taking care that no red part be near the surface. If the hand be now applied to the side of the vessel, a most violent tremor is felt, and sometimes strong thumps; these arise from the collapsing of very large bubbles. If the upper part of the iron be too hot, it warms the surrounding water so much, that the bubbles from below come up through it uncondensed, and produce ebullition without concussion. The great resemblance of this tremor to the sensation which we experience during the shock of an earthquake has led many to suppose that the latter is produced in the same way; and their hypothesis is by no means unfeasible. Any obstruction on the bottom of a boiler on the inside, as a piece of metal or stone introduced among the water, may

Considerations regarding Steam.

produce a succession of smart concussions by the sudden condensation of gas collected under it.

The permanence of the boiling point is one of the most remarkable of the phenomena of ebullition. When water has once been brought to boil in an open vessel, it is not possible to make the water sensibly hotter, however strongly the fire may be urged or its intensity increased. This circumstance is very striking, because we know that heat continues to be thrown in exactly as fast as before the boiling point; and that, in that case, the heat rose rapidly, whereas now it has altogether ceased to increase. If a thermometer of mercury, air, oil, or metal be placed among the water, the temperature will constantly increase, and expand the matter of the thermometer until the water boils; and then, whether it boil slowly or rapidly, with a strong fire or a gentle one, the thermometer will continue to stand at the same point. This point is so well defined as to furnish our standard for the comparison of temperature, and is the same on all thermometers, being called the *boiling point*, although it is differently numbered on each, being called 212° on our common thermometer, or Fahrenheit's, 80° on Reaumur's, and 100° on the centigrade thermometer.

It is also to be remarked that the temperature of the steam issuing from boiling water is the same with the temperature of the water itself, and remains equally invariable; so that all the steam produced from water boiling at 212° is itself at 212°. This remark will assist us in accounting for the disposal of the heat which the fire gives out during the time of ebullition; for it is manifest that the heat is all the while carried off by the large volumes of steam, at a temperature of 212°, that are diffused through the air; and so it happens that an increase of heat in the fire, instead of increasing the heat of the water, only increases the volumes of the steam thrown off and the quantity of heat carried away. This view of the subject is confirmed by a simple experiment. Take a strong glass flask, place water in it, and a thermometer among the water, and let it be held over a lamp until the water boil, and the thermometer will be observed rising till it reach 212°, when the steam will begin to escape rapidly from the neck of the flask. Let it now be corked tightly, and the heat continually applied; and it will be observed that the thermometer does not now stand at 212°, but rises rapidly from that point up to 220° and 230°, showing that the free escape of the steam into the open air is necessary to the permanence of the boiling point. If the heat be still applied, the experiment may be rendered still more instructive by suddenly pulling out the cork of the flask, when the vapour will instantly rush out in a large volume, and the thermometer sink down to 212°, showing that all the excess of heat has been carried off by the steam into the air.

It has thus been seen that a large quantity of heat may be given out in the particles of a certain quantity of water, converting them into steam; and yet that the thermometer shall afford no indication of this quantity. As soon as water boils the whole mass is heated up to 212°; and although the same heat that produced the ebullition be still continually applied, and although we know that this heat must be continually entering into the water, still it is not detected, or in any way exhibited by the thermometer. On this account the heat given to water during ebullition is said to become *latent*, or lie hid from the thermometer; and, indeed, the thermometer merely indicates the intensity of heat; the calorimeter alone can measure its quantity. The quantity of heat given out to water after it has begun to boil is more than fivefold that which is sufficient to bring it from the freezing up to the boiling point; for, if we continue the fire with the same intensity that was used in bringing it to boil, it will require more than fivefold that duration and quantity of fuel to boil all the water away, or convert it all into steam of 212° of heat. Thus the sensible heat, added from 32°, will be 180°, and that latent in the steam is more than fivefold; or, in other words, the insensible caloric in steam is fivefold its sensible heat; or the same quantity of matter in the condition of steam at 212°, and of water at 212°, will hold different quantities of caloric, in the proportion of above 6 to 1. This is called the greater capacity of steam for caloric than of water for that substance; and it is in part accounted for by the greater distances of the particles of the matter of steam and water from each other in the former than the latter condition. Dr Black was the discoverer of the admirable doctrine of latent heat.

Considerations regarding Steam.

Dr Dalton has thus illustrated the doctrine of latent heat, and of the increased capacity of a liquid for holding caloric when it passes into the condition of vapour. The liquid and its vapour may be considered as two reservoirs of caloric, capable of holding different quantities of that fluid. Let fig. 1 represent to us such an arrangement: the internal cylinder of smaller capacity; the external one of enlarged capacity, surrounding and extending far above it; and a small open tube of glass, communicating freely at the bottom with the internal cylinder. Let us now conceive water to be poured into the internal cylinder; the water will manifestly flow into the slender tube till it stand on the same level in the tube as in the cylinder. If any additional quantity be now poured into the internal cylinder, the rise of water in the slender glass tube will serve as an index of the quantity of added fluid; and when it is filled to

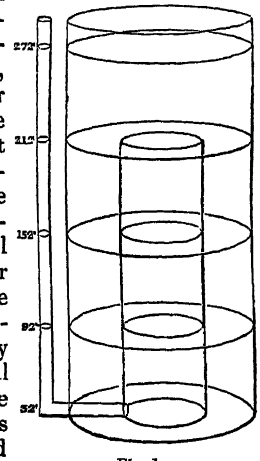

Fig. 1.

the top, the fluid will stand at the height marked 212°, and will still be a correct index of the addition of fluid. But if more water be now added to it, it will not make its appearance in the slender tube, but will simply overflow from the internal cylinder over into that of enlarged capacity, so that while a large quantity is passing into the vessel and gradually filling it up to 212°, no additional rise takes place until the whole of the outer cylinder become filled to that point, after which any further addition will again become sensible by a corresponding rise in the tube. This process is in precise analogy to the succession of circumstances in heating a liquid and converting it into a steam. The internal cylinder represents the liquid; the external one, the vapour of greater capacity; and the slender glass tube at the side, the thermometer placed in communication with them. When heat flows into the liquid, it passes equally into the thermometer; and each increment of the one produces an equal increment in the other, until the liquid reaches the limit of its capacity, when it suddenly begins to enlarge its bulk and take the form of steam; but the quantity of heat required to fill up this enlarged capacity is so great as to require about $5\frac{1}{2}$ times as much to fill it as was contained in the whole liquid before, so that all this time the thermometer is standing still, and it is not until the whole of the steam is thus supplied with 212° of caloric that the thermometer will begin to show any further elevation; after which, any increment of heat thrown into the steam will make its appearance on the thermometer, and proceed, as formerly, by simultaneous increments.

It appears, therefore, that the cause why water boiling under the open air does not reach a higher temperature than 212° is, that the steam which is raised by any additional heat carries that additional quantity of heat along with it into the air. But here a question occurs at once

Considerations regarding Steam.

Considerations regarding Steam.

to the inquirer into these phenomena, viz., Why does water require to be heated up to 212° before it will throw off its increments of heat and vapour into the air? Why does not steam rise equally strongly from water at 200° or 180°? The categorical reply is, that the elastic force of the heat is not sufficient to enable the steam to force its way against the pressure of the air until it reaches this point. In order to understand the means by which we arrive at this conclusion, it is necessary to know that, when the pressure of air on the surface of the water is artificially diminished, the steam does actually rise, and the water bubbles and boils with great violence, at temperatures far below 212°. It is only when the surface of the water is exposed to the full *pressure of the air* in a common vessel that it is prevented from rising in vapour, at temperatures lower than the usual boiling point. If the surface of the hot water be protected from the pressure of the air, by being placed under a glass shade, and the air removed from the inside of it by an air-pump, the water may be made to boil at all temperatures below 212°.

Conceive a vessel of water first of all boiling at 212° in the open air, as the vessel A in fig. 2, the thermometer I

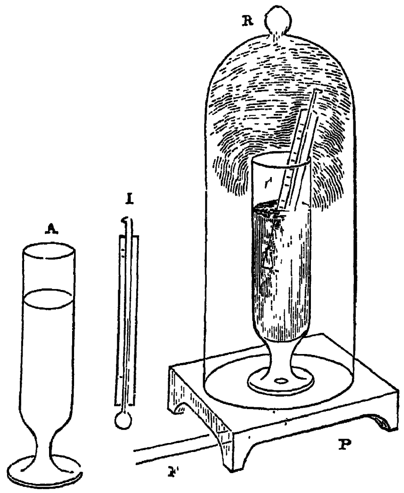

Fig. 2.

being placed in it. After allowing the water to cool to 200°, let the vessel of water and the immerged thermometer be now placed on the plate-stand P of an air-pump, and covered over with a strong glass receiver R; and let a portion of the enclosed air be now withdrawn by the pump from the inside of the receiver by the pipe F; and suppose that there are in all 30 cubic inches, or other volumes, of air in the receiver at first; then the water being at 200°, when about 7 out of the 30 parts of the air have been withdrawn, leaving only about 23 parts out of 30 pressing on the water, it will be observed instantly to commence giving off steam in rapid ebullition. If next, the process be repeated, only allowing the water to cool to 190°, the ebullition will not commence at this lower temperature till about 12 out of the 30 volumes of air have been withdrawn; and if, in a third experiment, the water be cooled down to 180°, the elastic force communicated by this degree of heat will not be capable of overcoming the resistance arising from the pressure of the air until one-half of the original pressure of 30 has been removed. To this process there is no limit, for as we go on lowering the temperature, we can always find a point at which the water will boil, provided the counteracting pressure be sufficiently diminished.

Distillation is a method of separating a liquid from extraneous matter, by first of all converting it into steam, and then condensing that steam so as to form the liquid. Different substances take the liquid form at various temperatures; and, therefore, the heat may be so regulated that only one substance of a mixture shall take the form of vapour, and being conveyed by a pipe through a vessel of cold water, or otherwise exposed to the cooling process, the vapour being condensed will give the pure liquid. A great improvement upon the process of separating liquids has been successfully introduced by Mr Howard. It consists of distillation or evaporation *in vacuo*, and has been most usefully employed in the refining process of sugar. When sugar is dissolved in water, it requires a much higher temperature than 212° to boil the mixture, or to convert the water into steam and separate it from the solid; and as the process goes on, and the solution comes to hold less and less water, the requisite degree of heat is further augmented, until the temperature becomes so high as to injure the colour and otherwise deteriorate the article of merchandise in its crystallized state. Instead of this increased temperature, Mr Howard places the syrup *in vacuo*, and thus boils it at a low and innoxious heat.

The pulse-glass, an invention attributed to Dr Franklin, is an apparatus illustrating beautifully the process of ebullition *in vacuo* at low temperatures. If two glass-balls, A and B (fig. 3), be connected by a slender tube, and one of them A be filled with water, a small opening or pipe *b* being left at the top of the other, and this be made to boil, the vapour produced by it will drive all the air out of the other, and will at last come out itself, producing steam at the mouth of the pipe. When the ball B is observed to be occupied by transparent vapour, we may conclude that the air is completely expelled. Now, shut the pipe by sticking into it a piece of tallow or wax, the vapour in B will soon condense, and there will be a vacuum. The flame of a lamp and blow-pipe being directed to the little pipe *b*, will immediately cause it to close and seal hermetically. We have now a pulse-glass. Grasp the ball A in the hollow of the hand; the heat of the hand will immediately expand the bubble of vapour which may be in it, and this vapour will drive the water into B, and then will blow up through it for a long while, keeping it in a state of violent ebullition, as long as there remains a drop or film of water in A. But care must be taken that B is all the while kept cold, that it may condense the vapour as fast as it rises through the water. Touching B with the hand, or breathing warm on it, will immediately stop the ebullition. When the water in A has thus been dissipated, grasp B in the hand; the water will be driven into A, and the ebullition will take place there as it did in B. Putting one of the balls into the mouth will make the ebullition more violent in the other, and the one in the mouth will feel very cold. This is a pretty illustration of the rapid absorption of the heat by the particles of water, which are thus converted into elastic vapour. We have seen this little toy suspended by the middle of the tube like a balance, and thus placed in the inside of a window, having two holes *a*, *b* cut in the pane, in such a situation, that, when A is full of water and preponderates, B is opposite to the hole *b*. Whenever the room became sufficiently warm, the vapour was formed in A and immediately brought the water into B, which was kept cool by the air coming into the room through the hole *b*. By this means B was made to preponderate in its turn, and A was then opposite to the hole *a*, and the process was now repeated in the opposite direction. This amusement continued as long as the room was warm enough. Instead of water, alcohol or ether may be substituted, and will act more readily.

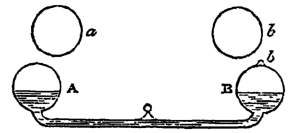

Fig. 3.

The following experiment, where ebullition is produced by the application of cold, is instructive. A Florence flask

Considerations regarding Steam.

E (fig. 4) is about one-third full of water, and is placed over

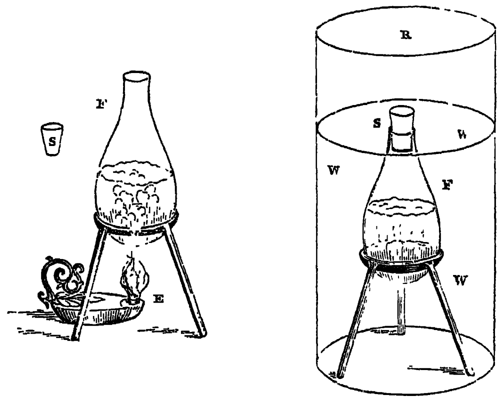

Fig. 4.

a lamp E until the water boils; and when the steam has been rising for a short time violently from the neck of the vessel, the cork S is to be applied as a stopper, and must fit with great accuracy. The flask thus closed is to be set aside for a few minutes till it have cooled considerably, and is then to be suddenly placed on a stand in the cold water W, contained in the glass reservoir R. The ebullition in the flask will recommence with a degree of violence proportioned to the coldness of the water W. The theory of this action is simple. When the flask is plunged in the cold water, two-fifths of its contents are steam: the chill water condenses it into water, it shrinks up into $\frac{1}{1642}$d part of its bulk, and would leave 1641 parts out of 1642 vacuous; but the warm water being now *in vacuo*, throws up in rapid ebullition copious volumes of vapour of its own temperature, which is, again, by coming into contact with the sides of the vessel and by directly giving off its heat to the water, chilled into water; and so in succession all the vapour thus sent up is in turn reconverted into water and the vacuum sustained, until at last, the equilibrium between the temperature of the water, within and around the flask, having been established, the interchange of caloric ceases; and even now, if the flask were plunged into freezing water, the ebullition would recommence as violently as before.

We have already noticed the fact, that, when water is confined in a close vessel, and heat is applied to it, the water will not boil even at a temperature of 212°. If heat be continually thrown into the water in this state, the particles will acquire a very high temperature; and, at the same time, the tendency of the enclosed fluid to burst the vessel will become very great. The following experiment upon this subject is one of the most interesting and the earliest of which we are in possession. It was published in 1663 by the Marquis of Worcester, and we give it in his own words:—"I have taken a piece of a whole cannon, whereof the end was burst, and filled it [with water] three-quarters full, stopping and screwing up the broken end as also the touch-hole, and making a constant fire under it; within twenty-four hours it burst, and made a great crack."

It is in virtue of the great elastic force by which water, when heated, tends to expand into many times its bulk, in the form of steam, that this element has become a mechanical mover, subject to the control of man. There are two great principles of classification upon which such machines are constructed; the one commonly called high-pressure or non-condensing steam-engines, and the other low-pressure or condensing steam-engines.

In order, however, to its successful application as a mechanical power, and its profitable use in each of the various functions which it is capable of performing, it is necessary to study its various phenomena in greater detail; to obtain an intimate acquaintance with its properties; to determine its laws in the various relations of space, time, and quantity; how much heat it requires; what fuel it consumes; what force it exerts; how fast it will move; how it will condense, expand, and contract; and what relation it bears to the fluid from which it is derived. These inquiries, and the manner in which these objects may be most satisfactorily obtained, is the subject of this article, and of the following articles on the steam-engine in its various applications.

Historical Notice of Experiments on Steam.

CHAP. II.—HISTORICAL NOTICE OF EXPERIMENTS ON THE PROPERTIES OF STEAM.

The earliest researches into the phenomena of steam, undertaken with the philosophical purpose of obtaining experimental data for the scientific investigation of its properties and relations, are to be met with in a scarce work, printed at Basle in 1769, written by Jo. Henrico Ziegler. Unhappily, he lived too remote from the scene of the philosophical discoveries of that period to adopt the precautions necessary to give value to his experiments. He allowed atmospheric air to mingle with the steam to such an extent as greatly to vitiate the results.

M. Betancourt, about the end of last century, undertook a series of experiments on the force of the vapour of water, alcohol, or other liquids, at various temperatures. His apparatus was tolerably perfect; and the precautions which he adopted for the removal of atmospheric air from intermixture with the vapour, gave his experiments considerable value and precision. Some of his experiments were made *in vacuo*; and he seems to have been one of the first philosophers who examined the production of steam at temperatures below the ordinary point of ebullition, under the pressure of the atmosphere. His experiments extend from 32° up to 279°, being 67° above the ordinary boiling point.

Of British philosophers, Dr Robison was one of the first to make accurate and systematic experiments on the phenomena of the temperature and elastic force of steam; they appear to have been made in 1778. Previously, however, Mr Watt had been led, in the course of his invention of the steam-engine, in 1764–65, to make experiments on the elastic force of steam. From the data he then obtained, he laid down a curve, in which he says, "the abscissæ represented the temperatures, and the ordinates the pressures, and thereby found the law by which they were governed, sufficiently near for my then purpose." In 1773–74, he resumed his experimental researches on the relative temperatures and pressures of saturated steam up to about 40 lb. total pressure per square inch. Having been dissatisfied with the irregularities of the results he obtained, Mr Southern and Mr Creighton, at his request, repeated his experiments in 1803, with the view of ascertaining the density of steam raised from water under different pressures above, as well as below, that of the atmosphere; they extended from a pressure of ·4 inch to 240 inches of mercury, or 8 atmospheres.

Dr Dalton appears to have been the first to escape from the natural enough error of assuming that the vapour of water at 32° Fahr., the freezing point, would be represented by 0. This apparatus was the most simple and refined of any that had been employed for temperatures below 212°, and his experiments continued for many years to possess the greatest authority. His experiments were first published in 1793; and afterwards, when more extended, in 1802. Dr Ure, in 1817, and subsequently Mr Philip Taylor, and Professor Arsberger, of Vienna, made experiments on high pressure steam through an extensive range of temperatures.

In 1823, the government of France having resolved to

Historical Notice of Experiments on Steam.

Historical Notice of Experiments on Steam.

legislate on the means for obtaining security in the use of steam-engines, consulted the Academy of Sciences upon the mode of most effectually promoting the public safety, without placing useless restrictions on commercial enterprise and manufacturing industry. The examination into the state of knowledge concerning the phenomena of vapour at elevated temperatures, which resulted from this application, having brought the imperfections of this part of science prominently into notice, the Academy were induced to undertake a long and laborious inquiry, not entirely free from personal danger, into the law connecting temperature with the pressure of steam. The commission consisted of the illustrious members of the Academy, Baron de Prony, Arago, Girard, and Dulong; and the results of their investigations, finished in 1829, were published in the *Memoirs of the Academy of Sciences* in 1831. The experiments were conducted principally by MM. Arago and Dulong, and on a scale of magnitude and expense suited to the munificence of the French government and the resources of the Academy; they were carried as high as to 24 atmospheres of pressure, or about 360 lb. per square inch.

Towards the end of 1830, a committee of the Franklin Institute, of the State of Pennsylvania, United States, was appointed to examine into the causes of the explosion of steam-boilers, and to devise the most effectual means of preventing the accidents. The committee experimented on the elastic force and temperature of steam, at pressures varying from 1½ to 10 atmospheres.

In 1844, Professor Gustav Magnus published, in Poggendorf's *Annalen*, No. 2, a memoir on the expansive force of steam, in which he notices the defects in former methods, arising from the difficulty of determining with accuracy the true temperature of the vapour, and also the correct pressure, owing to the unequal heating and consequent partial expansion of the mercurial column; and explains the method he adopted to obviate these difficulties.

In July 1844, M. V. Regnault published his very valuable memoir on the *Elastic Force of Aqueous Vapour*, in the *Annales de Chimie et de Physique*, and since, more fully, in the *Memoirs* of the Institute, in 1847. "To establish a physical fact," says this ingenious and accurate physicist, "we must not confine ourselves to a single method of investigation. It is necessary to employ various methods, and even to repeat those made use of by former experimenters, unless they are absolutely faulty; and we must show that all, when used with proper precaution, conduct to the same result; or, if this be not the case, we must point out by direct experiment the cause of error in the defective methods." Acting on this principle, M. Regnault repeated the methods of Dalton, Ure, Magnus, Dulong, and Arago, with such modifications as the improved state of experimental science, and his own skill and experience suggested; and he has pointed out the defects under which they labour, and the limits within which their results may be relied on.

Mr Dalton's method may be described as consisting essentially in determining the heights of the mercurial column in two barometer tubes, the chamber of one being occupied with vapour and the other being a vacuum. In this method the temperature of the vapour is determined by that of a water-bath surrounding the chamber, and either the whole or a part of the mercurial column is maintained by the same means at the same temperature. M. Biot has remarked, that the chief defect in this method arises from the fact, that it is impossible to maintain the water surrounding the tubes at a constant temperature through all its depth, if this depth is considerable, and its temperature differs much from that of the surrounding medium. Mr Ure attempted to remedy this defect by limiting the space occupied by the vapour, and thus reducing the depth of the bath, and in this respect, certainly, his modification of Mr Dalton's method was a decided improvement. M. Regnault has shown that, if the whole of the tubes be surrounded by water, for the purpose of maintaining the columns at the same known temperature, Mr Dalton's method is capable of giving accurate results between the limits + 10° C., and + 30° C., provided the water be incessantly and rapidly agitated, the agitation being merely interrupted for a moment to observe the heights of the mercurial column. Above the higher limit, however, the separation of the liquid into strata of unequal temperature commences the instant the agitation ceases, and the observations are accordingly rendered uncertain. The following account of the apparatus and method of experiment adopted by Regnault, is derived from Dixon's *Treatise on Heat.*

Where it was intended only to raise the chambers and a part of the mercurial column to the temperature of the vapour, M. Regnault made use of the following form of apparatus:—Two barometers B, B, as similar as possible, of about 14 millimetres internal diameter, are arranged, side by side, on a frame (fig. 5). These barometers pass

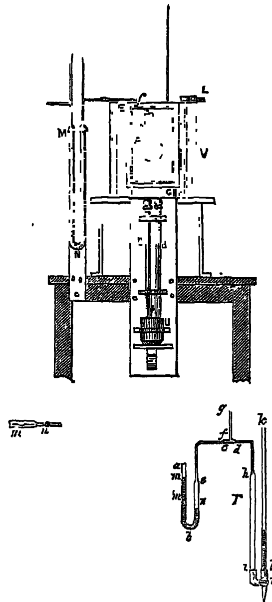

Fig. 5.

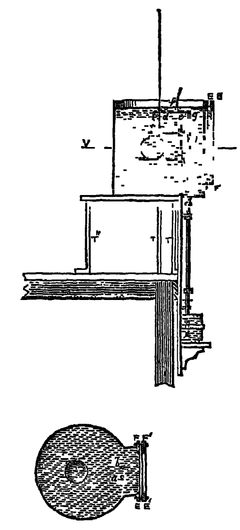

Fig. 6.

through two tubular openings in the bottom of a vessel V of galvanized sheet-iron, and are secured by means of caoutchouc collars. The vessel V, shown in section and plan in fig. 6, has, on one side, a rectangular aperture, round which is fixed an iron frame. A plate of glass, with perfectly parallel faces, is secured to this frame by means of a similar frame attached to the former by screws. A slip of caoutchouc, of the form of the contour of the aperture, is placed between the glass and the frame, and renders the joint perfectly water-tight. The two barometers are plunged in the same reservoir U. The capacity of the vessel is about 45 litres. This vessel is filled with water, which is continually agitated, and its temperature is given by a very sensitive mercurial thermometer immersed in it, which is observed by means of a small horizontal telescope L. The height of the column in the barometer is read off by means of a kathetometer, the agitation of the water being stopped for an instant at the time of the observation of each column. Observations are made with great precision at the temperature of the surrounding air; to observe the force at higher temperature, a small quantity of water is removed from the vessel by means of a syphon, and replaced with a corresponding quantity of hot-water. A spirit-lamp is then placed under the vessel, and its distance from

it, as well as the height of its wick, is so arranged that the temperature of the water, which is still kept in a state of brisk agitation, finally becomes constant. This condition is easily obtained after some trials, and if the temperature does not surpass 50° C., it may be maintained stationary and uniform for any length of time, provided only that the agitation of the water is brisk and constant. Three or four observations were made every time that the temperature was rendered stationary, an interval of eight or ten minutes being left between each. In this method of operating, the portions of the columns outside the vessel are in circumstances completely identical, and the difference of height of the portions within, which are at the temperature of the bath, being reduced to 0°, measures exactly the tension of the vapour, allowance, of course, being made for the pressure of the film of water. It is unnecessary to point out how much more accurate this method of ascertaining the temperature corresponding to observed forces is, than either M. Betancourt's or Mr Dalton's.

A second series of experiments M. Regnault made with the following apparatus:—A balloon A (figs. 5 and 6), whose capacity equals 500 cubic centimeters, contains a little glass vessel full of water recently boiled. The balloon is soldered to a curved tube, cemented into a tubular piece of copper, with three branches, *d*, *e*, *f*. In the branch *e* is cemented a tube soldered to the upper part of the barometer *h*; and in the branch *f* a tube, communicating with an air-pump, by means of the desiccating apparatus MN, filled with powdered pumice, steeped in sulphuric acid. The tube O is a perfect barometer as before. The apparatus being arranged, as in the figures, a vacuum was made forty or fifty times successively; and each time the air slowly readmitted; by this means the interior of the balloon and barometric chamber was completely dried. The vacuum was then finally made as perfectly as possible, and the tube *f* sealed by a blow-pipe. At first M. Regnault was unable to reduce the vacuum below two millimetres, but his air-pump having been cleaned, he subsequently succeeded in bringing it below one millimetre. The balloon was then surrounded with melting ice, and the difference of the columns in the two tubes gave the elastic force at 0° of the remaining air. The ice having been removed, the vessel V was filled with water, and its temperature being sufficiently raised, the little glass vessel was burst by the expansion of the water it contained, and the balloon and chamber filled with aqueous vapour, whose force at the corresponding temperatures was observed as before.

This method answers very well for temperatures below that of the surrounding medium, and for 10° or 15° C. above it; it also answers for determining the force of aqueous vapours in air of any density within those limits of temperature.

Those two forms of apparatus do not answer for tensions above 200 millimetres; beyond this force M. Regnault employed the following, which in principle is similar to Professor Magnus's, and which he also employed in the case of liquids more volatile than water.

A syphon-shaped tube *a b e* (fig. 5), of about 15 millimetres internal diameter, terminates in a fine curved tube *c e*. The closed branch *a b* is filled with mercury, which is carefully boiled to expel all air and moisture. When the mercury is cool, a small quantity of volatile liquid is introduced into the branch *b e*, and boiled for some minutes; the tube is then inclined, and a little of the liquid, yet hot, is passed up into the branch *a b*; the branch *b e* is then completely dried. The tube is now fixed in a perfectly vertical position in the vessel V, in front of the glass-plate. The tube *c e* is cemented into one branch of a piece of copper *c d f*, whose other branches communicate, one *d*, with a manometric apparatus with a stop-cock *r*, and the other *f* with an air-pump, if necessary. The tubes *h i*, *k l*, are first completely filled with mercury, the air being expelled through *f g*; the tube *f g* is then closed with the blow-pipe and a portion of the mercury being allowed to flow out through the stop-cock *r*, the pressure of the air in the branch *n e c* is so far diminished as ultimately to become nearly equal to the pressure of the vapour in *a m*, when the mercury in the two branches of the syphon-shaped tube falls nearly to the same level. The force of the vapour is then measured by the atmospheric pressure, diminished by the column *r s* in the manometer, and the column *m n* in the tube *a b*, both these columns, whose temperatures are known, being reduced to their heights at 0°. The temperature of the vapour is ascertained as in the preceding experiment.

None of the foregoing methods answer for temperatures above 60° or 70° C. At higher degrees the water in the vessel V separates so promptly into strata of different temperatures as to require constant agitation to prevent this result from taking place. For temperatures above 100° C., moreover, those methods become impracticable from other causes. For higher degrees, therefore, M. Regnault had recourse to the well-known method employed by Mr Dalton, and other physicists subsequently, of ascertaining the temperature of the vapour of water boiling under determined pressures.

In order to obtain results of the degree of accuracy which this method is capable of giving, it is necessary to boil the water in a vessel communicating freely with a space of tolerable capacity, in which we can dilate or condense at will; and by this means form an artificial atmosphere, which exerts a determined pressure on the surface of the heated liquid. We thus obtain a temperature of ebullition as perfectly stationary as that of water boiling in free air, and we can maintain this temperature stationary as long as we will. The apparatus employed for this purpose by M. Regnault is represented in fig. 7. It consists of a

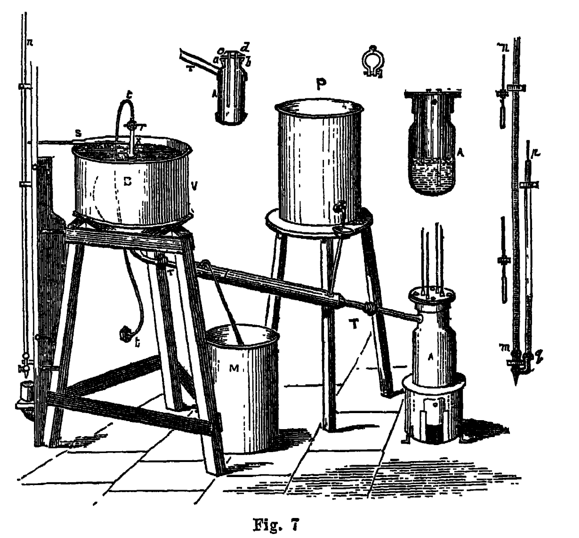

Fig. 7

retort of red copper A, closed with a cover. This cover carries four iron tubes closed below; of these, two descend to the bottom of the retort, the others only reach half-way down. These tubes, which are 7 millimetres in internal diameter, and about 1 millimetre thick, are surrounded by a case of very thin copper attached to the cover, and having apertures in its upper part. They are filled with mercury to within a few centimetres of their upper edge, and hold four mercurial thermometers, whose bulbs descend to the bottom of the tubes. From the arrangement of the tubes, it appears that two of the thermometers are plunged in vapour and two in water, as shown in section. The neck of the retort is connected with a tube TT′, about 1 metre

Historical Notice of Experiments on Steam.

Historical Notice of Experiments on Steam.

in length, surrounded by a copper cylinder, through which flows a constant current of cold water, supplied by a reservoir P. This tube communicates with a copper balloon B of about 24 litres in capacity, contained in a vessel V full of water at the temperature of the surrounding medium. To the balloon is attached a pipe, with two branches, one of which is cemented to the tube *e g h* of the apparatus represented in fig. 6, when the experiments are made at pressures inferior to that of the atmosphere, or with the tube *p q* of the apparatus in fig. 7, for greater pressures. The second branch is connected by means of a lead tube *t t*, with an exhausting or condensing air-pump.

For pressures inferior to the atmospheric, the air in the balloon having been rarefied, the water in the retort is heated until ebullition commences. The vapour, according as it forms, is condensed in the refrigerator TT′, and falls back into the retort. The pressure is measured by the difference of heights of the mercury in the barometric tubes. It may be remarked that the column in the barometric tube connected with the balloon, is never absolutely stationary; the amplitude of its oscillations, however, when the fire is properly regulated, is very small, not exceeding one-tenth of a millimetre. The mercury in the barometer *o*, on the other hand, remains perfectly stationary. The difference of the heights of these columns is observed by means of a kathetometer; and an assistant, at the same instant, notes the height of the thermometers. Several observations were made, at intervals of eight or ten minutes, under the same pressure; and it was thus easy to perceive the perfect constancy of the temperatures indicated by the thermometer for the same pressure, and to show that the least change in the latter was followed by a corresponding change in the former.

The height of the kathetometers not exceeding one metre, when greater differences of level in the apparatus required to be measured, it was necessary to employ two of them. In order to ascertain if the divisions of the scales of the two instruments were identical, M. Regnault read off the divisions of one, in lengths of centimetres, by means of the other; and such was the accuracy of their graduation, that he, in no case, encountered a difference of more than one-twentieth of a millimetre. To attain such a degree of precision in the measures, it is evident that the instruments must be constructed with the greatest accuracy; the telescopes must not have too great a focal length ($0^{m}.30$), and the levels, in particular, must possess extreme sensibility. Those in the kathetometers constructed by M. Gambey indicated inclinations of one second. The verniers gave directly one-fiftieth of a millimetre, and easily admitted of the estimation of one-hundredth.

The thermometers, says M. Regnault, employed in the experiments, made at pressures inferior to the atmospheric, ranged from 0° to 100° C.; they had from six to eight divisions in 1° C.; it was, consequently, easy to read with certainty the one-sixtieth of a degree. Those employed for higher pressures had a range from 0° to 240°, and 1° C. contained 2·5 or three divisions of their scale. All these instruments were graduated and verified with the greatest care. In estimating the temperature from the indication of the thermometers, a correction required to be made for the portion of mercury in the stem unassimilated in the temperature. The temperature of this portion was ascertained by means of a sensitive mercurial thermometer suspended between the four stems. It may be remarked, that the temperature indicated by the thermometer in the liquid was always higher, at low temperatures, than that indicated by those in the vapour; the difference in some cases amounted to 0°·7. As the pressure approached the atmospheric, this difference became less, and, at high temperatures, was quite insensible.

The method by which M. Regnault investigated the force of vapours at high temperatures was similar to that last described; and the apparatus which he employed for this purpose differed from the preceding merely in the size and strength of the parts. The boiler was made of copper, about 5 millimetres thick, and had a total capacity of 70 litres. The reservoir B forming the artificial atmosphere was also of copper, 13 millimetres thick, and contained about 280 litres. The manometer destined to measure the pressure of the artificial atmosphere, and thus of the vapour in the boiler, consisted of a tube, or rather a series of tubes, placed vertically over one another, and attached to the walls of the building in the vicinity of which the experiments were performed, and continued along a strong pole or mast firmly secured to the top of the wall. This system of tubes was open above, and contained the column of mercury, which measured the tension in B. Its total height was 24 metres, and it was accordingly able to measure a pressure of 30 atmospheres.

The experiments were conducted as follows:—The water in the boiler having been raised nearly to its boiling point, the air in the reservoir B was compressed, until it had reached the pressure under which it was desired to make the experiment. A column of mercury of the corresponding height was next forced up the manometer from below by means of a force-pump, and connection was then made between the manometer and the reservoir. Meanwhile, the temperature of the water in A was rising, and continued to increase until it reached its boiling point under the pressure to which it was exposed. It was then kept in a state of ebullition for at least half an hour, and no observation was made until it was ascertained that the mercurial thermometers connected with the boiler were perfectly stationary. The temperatures indicated by these thermometers were then observed, and also the indications of an air thermometer, which, to insure greater accuracy, was employed in addition to the former. At the same time, the difference of level of the mercury in the branches of the manometer was noted. M. Regnault's experiments with this apparatus extended to a pressure of about 28 atmospheres, corresponding to a temperature of 230°·56 C. measured on the air thermometer.

Mechanical Theory of Heat.

CHAP. III.—THE MECHANICAL THEORY OF HEAT.

An important and interesting inquiry relative to steam and its operation in the steam-engine, is that which traces the connection between the heat expended and the dynamical effect, or work, produced. The method of separate condensation, and the application of the force of expanding steam, changed to an important extent the accepted relations of heat to power, and added remarkably to the dynamical effect of the fuel; and though the steam-engine has been progressively improved by the continual elaboration of small economies, there is yet good reason to believe that the field of improvement is wide, and that the labourer in that field has the prospect of a good return. The inquiries of scientific men on the subject of the relation of heat to mechanical effect, have resulted in the establishment of the principle that heat and mechanical force are identical and convertible, and that the action of a given quantity of heat may be represented by a constant quantity of mechanical work performed. "Motion and force," says Professor Rankine, "being the only phenomena of which we thoroughly and exactly know the laws, and mechanics the only complete physical science, it has been the constant endeavour of natural philosophers, by conceiving the other phenomena of nature as modifications of motion and force, to reduce the other physical sciences to branches of mechanics. Newton expresses a wish for the extension of this kind of investigation. The theory of radiant heat and light having been reduced to a branch of mechanics by means of the hypo-

Mechanical Theory of Heat.

thesis of undulations, it is the object of the hypothesis of molecular vortices"—oscillation or vibratory motion—" to reduce the theory of thermometric heat, and elasticity also, to a branch of mechanics, by so conceiving the molecular structure of matter that the laws of these phenomena shall be the consequences of those of motion and force. This hypothesis, like all others, is neither demonstrably true nor demonstrably false, but merely probable in proportion to the extent of the class of facts with which its consequences agree." It must, however, be remarked that, whether the hypothesis of molecular motion be probable or improbable, the theoretical and practical results arrived at in regard to the mechanical action of heat remain unaffected, being deduced from principles which have been established by experiment and demonstration. From these principles, Professor Rankine announced the specific heat of air before it was otherwise known,—the accuracy of his deductions having since been verified to within less than 1 per cent. by the experiments of Regnault. The best experiments, previous to those made by Regnault, in regard to the specific heat of air, were those of Delaroche and Berard, from which they deduced a specific heat of ·266; but, arguing from the mechanical theory of heat, Professor Rankine declared that this value must be erroneous, and that the specific heat of air could not exceed ·240. It has been found accordingly, by Regnault, since the statement was made, as the result of a hundred experiments, that the specific heat of air was ·238, and that it is constant for all pressures from one to ten atmospheres, or at least differs almost inappreciably. This coincidence of theoretical prediction with experimental evidence, it has been well observed, should have something like the same tendency in strengthening our belief of the theory upon which Professor Rankine's estimate was based, as the discovery of an unknown planet, previously indicated by Le Verrier and Adams, had in confirming our faith in the science of astronomy.

The principle of the dynamical or mechanical theory of heat, as already stated, is that, independently of the medium through which heat may be developed into mechanical action, the same quantity of heat converted is invariably resolved into the same total quantity of mechanical action. For the exact expression of this relation, of course, units of measure are established:—in terms of the English foot, as the measure of space; the pound avoirdupois, as the measure of weight, pressure, elasticity; and the degree of Fahrenheit's scale, as the measure of temperature and heat. Work done consists of the exertion of pressure through space, and the English unit of work is the exertion of 1 lb. of pressure through 1 foot, or the raising of 1 lb. weight through a vertical height of 1 foot: briefly, a foot-pound. The unit of heat is that which raises the temperature of 1 lb. of ordinary cold water by 1 degree Fahr. If 2 lb. of water be raised 1 degree, or 1 lb. be raised 2 degrees in temperature, the expenditure of heat is, equally in both cases, two units of heat. Similarly, if 1 lb. weight be raised through 1 foot, or 2 lb. weight be raised through 2 feet, the power expended, or work done, is equally in both cases two units of work, or two foot-pounds. From these definitions, then, the comparison lies between the unit of heat, on the one part, and the unit of work, or the foot-pound, on the other.

M. Clapeyron, in his treatise on the moving power of heat, and M. Noltzman, of Manheim, in 1845, who availed himself of the labours of M. Clapeyron and M. Carnot in the same field, grounding their investigations on the received laws of Boyle, or Marriotte, and Gay Lussac, which express the observed relations of heat, elasticity, and volume, in steam and other gaseous matter, concluded that the unit of heat was capable of raising a weight, between the limits of 626 lb. and 782 lb., 1 foot high; that is to say, that one unit of heat was equivalent to from 626 to 782 foot-pounds. By this mode of investigation, they suppose a given weight of steam, or gaseous matter, to be contained in a vertical cylinder formed of non-conducting material, in which is fitted an air-tight but freely-moving piston, which is pressed downwards by a weight equal to the elasticity of the gas. Now, the weight, initial temperature, pressure, and volume being known, a definite quantity of heat from without is supposed to be imparted to the vapour; and the result is partly an elevation of the temperature of the vapour, and partly a dilation or increase of volume, or, in other words, an exertion of pressure through space—the elasticity remaining the same. But the result may be represented entirely by dilation, so that there shall not be any final alteration of temperature; and for this purpose, it is only necessary to allow the vapour to dilate without any loss of its original or imparted heat until it re-acquires its initial temperature. In this case, the ultimate effect is purely dilatation, or motion against pressure; and the work done is represented by the product of that pressure into the space moved through.

Mr Joule, of Manchester, in 1843–47, proceeded, by entirely different, independent, and, in fact, purely experimental methods, to investigate the relation of heat and work:—1*st*, By observing the calorific effects of magneto-electricity. He caused to revolve a small compound electro-magnet, immersed in a glass vessel containing water, between the poles of a powerful magnet: heat was proved to be excited by the machine, by the change of temperature in the water surrounding it, and its mechanical effect was measured by the motion of such weights as by their descent were sufficient to keep the machine in motion at any assigned velocity. 2*d*, By observing the changes of temperature produced by the rarefaction and condensation of air. In this case, the mechanical force producing compression being known, the heat excited was measured by observing the changes of temperature of the water in which the condensing apparatus was immersed. 3*d*, By observing the heat evolved by the friction of fluids:—a brass paddle-wheel, in a copper can containing the fluid, was made to revolve by descending weights. Sperm oil and water yielded the same results. Mr Joule considered the third method the most likely to afford accurate results; and he arrived at the conclusion that one unit of heat was capable of raising 772 lb. 1 foot in height; or, that the mechanical equivalent of heat was expressible by 772 foot-pounds for 1 unit of heat,—known as "Joule's equivalent."

The following are the values of Joule's equivalent for different thermometric scales, and in English and French units:—

1 English thermal unit, or 1 degree of Fahrenheit in 1 pound of water	772 foot-pounds.
1 centigrade degree in 1 pound of water......... (or nearly 1390).	1389·6 „
1 French thermal unit, or 1 centigrade degree in a kilogramme of water	423·55 kilogram-metres.

The mechanical theory of heat rests upon a wide basis, and proofs in verification of the theory are constantly accumulating. When the weight of any liquid whatever is known, with the comparative weight of its vapour at different pressures, the latent heat at the different pressures is readily estimated from the theory; and this method of estimation agrees with the best experimental results, as may afterwards be shown; and when the latent heat is also known, the specific heat of the liquid can be determined by means of the same theory: in other words, the quantity of work, in foot-pounds, may be determined, which would, by agitating the liquid or by friction, be required to raise the temperature of any given quantity of the liquid by, say, one degree, altogether independently of Joule's experiments. The theory enables us to discover the utmost power it is possible to realize from the combination of any given weight of carbon and oxygen, or other elementary substances, with

Mechanical Theory of Heat.

nearly as much precision as we can estimate the utmost quantity of work it is possible to obtain from a known weight of water falling through a given height. It is not difficult to comprehend, then, that the theory of the mechanical equivalent of heat proves of great practical utility.

According to the mechanical theory of heat, in its general form, heat, mechanical force, electricity, chemical affinity, light, sound, are but different manifestations of motion. Dulong and Gay Lussac proved, by their experiments on sound, that the greater the specific heat of a gas, the more rapid are its atomic vibrations. Elevation of temperature does not alter the rapidity, but increases the length of their vibrations, and in consequence produces "expansion" of the body. All gases and vapours are assumed to consist of numerous small atoms, moving or vibrating in all directions with great rapidity; but the average velocity of these vibrations can be estimated when the pressure and weight of any given volume of the gas is known, pressure being, as explained by Joule, the impact of those numerous small atoms striking in all directions, and against the sides of the vessel containing the gas. The greater the number of these atoms, or the greater their aggregate weight, in a given space, and the higher the velocity, the greater is the pressure. A double weight of a perfect gas, when confined in the same space, and vibrating with the same velocity—that is, having the same temperature—gives a double pressure; but the same weight of gas, confined in the same space, will, when the atoms vibrate with a double velocity, give a quadruple pressure. An increase or decrease of temperature is simply an increase or decrease of molecular motion. The truth of this hypothesis is very well established, as already intimated, by the numerous experimental facts with which it is in harmony.

When a gas is confined in a cylinder under a piston, so long as no motion is given to the piston, the atoms, in striking, will rebound from the piston after impact with the same velocity with which they approached it, and no motion will be lost by the atoms. But when the piston yields to the pressure, the atoms will not rebound from it with the same velocity with which they strike, but will return after each succeeding blow, with a velocity continually decreasing as the piston continues to recede, and the length of the vibrations will be diminished. The motion gained by the piston will, it is obvious, be precisely equivalent to the energy, heat, or molecular motion lost by the atoms of the gas. Vibratory motion, or heat, being converted into its equivalent of onward motion, or dynamical effect, the conversion of heat into power, or of power into heat, is thus simply a transference of motion; and it would be as reasonable to expect one billiard-ball to strike and give motion to another without losing any of its own motion, as to suppose that the piston of a steam-engine can be set in motion without a corresponding quantity of energy being lost by some other body.

In expanding air spontaneously to a double volume, delivering it, say into a vacuous space, it has been proved repeatedly that the air does not fall appreciably in temperature, no external work being performed; but, on the contrary, if the air, at a temperature, say of 230° Fahr., be expanded under pressure or resistance, as against the piston of a cylinder, giving motion to it, raising a weight, or otherwise doing work, by giving motion to some other body, the temperature will fall nearly 170° when the volume is doubled, that is, from 230° to about 60°; and, taking the initial pressure at 40 lb., the final pressure would be 15 lb. per square inch.

When a pound weight of air, in expanding, at any temperature or pressure, raises 130 lb. 1 foot high, it loses 1° in temperature; in other words, this pound of air would lose as much molecular energy as would equal the energy acquired by a weight of 1 lb. falling through a height of 130 feet. It must, however, be remarked, that but a small portion of this work, 130 foot-pounds, can be had as available work, as the heat which disappears does not depend on the amount of work or duty realised, but upon the total of the opposing forces, including all resistance from any external source whatever. When air is compressed, the atmosphere descends and follows the piston, assisting in the operation with its whole weight; and when air is expanded, the motion of the piston is, on the contrary, opposed by the whole weight of the atmosphere, which is again elevated. Although, therefore, in expanding air, the heat which disappears is in proportion to the total opposing force, it is much in excess of what can be rendered available; and, commonly, where air is compressed, the heat generated is much greater than that which is due to the work which is required to be expended, the weight of the atmosphere assisting in the operation.

Let a pound of water, at a temperature of 212° Fahr., be injected into a vacuous space or vessel, having 26·36 cubic feet of capacity—the volume of 1 pound of saturated steam at that temperature—and let it be evaporated into such steam, then 893·8 units of heat would be expended in the process. But, if a second pound of water, at 212°, be injected and evaporated at the same temperature, under a uniform pressure of 14·7 lb. per square inch due, to the temperature, the second pound must dislodge the first, by repelling that pressure, involving an amount of labour equal to 55,800 foot-pounds (that is, 14·7 lb. × 144 square inches × 26·36 cubic feet), and an additional expenditure of 72·3 units of heat (that is, 55,800 ÷ 772), making a total for the second pound of 965·1 units.

Similarly, when 1408 units of heat are expended in raising the temperature of air at constant pressure, 1000 of these units increase the velocity of the molecules, or produce a sensible increment of temperature; while the remaining 408 parts which disappear as the air expands, are directly expended in repelling the external pressure.

Again, if steam be permitted to flow from a boiler into a comparatively vacuous space, without giving motion to another body, the temperature of the steam entering this space would rise much higher than that of the steam in the boiler. Or, suppose two vessels, side by side, one of them vacuous, and the other filled with air at, say two atmospheres, a communication being opened between the vessels, the pressure would become equal in the two vessels; but the temperature would fall in one vessel and rise in the other; and although the air is expanded in this manner to a double volume, there would not on the whole be any appreciable loss of heat, for if the separate portions of air be mixed together, the resulting average temperature of the whole would be very nearly the same as at first. It has been proved experimentally, corroborative of this argument, that the quantity of heat required to raise the temperature of a given weight of air, to a given extent, was the same, irrespective of the density or volume of the air. Regnault and Joule found that, to raise the temperature of a pound weight of air, 1 cubic foot in volume, or 10 cubic feet, the same quantity of heat was expended.

In rising against the force of gravity, steam becomes colder, and partially condenses while ascending, in the effort of overcoming the resistance of gravity, by the conversion of heat into water. For instance, a column of steam weighing, on a square inch of base, 250·3 lb., that is, a pressure of 250·3 lb. per square inch, would, at a height of 275,000 feet, be reduced to a pressure of 1 lb. per square inch, and, in ascending to this height, the temperature would fall from 401° to 102° Fahr., while, at the same time, nearly 25 per cent. of the whole vapour would be precipitated in the form of water, if not supplied with heat while ascending.

If a body of compressed air be allowed to rush freely into the atmosphere, the temperature falls in the rapid part of the current, by the conversion of heat into motion, but the heat is almost all reproduced when the motion is quite subsided; and from recent experiments, it appears that nearly similar results are obtained from the emission of steam under pressure.

When water falls through a gaseous atmosphere, its motion is constantly retarded as it is brought into collision with the particles of that atmosphere; and by this collision it is partly heated and partly converted into vapour.

If a body of water descends freely through a height of 772 feet, it acquires from gravity a velocity of 223 feet per second; and if suddenly brought to rest when moving with this velocity, it would be violently agitated, and raised one degree in temperature. But suppose a water-wheel, 772 feet in diameter, into the buckets of which the water is quietly dropped, when the water descends to the foot of the fall, and is delivered gently into the tail-race, it is not sensibly heated. The greatest amount of work it is possible to obtain from water falling from one level to another lower level, is expressible by the weight of water multiplied by the height of the fall.

The objects of these illustrative exhibitions of the nature and reciprocal action of heat and motive power, with their relations, are,—first, to familiarise the reader with the doctrine of the mechanical equivalence of heat; second, to show that the nature and extent of the change of temperature of a gas while expanding, depends nearly altogether upon the circumstances under which the change of volume takes place.

CHAP. IV.—GENERAL RELATIONS OF GASEOUS BODIES.

Gases are divided into the two classes,—permanent gases, and vapours. The former were originally so called, under the impression that they existed permanently in the gaseous state, and could not possibly be reduced to the liquid form; while those which could be so reduced, and could be reconverted to the state of gas, were called vapours. It has, however, been shown by Sir Humphrey Davy and Mr Faraday, that by the conjoined effects of great pressure, and of a high degree of cold, most of the permanent gases may be liquefied. The under-mentioned still retained the gaseous state at the annexed temperatures and pressures:—

Hydrogen..........	at	−166° Fahr.	and	27	atmospheres.
Oxygen............	„	−166	„	27	„
Do................	„	−140	„	58·5	„
Nitrogen..........	„	−166	„	50	„
Nitric Oxide......	„	−166	„	50	„
Carbonic Oxide....	„	−166	„	40	„
Coal-gas..........	„	−166	„	32	„

Several of the liquefied gases are further capable of being reduced to the solid state. Thus, sulphurous acid becomes solidified at −105°; sulphuretted hydrogen at −122°; carbonic acid at −72°; ammonia at −103°. The difference, then, between the permanent gases and vapours, is merely one of degree, and depends upon the temperature at which the change from the fluid to the gaseous state occurs. Those which exist in the fluid state under ordinary temperatures and pressures are called vapours; those which require strong pressure and extremely low temperatures to reduce them to the liquid form, are called permanent gases.

Steam, as the elastic vapour of water, is amenable to the laws of gaseous fluids; and, according to these laws, the pressure, the density or the volume, and the temperature, bear fixed relations to each other. The influence of temperature on the expansion of permanent gases under constant pressures is such, that, for equal increments of temperature, the increments of volume by expansion are also equal, and they are nearly the same for different gases. The expansion of air by increase of temperature may be assumed to represent that of other gases; and, it may be added, the most exact measure of real temperature is to be found in the expansion of air, or any other perfect gas. By real or absolute temperature is signified the measure of the whole of the heat of a body; and at the absolute zero point of the scale, all gases would cease to have elasticity or molecular motion. As the expansion of air under constant pressure is found experimentally to be uniform for uniform increments of temperature, it is inferred, conversely, that it would contract uniformly, under uniform reduction of temperature, until, on arriving at a temperature 461° below zero of Fahrenheit's scale, or, exactly −461·2°, the air would be in a state of collapse, without appreciable elasticity. This point has, therefore, been adopted as that of absolute zero, standing at the foot of the natural scale of temperature. For example, let a volume of air, 673 cubic inches in bulk, at a temperature of 212° Fahr., be confined at a constant pressure in a cylinder, under a piston movable without friction. If the gas be cooled 10°, the piston will descend through 10 cubic inches; if cooled 100°, the piston will descend, and the air will contract, through 100 cubic inches; and so on, in the same ratio; so that, by lowering the temperature 673°, the air would not possess appreciable volume; and $673 - 212 = 461°$ below the artificial zero of Fahr., would, therefore, be arrived at as the point of absolute zero.

Again, if a given weight of air at 0° Fahr. be raised in temperature to 461° under a constant pressure, its volume will be doubled by expansion; and, if heated to $461 \times 2 =$ 922°, its volume will be trebled; in short, for every increment of one degree of temperature, its volume will be enlarged by equal increments uniformly $\frac{1}{461}$ part of the volume at 0°.

The following, then, are the established relations of the properties of permanent gases:—

With a constant temperature, the pressure varies simply as the density, or inversely as the volume. This is known as Boyle's or Marriotte's law.

With a constant pressure, expansion is uniform under a uniform accession of heat or rise of temperature, at the rate of $\frac{1}{461}$ part of the volume at 0° Fahr. for each degree of heat. If, then, 461° be added to the indicated temperature by Fahrenheit's scale, the sum, or absolute temperature, varies directly as the total volume, expanding or contracting, and inversely as the density. This is known as the law of Gay Lussac.

With a constant volume, or density, the increase of pressure is uniformly at the rate of $\frac{1}{461}$ part of the pressure at 0° Fahr. for each degree of temperature acquired. Adding 461° to the indicated temperature, the sum, or absolute temperature, varies directly as the total pressure.

In brief, 1*st*, the pressure varies inversely as the volume when the temperature is constant; 2*d*, the volume varies as the absolute temperature when the pressure is constant; 3*d*, the pressure varies as the absolute temperature when the volume is constant.

The foregoing enunciation of the relations of temperature, pressure, and density, should be qualified by the remark, that the more easily condensible gases, as they approach the liquefying point, become sensibly more compressible than air; and that they do not strictly conform to the relations of pressure and volume belonging to the permanent gases. It has been found that, as far as 100 atmospheres, oxygen, nitrogen, hydrogen, nitric oxide, and carbonic oxide, follow the same law of compression as atmospheric air, these being amongst the incondensible gases; and that sulphurous acid, ammoniac gas, carbonic acid, and protoxide of nitrogen—proved to be condensible—commence to be sensibly more compressible than air when they have been reduced to one-third or one-fourth of their

General Relations of Saturated Steam.

original volume. Carbonic acid, for example, in place of following the simple ratio of the pressure and density for a constant temperature, increased in density in a greater ratio than the pressure, as indicated in the following table, showing, in the third column, the volume of carbonic acid and increasing pressures relative to that of air, which is expressed by unity:—

Table of the Compressibility of Carbonic Acid, as referred to Air. Temperature, 10° Centig., or 50° Fahr.

Pressures.	Theoretic Volumes.	Compressibility of Carbonic Acid.
Atmospheres.		Air=1·000
1	1000	1·000
2	500	1·000
4	250	1·000

6·67	150	·980
10	100	·965
15·38	65	·934
20	50	·919
25	40	·880
33·3	30	·808
40	25	·739
45	...	liquefied.

The deviations from unity in the last column express the deviations from the law of Boyle, as applicable to dry air at a constant temperature; and they show that, under a pressure of 40 atmospheres, carbonic acid, near the condensing point, occupied rather less than three-fourths of the volume which would have been occupied by air under the same circumstances. This accelerated density, or incipient condensation, characteristic of carbonic acid and other condensible gases, in approaching the point of liquefaction, foretells the approaching change. It is, nevertheless, established that all gases, at some distance from the point of maximum density for the pressure, do virtually follow the law of Boyle, according to which the pressure and the density vary directly as each other when the temperature is constant; and, on such conditions, they rank as perfect gases.

CHAP. V.—GENERAL RELATIONS OF ORDINARY OR SATURATED STEAM.

The accelerated reduction of volume and increase of density, observable in the condensible gases, as they approach their condensing points, hold likewise with steam. Steam produced in an ordinary boiler, over water, is generated at its maximum density and pressure for the temperature, whatever this may be. In this condition of maximum density, steam is said to be saturated, being incapable of vaporizing or absorbing more water into its substance, or increasing its pressure, so long as the temperature remains the same. Nor, on the contrary, will steam be generated with less than the maximum constituent quantity of water which it is capable of appropriating from the liquid out of which it ascends. It stands both at the condensing point and at the generating point; so that a change in any one of the three elements of pressure, density, or temperature, is necessarily accompanied by a change of the two others. One density, one pressure, and one temperature, unalterably occur in conjunction: the same density is invariably accompanied by the same pressure and temperature.

If a part of the heat of saturated steam be withdrawn, the pressure will fall, and also the density, by the precipitation of a part of the steam in the liquid form.

If, while the temperature remains constant, the volume of steam over water be increased, then, as long as there is liquid in excess to supply fresh vapour to occupy the increased space opened for its reception, the density will not be diminished, but will, with the pressure, remain constant, —the maximum density and pressure due to the temperature being maintained.

Relation of the Pressure and Temperature of Saturated Steam.

If, when all the liquid is evaporated, the fire or source of heat be removed, the pressure and density diminish when the volume is increased, as in permanent gases; and, if the volume be again reduced, the pressure and density increase until the latter returns to the maximum due to the temperature—that is to say, reaches the condensing point; and the effect of any further diminution of volume, or attempt to further increase the density at the same temperature, is simply attended by the precipitation of a portion of the vapour to the liquid state,—the density remaining the same.

On the contrary, if when all the liquid is evaporated, the application of heat be continued, the state of saturation ceases, the temperature and pressure are increased, whilst the density remains the same: the steam is said to be superheated, or surcharged with heat, and it becomes more perfectly gaseous. And were it, whilst in this condition, to be replaced in contact with water of the original temperature, it would evaporate a part of the water, transferring to it the surcharge of heat, and would resume its normal state of saturation.

Further, let the space for steam over the water remain unaltered, then, if the temperature is raised by addition of heat, the density of the vapour is increased by fresh vaporization, and the elastic force is consequently increased in a much more rapid ratio than it would be in a permanent gas by the same change of temperature. Conversely, if the temperature be lowered, a part of the vapour is condensed, the density is diminished, and the elastic force reduced more rapidly than in a permanent gas.

An account of the special results of M. Regnault's experiments, and of the investigations and deductions of himself and others based upon them, is given in detail in the following sections.

CHAP. VI.—RELATION OF THE PRESSURE AND TEMPERATURE OF SATURATED STEAM.

The admirable investigations of the constants relating to the economical employment of steam as a motive agency, conducted by M. Regnault, may be fairly considered as affording conclusive data of all the phenomena included within the range examined, until some new discovery in science, of a fundamental character, shall offer additional facilities of research. The direct methods of trial and observation may, in the meantime, be regarded as exhausted, and to have yielded the full measure of accuracy of which they are susceptible. It, therefore, only remained to give effect to the results obtained by reducing them to rules of calculation, of ready application, and the most simple of which the relations admit.

One of the most important of those relations is that subsisting between the temperature and the pressure, or elasticity of the steam in contact with the fluid from which it is generated. As yet this relation has only been expressed approximately, and by empirical formulas. The true law of connection has hitherto eluded analysis; and one is compelled to rely in most important calculations on rules which represent the law more or less distinctly, and usually over a very small portion of the curve graphically representing the pressures. There are many such rules, and some of them represent very exactly the data on which they are founded; but as these data are much less complete than those obtained from the elegant and extended researches of Regnault, it becomes necessary, even supposing the forms the most convenient, to lay aside the constants they contain, and to derive them anew from the more recent data.

There are two qualities required in a formula of this kind,—accuracy and simplicity. The first is obtainable by such a form of equation as that suggested by Laplace, which

Relation of the Pressure and Temperature of Saturated Steam.

expresses the expansive force by a series arranged according to the ascending powers of the temperature. This suggestion was afterwards modified by Biot, whose form has been adopted, in the main, by Regnault, as the basis of his principal and most approved and exact formulas. The general form given by Regnault is the following:—

$$\text{Log F} = a\,\text{A}^{\theta} + b\,\text{B}^{\theta} + c\,\text{C}^{\theta} +$$

in which θ is a function of the thermometrical temperature; the other literal quantities are constants, to be determined from the series of experiments which the formula is intended to represent.

Egen's formula is also susceptible of accuracy. It is, in some measure, the inverse of that of Biot, and expresses the temperature by a series arranged according to the ascending powers of the logarithms of the elasticity.

Formulas, according to these models, may include any number of points of the curve of pressures, and may therefore be made to express any required degree of exactness. But such formulas become exceedingly unwieldy and inconvenient for the ordinary purposes of calculation; and they, moreover, do not admit of direct inversion. The formula of Dr Thomas Young, on which those of Creighton, Southern, Tredgold, Mellet, Coriolis, the Commission of the French Academy, the Committee of the Franklin Institute, and others, are founded, is comparatively simple in form; but it does not admit of very great exactness over any considerable extent of the curve. The expression in its most general form is

$$\text{F} = (a + bt)^{m}$$

This equation passes the curve through three given points, and when these are taken at no great distance apart, it may be employed to interpolate; but it cannot with safety be extended to any considerable distance beyond the assumed limits.

Another class of formulas is founded on that proposed by Professor Roche in 1828, from theoretical considerations. It expresses the elasticity by a constant number multiplied by a second constant raised to a power of which the exponent is a fraction, having the temperature in the nominator, and some function of the temperature in the denominator, thus —

$$\text{F} = a\,\text{A}^{\frac{t}{\gamma + t}}.$$

This form has been virtually adopted by August and Strehlke, Von Wrede, Magnus, Holtzmann, and Shortrede. It is greatly superior, as a formula of interpolation, to that of Dr Young in extent and accuracy, and to that of Biot in point of simplicity. It approaches more nearly to the double condition of accuracy and simplicity than any other expression which has yet been proposed; and, in fact, as a practical formula applicable to calculations relative to the steam-engine, leaves little to be regretted that it is not absolute. The most simple and convenient form to which this expression is reducible is, for the elastic force,

$$\text{Log F} = \text{A} - \frac{\text{B}}{t + \text{C}};$$

and the inverse formula for finding the temperature, when the pressure is given, is, accordingly,

$$t = \frac{\text{B}}{\text{A} - \log \text{F}} - \text{C}.$$

The late Mr W. M. Buchanan, of Glasgow, adopted this general equation as the basis of his formula, of which he published an account, in 1850, in the *Practical Mechanic's Journal*, and he tested it by a number of very careful determinations of the constants, from the graphic curve of pressures constructed by Regnault to represent the mean results of his experiments. He was led to conclude that no three points of that curve, which can be taken as data for the values of the constants, render the expression satisfactory throughout the entire range, experimentally represented. That range, however, extends over a space of 262° of the centigrade scale, equal to 471·6° of Fahrenheit's thermometer; namely, from 25·6° below 0° Fahr., at which the pressure is less than 0·006 lb. on the square inch of surface, to 446° Fahr., at which the pressure is over 400 lb. on the square inch. Both extremes of this range are at present much beyond the limits at which a practical formula is required for calculations relating to the steam-engine. The lower limit, especially, is obviously of no moment for such an object, however important it may be for other scientific purposes. Bearing in mind these considerations, Mr Buchanan adopted a temperature of 120° Fahr. as the lower limit of temperature at which it is practically necessary to consider the elasticity of steam as a motive-power, and he determined the constants from that limit to the higher extremity of the given curve, for the results obtained, both by the air and the mercurial thermometer. The values of these constants are arranged in the following statement:—

When the elasticity of the steam is expressed in atmospheres of 29·9212 inches of mercury, =14·68728 lb. on the square inch of surface	then	A=5·0324128 for the air thermometer. =4·8988483 for the mercurial do.
When the elasticity is expressed in atmospheres of 30 inches of mercury=14·726 lb. on the square inch	then	A=5·0312707 for the air thermometer. =4·8977061 for the mercurial do.
When the elasticity is expressed in inches of mercury of specific gravity 13·59596, which corresponds to the density at 32° Fahr.	then	A=6·5083919 for the air thermometer. =6·3748274 for the mercurial do.
When the elasticity is expressed in lbs. on the square inch	then	A=6·1993544 for the air thermometer. =6·0657899 for the mercurial do.

For the air thermometer	B=2938·16.
„ mercurial thermometer	B=2795·97.
„ air thermometer	C= 371·85.
„ mercurial thermometer	C= 358·74.

The formulas for p lb. pressure on the square inch, by the two modes of measuring the temperature are, therefore—

For the Air Thermometer.

$$\text{Log } p = 6{\cdot}1993544 - \frac{2938{\cdot}16}{t + 371{\cdot}85};$$

$$t = \frac{2938{\cdot}16}{6{\cdot}1993544 - \log p} - 371{\cdot}85.$$

For the Mercurial Thermometer.

$$\text{Log } p = 6{\cdot}0657899 - \frac{2795{\cdot}97}{t + 358{\cdot}74};$$

$$t = \frac{2795{\cdot}97}{6{\cdot}0657899 - \log p} - 358{\cdot}74.$$

Mr Buchanan observes, that "the indications by the air thermometer are greatly more to be relied upon than those of the mercurial. The air thermometer is not only more sensitive, but likewise admits of the employment of a relatively larger volume of the expanding fluid, compared with the volume of the glass envelope in which it is enclosed, The errors arising from the different expansibilities of different qualities of glass are, in consequence, much reduced relatively in amount; and, besides, the expansion of the fluid is very nearly uniform for equal increments of temperature. It is, however, the mercurial thermometer which is ordinarily employed in the measurement of temperatures, and accordingly it is of importance that the indications of the ordinary instrument should be represented by an appropriate formula. This formula, it is true, cannot possess

Relation of the Pressure and Temperature of Saturated Steam.

more than an average approximation to the measurement by any particular instruments; for all thermometers made from different qualities of glass, and even when the usual fixed points are exactly and accurately determined, differ from one another at the higher temperatures. This is fully illustrated by the comparisons given by M. Regnault, in his memoir on the measurement of temperature, which has been justly characterized as one of the most elegant and successful examples we possess of the combination of experimental adaptation with inductive application of the results obtained. Let us take a single line of one of the many tables furnished; it compares four of the mercurial thermometers used with each other, and with the temperature indicated by the standard air thermometer. Take the temperature of 250° C. by the standard: in the medium having that temperature, the mercurial thermometer of

Choisy-le-Roi crystal, indicated	253·00 C.
Ordinary glass	250·05
Green glass	251·85
Swedish glass	251·44

At 100° higher, namely, 350° C., by the air thermometer, the first of these four thermometers gave 360·5°; and the second, 354°, as the temperature of the same medium. In this, it is to be remarked, that the deviations of the ordinary glass thermometer are the least; and this is true throughout the whole extent of the table,—a circumstance which ought to attract the attention, especially of the makers of these instruments. The wide differences thus shown to exist among thermometrical instruments of the very best description, render it little surprising that there should have existed very considerable discrepancies among the results obtained by different experimenters, in investigations involving the measurement of temperature. Both Regnault and Magnus have fortunately avoided this source of uncertainty in their researches relative to the elasticity of gaseous fluids, and accordingly their results agree with remarkable nearness."

The formulas employed by Regnault to connect the temperature with the pressure of steam in a state of saturation, chiefly constructed on the model of Biot's equation, though greatly more laborious, do not appear to be much, if in any degree, more exact than those constructed on Professor Roche's model. The wide range over which Buchanan's rules extend, based on Roche's model, and the great accuracy which they exhibit within the limits for which they are determined, seem to indicate that they contain at least the first terms of the absolute law. This supposition is further countenanced by the circumstance referred to by Mr Buchanan, that the same form expresses, better than any other, the tension of the vapours of some other liquids, as ether and alcohol; and he suggests that the formula ought to contain higher powers of the temperature than the first; that it ought to take some such form as the following:—

$$F=\frac{t}{x\,A^{a}+\beta t+\gamma t^{2}+}.$$

M. Bary applied the formula in this form, continued to the third power of t, to vapours.

Professor Rankine, of Glasgow, in 1849, published a formula for vapours in general, as follows:—

$$\operatorname{Log} p=a-\frac{b}{t}-\frac{c}{t^{2}},$$

in which log p represents the logarithm of the pressure of vapour at saturation; t, the absolute temperature; a, b, c, three constants, to be determined from three experimental data for each fluid. When the pressure is expressed in inches of mercury, and the temperature in degrees of Fahrenheit, the values of these constants, for steam, are as follows:—

$$a=6{\cdot}426421;\ \log b=3{\cdot}4403816;\ \log c=5{\cdot}5932626.$$

The inverse formula, for calculating the temperature from the pressure, is—

$$\frac{1}{t_{\prime}}=\sqrt{\frac{a-\log p}{c}+\frac{b^{2}}{4c^{2}}}-\frac{b}{2c};$$

in which $\frac{b}{2c}=0{\cdot}0035163$, $\frac{b^{2}}{4c^{2}}=0{\cdot}000012364$.

The operations of this formula are considerable, but in point of accuracy it is generally very satisfactory. Extending from $-22°$ to 446° of Fahrenheit's scale, it is the most exact of all the formulæ hitherto proposed for the same width of range. It is, however, much more tedious, especially in the inverse form, and is at least not more exact than Mr Buchanan's formula, between the same limits.

Constituent Heat of Saturated Steam.

CHAP. VII.—CONSTITUENT HEAT OF SATURATED STEAM.

The relation of the sensible temperature, measured by the thermometer, and the pressure of saturated steam, having been approximately determined and formulated, the next stage of the inquiry is the relation which the sensible temperature bears to the total heat of saturated steam. The total heat of steam comprises the latent heat, in addition to the sensible heat or temperature; that which is not directly measurable by the thermometer, and therefore called latent, together with that which is directly sensible to, and measurable by it. The total heat of steam would appear, at first sight, to be in some way related to, if not identical with, total or absolute temperature. The latter is, however, a speculative quantity, employed in the consideration of gaseous bodies, for the convenient expression of their known properties. The total heat of steam, according to the general acceptation, as defined by M. Regnault, is that quantity of heat which would be transferred to some other body in condensing the steam at the same temperature and pressure as those at which it was generated, and in cooling the condensed steam, or water, down to the freezing point. That is to say, conversely, if water be supplied at the freezing point of temperature, 0° centigrade, or 32° Fahrenheit, for evaporation into steam, the total quantity of heat applied to the water, and consumed in generating steam of any pressure and temperature from it, is said to be the total heat of the steam of the given pressure and temperature; and in general, whatever may be the actual temperature of the water from which the steam is generated, the total heat of the steam is reckoned from the freezing point. The adoption of the freezing-point as the zero for total heat, as well as for that of the sensible temperature in the case of the centigrade thermometer, is not done, of course, with any purpose of fixing an absolute datum for total constituent heat; but for convenience, being situated sufficiently low in the scale of temperature to underlie all the ordinary calculations about steam.

It was determined experimentally by Regnault, that the latent heat of saturated steam, at 0° C., was 606·5° C.; so that the latent heat of 1 lb. of steam, at 0° C., would raise the temperature of 606·5 lb. of cold water through 1°. The total heat of steam at 0° C. is the same as the latent heat, namely, 606·5° C.; and it was found that the total heat of saturated steam increased uniformly between the temperatures of 0° and 230° C., by ·305°, with each increment of 1° of temperature. The specific heat of ordinary steam is thus ·305°, that of water being $=1$. The total heat H of saturated steam of any temperature t, in centigrade degrees, is therefore expressed by the equation—

$$H=606{\cdot}5+{\cdot}305\,t.$$

From this equation it appears, that, whilst the sensible heat or temperature rises 1°, the total heat increases only ·305°, or less than a third of a degree. The latent heat

Constituent Heat of Saturated Steam.

must, therefore, necessarily be diminished as the temperature rises, other circumstances being the same, by as much as $\cdot 305°$ falls short of $1°$, or $1 - \cdot 305 = \cdot 695°$ for each degree of temperature; and the decreasing latent heat would be expressed by $606 \cdot 5° - \cdot 695° t$. There is one slight disturbing element, however,—the specific heat of water, which is not constant for all temperatures, but is slightly increased by a rise of temperature; and by as much as the specific heat of the water is increased, the latent heat of the steam is still further diminished, and the true rate of reduction is expressed by a higher fraction than $\cdot 695\, t$. In fact, if the specific heat of water, at temperatures between 0° and 30° C., be represented by an average of unity, it will be equal to 1·005 between 30° and 120°, and 1·013 between 120° and 190° C., or 374° Fahr. M. Regnault embodies this slight rate of increase in the formula, $C = 1 + \cdot 00004\ t + \cdot 0000009\ t^2$, in which C is the specific heat of water at any temperature t, that at 0° C., the freezing-point, being = 1. The introduction of this element into a general formula for the latent heat of steam, would complicate it too much for general use; and for present purposes, the equation employed by Clausius is preferred, namely,

$$L = 607 - \cdot 708\, t,$$

in which L is the latent heat due to the temperature t; and it may be noted that the co-efficient of t is slightly increased above that which would be due to a constant specific heat of water, as the deduction due to a slightly increasing specific heat. That the results afforded by the simpler equation are sufficiently near correctness, appears by the following comparative instances of its application, at different temperatures, by Fahrenheit's scale, as against the use of Regnault's correct but more complicated process:—

	100°	200°	212°	300°	400° F.
By Clausius,	L=1044·4	973·6	965·1	902·8	832
By Regnault,	L=1044·47	974	965·7	902·9	829·84

In estimating the latent heat of steam at 100° C., or 212° Fahr., Regnault found, that on account of the slight variation of the specific heat of water, 100·5 centigrade units, or 180·9 Fahrenheit units, of heat, were required to raise the unit of water from 0° to 100° C., or through 180° Fahr.; and he found that the total heat of steam, at 100° C., was 636·67° C. From this deduct 100·5°, and the difference, $636 \cdot 67 - 100 \cdot 5 = 536 \cdot 17°$ C., represents the true latent heat of steam at 100° C. But as, in the compilation of his tables, Regnault started with the integral number 637°, the latent heat of saturated steam, at 100° C., or 212° Fahr., is estimated by him at 536·5° C. = 965·7° Fahr.

To modify the formula for the total heat of steam, in terms of Fahrenheit degrees, $606 \cdot 5°\ C. \times 9 \div 5 = 1091 \cdot 7°$ Fahr., is the total heat at 32° Fahr.; and as t represents the indicated temperature, the total heat would be expressed by $1091 \cdot 7 + \cdot 305\ (t - 32)$, or, in a more general form, by $(1123 \cdot 7 - 32) + (\cdot 305t - 9 \cdot 76) = (1113 \cdot 94 - 32) + \cdot 305t$. The first element in this expression should be reduced to 1113·4, in order to produce exact conformity with the observed total heat at 212° Fahr., Regnault's starting-point; and the formula for the total heat, in terms of Fahrenheit degrees, becomes,

$$H = (1113 \cdot 4 - 32) + \cdot 305t;\ \text{or},$$
$$H = 1081 \cdot 4 + \cdot 305t.$$

By this equation, the total heat of steam generated at 212° Fahr. is equal to $1113 \cdot 4 - 32 + (\cdot 305 \times 212) = 1146°$ Fahr.; and this represents what would be consumption of heat in generating the steam, if the water were supplied at 32° Fahr. By means of the same form of equation, the total expenditure of heat consumed in raising steam from water supplied at ordinary temperatures may be calculated, by substituting for 32 in the formula, the initial temperature of the water supplied for evaporation, subject to an allowance, if deemed sufficiently important, for the slight increase of specific heat of the water of higher temperature. Thus, when the water is supplied at 62° Fahr., the average temperature of cold water, the extra specific heat may be neglected, and the heat expended in generating steam from the water is expressed by the equation,

$$H_1 = (1113 \cdot 4 - 62) + \cdot 305t;\ \text{or}$$
$$H_1 = 1051 \cdot 4 + \cdot 305t.$$

If, as in condensing engines, the water be supplied at, say 100° Fahr., the heat expended in generating steam from it, again neglecting the specific heat, is expressed as follows:—

$$H_2 = (1113 \cdot 4 - 100) + \cdot 305t;\ \text{or},$$
$$H_2 = 1013 \cdot 4 + \cdot 305t.$$

Again, if the water be supplied at a boiling temperature, 212° Fahr., the specific heat of the water at 212°, as already noted, would be ·9 unit, or degree, of heat in excess of that at 32°, and $212 + \cdot 9 = 212 \cdot 9°$ should be substituted. Hence, for an initial temperature of 212° Fahr., the expenditure of heat in generating steam would be

$$H_3 = (1113 \cdot 4 - 212 \cdot 9) + \cdot 305t;\ \text{or},$$
$$H_3 = 900 \cdot 5 + \cdot 305t.$$

To convert Clausius's formula for the latent heat of steam, namely, $L = 607 - \cdot 708t$, into Fahrenheit's measure, $607°\ C. \times 9 \div 5 = 1092 \cdot 6°$ Fahr., and for $t°$ C. substitute $(t - 32)$ Fahr., then $L = 1092 \cdot 6° - \cdot 708\ (t - 32)$ Fahr., or finally, by the Fahrenheit scale,

$$L = 1115 \cdot 2 - \cdot 708t.$$

It is convenient to bear in mind that the same figures which express in degrees the relations of the constituent heat of steam, as ratios simply, not as absolute quantities, express also positive values—in units of heat—when applied to 1 pound-weight of steam, in accordance with the definition of the heat-unit, or the thermal unit. Now, to trace the appropriation of all the heat which contributes to the formation of a pound of steam, in terms of thermal units, as well as of dynamic units or foot-pounds, take 1 pound of water at 32° Fahr., to be converted into saturated steam at 212°. The first instalment of heat is provided to elevate the temperature to 212°, through 180°; in other words, to increase the molecular velocity and slightly expand the liquid, which appropriates 180·9 units of heat, equivalent to $180 \cdot 9 \times 772 = 139655$ foot-pounds. Secondly, heat is absorbed in overcoming the molecular attraction, and separating the particles; that is, in the formation of steam, appropriating 892·8 units of heat = 689,242 foot-pounds. Thirdly, in repelling the incumbent pressure, whether of the atmosphere, or of the neighbouring steam; that is, to raise a load of 14·7 lb. per square inch, or 2116·8 lb. on a square foot, through a cubic space of 26·36 cubic feet, which is the volume of 1 pound of saturated steam: equal to 55,815 foot-pounds, or 72·3 units of heat. Strictly, there is the initial volume of the original pound of water to be deducted from this total volume; but it is relatively small, and need not be further considered. The second of the above proportions of heat is formed by subtracting the sum of the first and third, which are both arrived at by direct observation, from the total heat. The first is the sensible heat, and the second and third together constitute the latent heat. With respect to the third constituent proportion of heat, it is simply an expression of the necessary mechanical labour of disengaging 26·36 cubic feet of steam, and forcing its way into space against a pressure of 2116·8 lb. per square foot; and these quantities being multiplied together, and divided by 772, are equivalent to 72·3 units of heat.

The proportions of the heat expended in generating saturated steam at 212° Fahr., and at 14·7 lb. pressure per square inch, from water supplied at 32°, may be exhibited thus:—

Constituent Heat of Saturated Steam.

	Units of Heat.	Mechanical Equivalent in foot-pounds.
The Sensible Heat:—		
1. To raise the temperature of the water from 32° to 212°, through 180°,................................	180·9 or	139,655
The Latent Heat:—		
2. In the formation of steam,.........	892·8 „	689,242
3. In resisting the incumbent pressure of 14·7 lb. per square inch, or 2116·8 lb. per square foot ...	72·3 „	55,815
Latent heat	965·1 or	745,057
Total heat	1146·0 or	884,712

Supposing, however, that 1 lb. of water, at 32° Fahr., were injected into a vacuous space or vessel, having 26·36 cubic feet of capacity. If heat were applied to evaporate this water into steam of 212°, and 14·7 lb. per square inch pressure, so as to fill the whole space with saturated steam, the expenditure of heat would consist only of the sensible heat, to raise the temperature of the water 180·9 units, *plus* the latent heat for the formation of the steam, 892·8 units, = 1073·7 units, as in this case there would be no incumbent pressure to resist, and no extraneous work. But, again, let a second pound of water be injected into the same vessel, already full of steam, to be evaporated into steam of 14·7 lb. pressure per square inch, so that the vapour of the second pound of water must expel the first, a uniform pressure of 14·7 lb. per square inch being maintained within the vessel. The expenditure of heat in the generation of the second pound will be 72·3 units in excess of that required for the first pound, being the additional quantity required to repel the incumbent pressure; and the total expenditure will be 1146 units. The 72·3 units excess of heat expended on the second pound of steam disappears, or rather it does not appear as heat, but is transformed into the work of expelling the first pound of steam; and, after its production, the second pound contains just the same quantity of heat as the first, namely, 1073·7 units, which may be proved by condensing them both into water of 32° Fahr.

The latent heat of steam, then, is not, as is sometimes supposed, an expression of the total work or energy in the steam; but is the work expended in overcoming the attraction of the particles, forcing them asunder, together with the work expended in repelling the external pressure under which the steam is generated. As the temperature rises, the centrifugal velocity, or vibratory motion of the minute particles is accelerated, the liquid expands, and the attraction of the particles is consequently diminished. Hence that part of the latent heat, or work, expended in effecting an entire separation of the particles, diminishes as the temperature rises. When water is evaporated at a low temperature, it is obvious that the particles are held together by a greater force than if it were evaporated at a higher temperature, after heat has been expended in accelerating the velocity of the particles, and expanding the liquid; and less work is expended in effecting their separation. At high temperatures the particles are already in part separated; they have a less hold on each other, and consequently an entire separation is more easily completed at higher than at lower temperatures. On the contrary, the second, but inferior portion of latent heat expended in repelling the external resistance—the product of increasing pressure into diminishing volume—increases slowly as the temperature rises; but the increase in this respect is less than the decrease in respect of the chief duty of the latent heat. In this manner it is to be explained, that though the total constituent heat of steam slowly increases as the temperature rises, in consequence of the comparative rapidity with which the sensible heat increases, the latent heat slowly diminishes as the temperature is elevated.

CHAP. VIII.—THE DENSITY OF SATURATED STEAM.

Density of Saturated Steam.

On the principle of the mechanical equivalence of heat, according to which heat, and work or duty performed, are convertible into and representative of each other, the investigation of the properties of steam may be conveniently conducted in terms of one form of expression or the other —heat, or dynamic effect—as the nature of the experimental evidence may demand. The density of saturated steam is one of its properties which has not yet been accurately determined by direct experiment; nor, of course, has the relative volume, which is inversely as the density. The density of steam is expressed by the weight of a given constant volume—say one cubic foot; and the relative volume by the number of volumes of steam produced by one volume of water—hence called relative. The density and the relative volume are, however, most accurately determinable by means of the pressure, temperature, and latent heat of steam, all of which have been subjects of careful and comprehensive experiment. When steam is freely generated in contact with water in a boiler, the actual process of generation consists, first, in heating the water to the temperature due to the pressure under which the steam is generated; second, in the absorption of a large quantity of heat which becomes latent—not affecting the thermometer—and is replaced physically by a quantity of steam of the same temperature—the sensible heat of the water continuing sensible in the steam. It is properly argued, then, that the specific function of converting the water into steam, of changing a non-elastic into an elastic substance, of thus developing a reservoir of motive-power where none existed before, is performed by the latent heat; and that, inasmuch as the process is just the conversion or change of form, of heat into elastic force, the force or power so manifested is simply commensurate with the latent heat; and if the latent heat, the amount of which is known experimentally, be converted into foot-pounds, in terms of Joule's equivalent, it will constitute one side of an equation, which will show on the other side the dynamic expression of the relative temperature and pressure, which also are directly known by experiment.

Suppose 1 pound of water in contact with other water, to be converted into 1 pound of steam within a boiler, and that the process of heating and conversion be commenced at the bottom of the scale of absolute temperature, at 461° below zero Fahrenheit. Whether it be possible or not, it is at least conceivable that the whole of the given weight of water may be in a state of vapour at 1° absolute temperature, of extreme tenuity, indefinitely large in volume, and indefinitely low in pressure; let it be supposed that this 1 pound of steam occupies the entire capacity of the boiler, and let the temperature be raised to 2°; another portion of vapour would be generated, occupying part of the capacity of the boiler, and forcing the prior steam into smaller compass, and thus increasing its density. If the temperature be thus continually elevated by degrees, the particular pound of steam under consideration would be continually reduced into smaller bulk, and its density would be increased, and likewise the pressure. It may properly be conceived, therefore, to undergo a process of compression from its conception to maturity—the increments of pressure accumulating with the increments of density and pressure. Now, the work or dynamic force accumulated in the given pound of steam, in virtue of the successive compression to which it may be supposed to have been subjected, is the same in quantity for each degree of temperature:—it is equal, in fact, to the product of the final increment of pressure multiplied into the final volume of the steam. Or—regarding the problem in another way—a pound of water is converted into a pound of steam, generating and occupying a certain volume, and this volume is consummated with a

Density of Saturated Steam.

final increment of pressure for the final degree of temperature.

This final increment of pressure, then, represents, for this particular volume, one degree of temperature; and if multiplied into the volume, is an expression of the action for one degree of temperature. If further multiplied by the absolute temperature in degrees, the resulting product expresses the whole of the latent heat of evaporation inherent in the given weight of steam.

In strict argument, this mode of estimation, in terms of the whole volume of the steam, gives a result slightly in excess of the literal result, as the volume actually generated is not the whole final volume, but only the excess of this above the volume of the water from which it is generated.

To vary the form of the argument, suppose the final volume of the given pound-weight of steam to be erected into a vertical column on 1 square foot of base, the column would of course weigh 1 pound; and if the height be multiplied by the final increment of pressure in lbs. per square foot for one degree of temperature, the product would express the height of a vertical column of the steam on 1 square foot of base, equal in weight to the final increment of pressure. If the weight be again multiplied by the absolute temperature, the ultimate product will express the latent heat of 1 pound weight of steam in "feet of fall" of 1 pound, that is, foot-pounds; and, further, dividing by 772, Joule's equivalent, the quotient will be the equivalent value of the latent heat in units or degrees of Fahrenheit's scale.

This form of reasoning, no doubt, contains a principle of hypothetical origin, according to which the actual heat present in a substance is simply proportional to its temperature, measured from a certain point of absolute cold, and multiplied by a specific constant; and "although," as Professor Rankine observes, "existing experimental data may not be adequate to verify this principle precisely, they are still sufficient to prove, that it is near enough to the truth for all purposes connected with thermo-dynamic engines, and to afford a strong probability that it is an exact physical law."

Let g = the increment of pressure for the final degree of temperature in lbs. on the square foot; 772 foot-pounds = the mechanical equivalent of one unit of heat, or so much heat as would raise the temperature of 1 pound of cold water 1°; L = the latent heat of 1 pound of water in units, which is of course identical with the latent heat in degrees deduced from the temperature; T = the absolute temperature; V = the volume of 1 lb. of steam in cubic feet, and v the volume of the water from which it is generated; then $V-v$ = the volume generated, and the contemplated equation would be as follows:—

$$772L = Tg\,(V-v);$$

or, for simplicity, let the volume of the water be neglected, as it is not practically important, then the equation would be—

$$772L = TgV.$$

From this equation, it follows that the latent heat of one pound of steam is

$$L = \frac{TgV}{772} \text{ units of heat; or,}$$

$$L = TgV \text{ foot-pounds.}$$

Consequently, also, the latent heat l, of one cubic foot of steam, dividing the above quantities by V, is

$$l = \frac{Tg}{772} \text{ units of heat; or,}$$

$$l = Tg \text{ foot-pounds.}$$

The volume of 1 lb. of steam in cubic feet, L being expressed in units of heat, is

$$V = \frac{772\,L}{T\,g} \text{ cubic feet.}$$

As the weight of 1 cubic foot of cold water is 62·3 lbs., it follows that 62·3V is the volume, in cubic feet, of the steam generated from 1 cubic foot of water. If n be the relative volume, then $n = 62{\cdot}3V$, and $V = n \div 62{\cdot}3$; and, by substitution,

$$\frac{n}{62{\cdot}3} = \frac{772\,L}{Tg};$$

from which the relative volume of the steam is

$$n = \frac{772L}{Tg \div 62{\cdot}3};$$

also, conversely, the latent heat, in Fahrenheit degrees, in terms of the relative volume, is

$$L = \frac{nTg}{772 \times 62{\cdot}3}.$$

For illustration, let the temperature be raised from $211\frac{1}{2}$ to $212\frac{1}{2}$°, through one degree, the pressure will rise from 2094 lb. to 2136 lb. per square foot, making the increment of pressure $g = 42$ lb. per square foot. The mean temperature is 212°, and the absolute temperature $T = 461 + 212 = 673°$. The latent heat Tg in foot-pounds, of 1 cubic foot of steam at 212°, and a pressure of 14·7 lb. per square inch, or 2116·8 lb. per square foot, is, therefore, $673 \times 42 = 28{,}266$ foot-pounds. To determine next the value of V, the volume of 1 lb. of steam at 212°, and at atmospheric pressure, let the steam be gaseous, then, by the equation for gaseous steam (which will be afterwards explained), $V = 85{\cdot}4\,T \div P = 85{\cdot}4 \times 673 \div 2116{\cdot}8 = 27{\cdot}16$ cubic feet; and substituting numerical values, we have for the latent heat of 1 lb. of gaseous steam at 212°, and atmospheric pressure,

$$L = \frac{TgV}{772} = \frac{673 \times 42 \times 27{\cdot}16}{772} = 994{\cdot}4,$$

which is precisely the latent heat of gaseous steam at 212°, as deduced by Mr Brownlee, in terms of Regnault's constant for the specific heat of gaseous steam, namely, ·475.

According to the preceding equations, the volume of 1 lb. of saturated steam at 212°, is

$$V = \frac{772\,L}{Tg} = \frac{772 \times 965{\cdot}1}{673 \times 42} = 26{\cdot}36 \text{ cubic feet;}$$

and the relative volume of the same steam is

$$n = \frac{772 \times 965{\cdot}1}{673 \times 42 \div 62{\cdot}3} = 1642 \text{ volumes,}$$

which has been, but erroneously, considered to be 1700 volumes.

The density or weight of 1 cubic foot of saturated steam is readily deducible from the equation for the volume in cubic feet of 1 pound of steam, in which $V = 772L \div Tg$; as the weight of a cubic foot is simply the inverse of this equation. Thus, the density D, or the weight in pounds of 1 cubic foot $= \frac{1}{V}$, or

$$D = \frac{Tg}{772\,L}.$$

Mr James Brownlee has deduced a simple expression for the density of saturated steam in terms of the total pressure, thus—

$$D = \frac{p^{\cdot 941}}{330{\cdot}36}; \text{ or,}$$

$$\text{Log } D = {\cdot}941 \log p - 2{\cdot}519;$$

in which D is the weight of 1 cubic foot of steam, of the pressure p Fahr. The results presented by means of this formula are very accurate; they do not differ from those

Gaseous Steam.

obtained in terms of the temperature and latent heat of steam for pressures from 1 lb. to 250 lb. per square inch by more than $\frac{1}{7}$th per cent. The volume in cubic feet of 1 pound of saturated steam is of course expressed by the inverse of the weight in pounds of a cubic foot of the steam,

thus $V=\frac{1}{D}$, consequently

$$V=\frac{330{\cdot}36}{p^{\cdot 941}}\text{; or,}$$

$$\text{Log } V=2{\cdot}519-{\cdot}941 \log p.$$

Again, the relative volume of the steam is expressed by the ratio of 62·3 lb., the weight of a cubic foot of water, to D, the weight of a cubic foot of steam; hence, $62{\cdot}3 \div \frac{p^{\cdot 941}}{330{\cdot}36}=62{\cdot}3\times 330{\cdot}36\div p^{\cdot 941}$, = the relative volume. Putting n = the relative volume.

$$n=\frac{20559}{p^{\cdot 941}}\text{; or,}$$

$$\text{Log } n=4{\cdot}3135-({\cdot}941\times \log p);$$

from which it appears that the relative volume of saturated steam of 14·7 lb. pressure per square inch, and 212° temperature, is 1642, the same as was found before in terms of the temperature and latent heat.

CHAP. IX.—GASEOUS STEAM.

If ordinary or saturated steam be superheated or "surcharged" with heat, it advances from the state of saturation into that of gaseity. The transition into the gaseous state involves a considerable elevation of temperature, by amounts which increase with the pressures; and steam, when thus sufficiently elevated in temperature above the saturation-point due to its density, is known as gaseous steam, distinctively from ordinary, or, as it may be called, imperfectly gaseous steam.

Regnault found, throughout the whole range of his observations, that the specific density of gaseous steam at all temperatures was ·622; that is to say, the weights of equal volumes of air and sufficiently superheated or gaseous steam, having the same pressures and temperatures, were as 1 to ·622, and that therefore the steam so treated was gaseous, as, the specific density being constant, the air and the gaseous steam, when taken at the same temperature, must expand alike when equally raised in temperature.

Confirmatory of Regnault's specific density of gaseous steam, the chemical union of oxygen and hydrogen, in the proportions to form steam, may be referred to. Two cubic feet of hydrogen and one of oxygen combining, will form two cubic feet of gaseous steam at the same temperature. The specific density of hydrogen is = ·06926, and that of oxygen = 1·10563, and the density of the product is in the combined ratio of the densities and the uniting volumes.

Hydrogen, 2 volumes,	× ·06926	=	·13852
Oxygen, 1 do.	× 1·10563	=	1·10563
Gaseous steam, 2 volumes..........			1·24415 ÷ 2
Specific density......................		=	·622

being the same as was determined by Regnault from direct observation.

In accordance with the relations of perfect gases, the weight of a cubic foot of air, expressive of the density, D, at any pressure per square inch, p, and temperature, $t°$, Fahrenheit, is expressed by the equation,

$$D=\frac{144\,p}{53{\cdot}15\,(t+461)},$$

in which $144\,p$ expresses the pressure per square foot, $t+461$ the absolute temperature, and 53·15 a constant determined for air. The same form will express the weight of steam by a modification of the constant in terms of the specific density; thus, for gaseous steam, $53{\cdot}15\div{\cdot}622=85{\cdot}4$ is the appropriate constant, and the weight of a cubic foot of gaseous steam is expressed by the equation,

Gaseous Steam.

$$D=\frac{144\,p}{85{\cdot}4\,(t+461)}=\frac{P}{85{\cdot}4\,T},$$

in which $P=144\,p$, and $T=t+461$.

As the pressure, volume, and temperature of gaseous steam, and other gases, vary with each other in simple ratios—the pressure and the volume inversely with each other, and both of them directly with the absolute temperature—their mutual relation for any given constant weight of gas is such, that the pressure multiplied by the volume is equal to the absolute temperature multiplied by a constant number. For gaseous steam, as the weight in pounds of 1 cubic foot is equal to $P\div 85{\cdot}4\,T$; then, conversely, the volume in cubic feet of 1 pound of steam is $85{\cdot}4T\div P$, and, generally, $PV=85{\cdot}4T$, for gaseous steam. For air, and a few other gases, the following are the general equations for a given weight, 1 pound of gas:—

Constants for One Pound Weight of Gas.

		Specific Density.
Air........................	PV = T × 53.15	1·000
Gaseous steam.........	PV = T × 85·4	·622
Oxygen gas	PV = T × 48·07	1·106
Hydrogen gas	PV = T × 767·4	·069
Sulphuric ether	PV = T × 20·8	2·556
Alcohol..................	PV = T × 33·45	1·589
Chloroform..............	PV = T × 10 0	5·300

In order to find the total heat of steam, it may be observed, that from some experiments made by Regnault, it appeared that ordinary steam is nearly gaseous at temperatures below 60° Fahr. Mr Brownlee has adopted a fundamental temperature of 40° Fahr. as that at which the saturated and the gaseous steams become identical in constitution. For gaseous steam, Regnault found the specific heat to be ·475°: that is, that the total heat of gaseous steam increases uniformly ·475° for each degree of sensible temperature; and it follows that an equation on the model of that for saturated steam may be found to express the total heat of gaseous steam. Proceeding on this basis, Mr Brownlee finds, by the formula for saturated steam, that the total heat of steam at 40° Fahr., and at the pressure due to saturation, is $1113{\cdot}4-32+({\cdot}305\times 40)=1093{\cdot}6°$ F.; and he substitutes for ·305 the gaseous constant ·475, and adjusts also the first quantity in the expression, reducing it to 1106·6,—by as much, in fact, as the constant ·475 adds to the first side of the equation. The expression, then, becomes $1106{\cdot}6-32+({\cdot}475\times 40)=1093{\cdot}6°$ F., showing the same total heat, 1093·6° Fahr., regarded as gaseous steam, as was found by the formula appropriate for saturated steam. The general formula for the total heat of gaseous steam, putting t for the temperature in Fahrenheit degrees, is, then,

$$H=1106{\cdot}6-32+{\cdot}475t\text{; or,}$$

$$H=1074{\cdot}6+{\cdot}475t.$$

To raise the temperature of the vapour generated at 40° to 212° through 172°, the pressure remaining the same, the additional heat is measured by ${\cdot}475\times 172=81{\cdot}7°$, and $1093{\cdot}6+81{\cdot}7=1175{\cdot}3°$, the total heat. Or, employing the above equation in the calculation, ${\cdot}475\times 212=100{\cdot}7$, and $H=1074{\cdot}6+100{\cdot}7=1175{\cdot}3°$, as before.

As already shown for saturated steam, the foregoing equation for the total heat of gaseous steam may be employed to find the actual expenditure of heat in raising gaseous steam from water of any temperature higher than 32° Fahr. The latent heat of this steam may be estimated from the total heat by deducting 180·9°, the heat necessary to raise the temperature of water from 32° to 212°; thus, $1175{\cdot}3-180{\cdot}9=994{\cdot}4°$, is the latent heat of any gaseous steam at 212°.

Table of the Properties of Saturated Steam.

As for saturated steam, so also for gaseous steam, the latent heat diminishes as the temperature rises, but not so rapidly in the latter as in the former, as the specific heat is greater; that is to say, the increment of total heat, ·475°, for each degree of sensible temperature of gaseous steam, is greater than the increment, ·305°, for saturated steam; and therefore the difference, 1 – ·475 = ·525°, being the reduction of latent heat for each degree of temperature for gaseous steam, is less than the difference, 1 – ·305 = ·695°, for saturated steam.

The actual expenditure of heat in generating gaseous steam from water of higher temperature than 32° Fahr., may be found by substituting the temperature for 32 in the last formula; as follows, for the common temperature 62° Fahr.:—

$$H_1 = 1106{\cdot}6 - 62 + {\cdot}475t;\ \text{or,}$$
$$H_1 = 1044{\cdot}6 + {\cdot}475t.$$

For a temperature of 100° Fahr. the formula is—

$$H_2 = 1106{\cdot}6 - 100 + {\cdot}475t;\ \text{or,}$$
$$H_2 = 1006{\cdot}6 + {\cdot}475t.$$

For a temperature of 212°, with the specific heat of water 212·9°, the formula is—

$$H_3 = 1106{\cdot}6 - 212{\cdot}9 + {\cdot}475t;\ \text{or,}$$
$$H_3 = 893{\cdot}7 + {\cdot}475t.$$

Table of the Properties of Saturated Steam.

TABLE OF THE PROPERTIES OF SATURATED STEAM.

The appended table of the properties of saturated steam has been calculated by means of the formulas in this article. The first column contains the ascending total pressures in pounds per square inch. The second column, of temperatures, was calculated from the pressures by the formula—

$$t = \frac{2938{\cdot}16}{6{\cdot}1993544 - \log. p} - 371{\cdot}85;$$

the third column, of total heat, was calculated by the formula $H = 1081{\cdot}4 + {\cdot}305\,t$; the fourth column, of latent heat, by the formula $L = 1115{\cdot}2 - {\cdot}708\,t$; the fifth column, of density, by the formula $\text{Log } D = {\cdot}941 \log. p - 2{\cdot}519$; the sixth column, of the volume of 1 lb. of steam, by the formula $\text{Log } V = 2{\cdot}519 - {\cdot}941 \log. p$; and the seventh column, of relative volume, by the formula $\text{Log } n = 4{\cdot}3135 - ({\cdot}941 \times \log p.)$

Table of the Properties of Saturated Steam.

Total pressure per square inch.	Temperature in Fahrenheit degrees.	Total Heat in Fahrenheit degrees from 32 degrees.	Latent Heat. Fahrenheit degrees.	Density or weight of one cubic foot.	Volume of one pound of Steam.	Relation Volume, or cubic feet of Steam from one cubic foot of Water.	Total pressure per square inch.	Temperature in Fahrenheit degrees.	Total Heat in Fahrenheit degrees from 32 degrees.	Latent Heat. Fahrenheit degrees.	Density or weight of one cubic foot.	Volume of one pound of Steam.	Relation Volume, or cubic feet of Steam from one cubic foot of Water.

Mr William Fairbairn and Mr Thomas Tate read a paper at the meeting of the British Association for the advancement of science in September 1859, containing some approximate results of experiments undertaken by them, for the purpose of determining the law of the density of steam and other condensable vapours, and of testing the deductions from the dynamic theory of heat of Professor Rankine and others, with respect to that subject. The new feature of the experiments consists in the use of the "saturation-guage," to aid in determining with precision the point of saturation of steam. Suppose two globes, called A and B, to be connected by a syphon tube, containing mercury, and the whole to be immersed in a bath, in which they can be raised to any required temperature. If an absolute vacuum be created in each globe, and 20 grains of water be introduced into A, and 30 or 40 grains into B; then, if the temperature be slowly and uniformly raised around the globes, the water within them will be gradually evaporated, and filled with steam of a density increasing with the temperature, until the whole of the water in A is converted into steam, when instantly the line of the mercury, heretofore undisturbed, will rise towards the globe A. The disturbance of level thus occasioned constitutes the saturation-test; it is caused by the change of the steam in A, from the condition of saturation to that of superheating, whilst that in B, which contains a surplus of water, must necessarily continue in the state of saturation, and there is no longer an equilibrium of pressure. The volume of the steam in A is known, and the temperature in the bath at the instant of the disturbance of the mercury is that of saturation. The following is a selection of temperatures and relative volumes of saturated steam approximately reduced from the experiments, with the corresponding volumes reckoned from the foregoing table of the properties of saturated steam:—

Temperature.	Relative Volume by Experiment.	Relative Volume by the Formula.	Difference by Experiment.
244°	896	935	−39
245	890	917	−27
257	751	753	− 2
262	684	695	−11
268	633	632	+ 1
270	604	613	− 9
283	490	504	−14

The nearness of the experimental results to those theoretically established is very remarkable. The differences, as Professor Rankine suggests, may arise from a difference in the value assumed for the volume of water.

The reader is referred to the end of the article STEAM-ENGINE for a list of references to works on steam. The first chapter of this article, it should be stated, is abridged from the article on STEAM in the previous edition of the *Encyclopædia Britannica*. (D. K. C.)

STEAM-ENGINE.

PART I.—HISTORY AND DESCRIPTIVE ACCOUNT OF THE STEAM-ENGINE.

SECTION I.

History and Descriptive Account.

It appears highly probable that the ancients knew more of the phenomena of steam than has been generally admitted; and one evident cause of this mistake is, that no specific term equivalent to the word steam was generally used by them; and water, when heated, was said to be converted into air. Hero of Alexandria, in his *Pneumatics*, written more than 120 years before the Christian era, collected the science and inventions of the ancients, along with some of his own, into a systematic treatise. His book commences with a lucid dissertation on the properties of air as a medium for the communication of pressure and motion, and especially upon the nature and effects of a vacuum, subjects to be thoroughly understood by all who would master the theory of the steam-engine.

The following description of the manner in which the force of steam issuing from a boiler may be applied to support a weight is given in the *Pneumatics*:—"A boiler (fig. 1) perforated on the top is placed on the fire. From the perforation there proceeds a tube on whose extremity is fixed a hollow hemisphere perforated in like manner. If then we place a light ball in the hemispherical cup, it will follow that the vapour rising up from the boiler through the tube will support the sphere, and it will appear to dance."

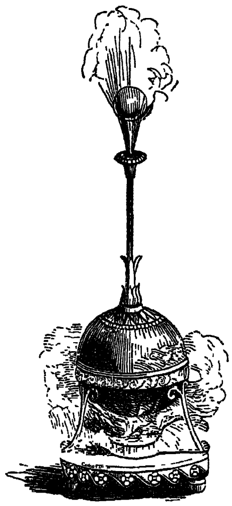

Fig. 1.

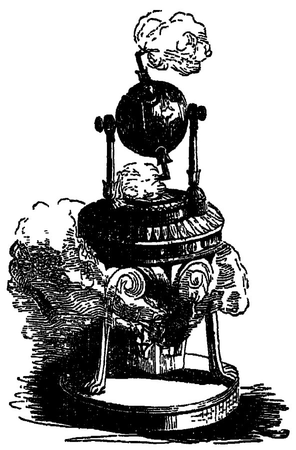

Fig. 2.

There is another apparatus in the *Pneumatics* for producing a revolving motion by the action of steam from a boiler, issuing through a couple of bent arms, from orifices at their extremities (fig. 2); the arms being free to revolve horizontally, do so in obedience to the action of the escaping jets of steam.

The same apparatus, on similar principles, is next applied by Hero to the construction of a machine still more curious. The agent mentioned in this case is rarified air, although the action is of precisely the same nature. Here the science of the philosopher appears to have been degraded to assist the priesthood in deceiving the populace by the resemblance of miraculous interference. "A fire having been kindled upon an altar, living figures will appear to lead a choral dance, even although the altar itself be of transparent glass or horn. Through the epipyrus a pipe is to be let down to the base of the altar, where it is to revolve on an iron pin, the other end being passed through a tubular fitting attached to the epipyrus. And this pipe is to have other little cross-pipes attached to it, and perforated (fig. 3), so as to communicate with it (which

History and Descriptive Account.

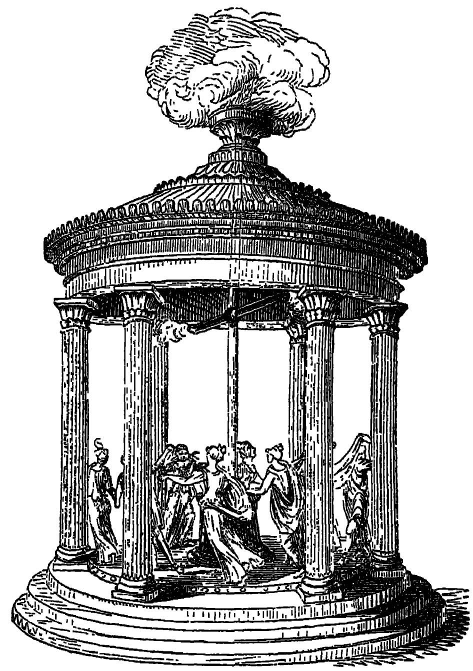

Fig. 3.

are to radiate opposite to one another around it), and turned alternately in opposite directions in the ends. There shall likewise be a drum attached to it, upon which the figures of the dance are to be set. Then by the action of the kindled fire, the air, being warmed, will proceed into the pipe, and from its being driven out through the bent tubes in the base of the altar, will turn round the pipe and its drum."

There is considerable reason to suppose that, to their knowledge of the elements of machinery, the Egyptians added some acquaintance with the power of steam, applied however, only to the degraded service of superstition. The statue of Memnon is said to have emitted sounds which Pausanias compares to those produced by the snapping of the strings of a harp. Strabo expressly states that he heard them; and Philostratus states, that when the sun shone strongly on the statue, sounds issued from its mouth similar to those of a stringed instrument.

The Romans appear to have done little for the mechanical arts, and nothing for the improvement of steam apparatus. It was not until the dawn of knowledge succeeded the darkness of the middle ages, that the light reflected from the works of Hero and the older mechanicians, rekindled the flame of mechanical invention. The works of Archimedes and of Hero were read with great avidity, and formed some of the most popular productions of the young art of printing.

Giambattista Della Porta, an Italian, was one of the ablest expositors of the principles of pneumatics. In his work published at Naples in 1601, he describes a beautiful and simple expedient designed for determining the philosophical question, How much aqueous vapour is formed by a given quantity of water? And it shows an acquaintance with the fact, that water heated by fire is converted into

History and Descriptive Account.

aqueous air, with sufficient force to raise water above its level and form a running stream.

Salomon de Caus, a French engineer, published at Frankfort, in 1615, some account of his works, constructed for the gratification of "gentille curiosité," in which he states that the violence with which water is dissolved into air by means of fire is very great, and that a ball of copper containing water, if placed in a fire, would certainly burst. He afterwards shows how a jet of water may be made to rise above its level, and play in the air by means of fire; a copper ball A (fig. 4) has an orifice D, at which water is poured in, and it is then closed with a stop-cock. Another tube BC is closely fitted to the same ball, but passes down near to the bottom, where it is open in the water: the pipe terminates above in an orifice for a small jet of water, which is regulated by a stop-cock. In fact, the apparatus is precisely that which Hero uses for raising a jet of water, but without the aid of heat, when he forces air above the water, till it raises a jet of water by its pressure. Of course the heat produces the same elastic force in De Caus's machine as the compression of air does in Hero.

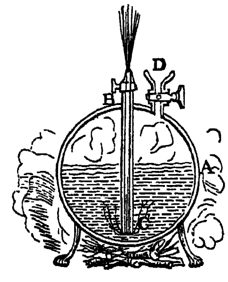

Fig. 4.

The direct emission of steam from an orifice of the boiler, which had been used by Hero to sustain the ball in the air, was applied by Branca, an Italian architect and engineer, to impress a revolving motion on the vanes of a wheel like a common mill-wheel, and this communicating with a series of toothed wheels gave motion to a series of pestles in mortars. This and many other machines were published by him at Rome in 1629. This period appears to have teemed with curiosities of mechanical invention:—Perpetual motions were very common; wings for enabling men to fly in the air, mechanical chariots for a similar purpose, conveyances to the moon, and engines for making continual and cheap music by mills or by fire, for rocking of cradles and turning of spits, were favourite subjects of design; and many of these curious contrivances, without serving any definite purpose, form elegant and curious pieces of apparatus.

The Marquis of Worcester invented and constructed the first actual steam-engine, announced in the *Century of Inventions* in 1663; none of the contrivances before his time were provided with means to make their action continuous. The instrument of De Caus had merely the power of emptying itself of the boiling-water with which it was filled; the engine of Worcester was provided with two vessels to act successively and continuously, in raising water. "Having found a way to make my vessels so that they are straightened by the force within them, and the one to fill after the other, I have seen the water run like a constant fountain, 40 feet high. One vessel of water rarified by fire driveth up 40 of cold water; and a man that attends the work is but to turn two cocks, that one vessel of water being consumed, another begins to force and refill with cold water, and so successively." The Marquis enumerates many important practical uses to which his engine might be applied, and many of them it certainly would have been competent to compass. Lord Worcester's "Water-commanding Engine" was the first machine moved by fire of efficacy and permanence: he actually erected one of his engines of about 2-horse power on the banks of the Thames, at Vauxhall, and it was employed in supplying the town with water. Not that any great merit is to be attached even to that contrivance, for it is deducible without any violent stretch of the imagination from the schemes of Hero; and there is no doubt, as Mr Bourne suggests, that the ancients would have realized an effectual steam-engine, if they only had possessed mines that required to be drained, and coal to bestow on such a purpose.

The next forward step of invention was the accomplishment of a vacuum by the agency of steam, by Captain Thomas Savery, who exhibited a model of his engine to the Royal Society in 1669. The Marquis's engine appears to have been placed on or below the level of the water to be raised, and, his vessels being filled, their contents were raised by the elastic force only of the steam; Savery, on the other hand, erected his engine at a height of nearly 30 feet above the level of the water. A large close vessel was filled with steam; this steam was reconverted, by cooling the outside of the vessel, into water, leaving the large space it had formerly occupied vacuous; into this vacuum water was raised, as into the vacuum of a common sucking-pump, by atmospheric pressure, and so within the limit of atmospheric pressure, raised 28 or 30 feet. After this was accomplished, the water was further raised by the elastic force of the steam, just as in the engine of the Marquis of Worcester. But the improvement was great, and led to the general use of steam as a means of raising water. Fig. 5 represents this engine as applied to draw water from deep mines. It is placed under ground, on a platform from 20 to 30 feet above the level of the water at A. The chimney ascends in the shaft of the mine along with a pipe, through which the water is forced to the surface. The engine consisted of two boilers, in which the necessary steam was generated, and two receivers with valves. The process of pumping was effected by admitting steam into one of the receivers *a*, and then cutting off the connection with the boiler. The steam was suddenly condensed by means of a jet of cold water, which, forming a vacuum, the water to be lifted rushed up the pipe *b*, to refill the receiver. Steam was then admitted from the boiler to press upon the water in the receiver, and all connection with *b* being cut off by a valve, the water was forced up the pipe *c*, and discharged into the trough *d*. The steam in the receiver *a*, being again condensed, the process was repeated; and thus by the alternate action of two receivers, a continuous stream was maintained.

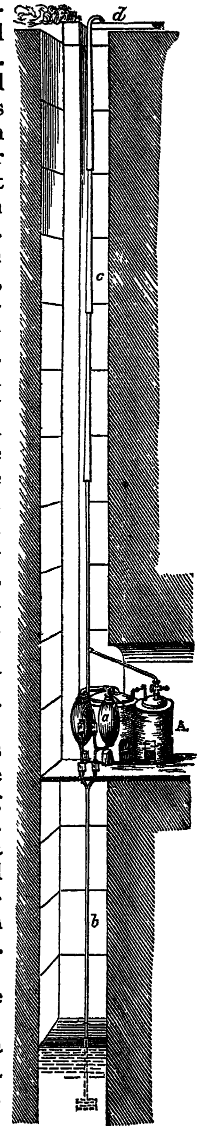

Fig. 5.

One of the first uses of Savery's engine, proposed by himself, was to raise water to fall on a mill-wheel, turning machinery as by a common fall of water. Several engines were erected by a Mr Joshua Rigley at Manchester, and throughout Lancashire, to impel the machinery of some of the earliest cotton mills and manufactories of the district. One was erected at St Pancras, London, at the manufactory of a Mr Kier, where it long continued to turn lathes, &c.

Dr Denis Papin, in 1690, proposed a scheme for producing a vacuum under a piston,—first of all by gunpowder, and afterwards by steam. He had a cylinder A B C D (fig. 6), containing a piston P, below which he placed a fire, and so as to generate steam from a little water in the bottom of the cylinder. This steam raised the piston, which was secured in its elevated position by a catch; then the fire was removed, the steam

condensed, and the piston was released and forced down by the pressure of the atmosphere. This plan, though crude, contained the earliest suggestion of a vacuum under a piston by the agency of steam.

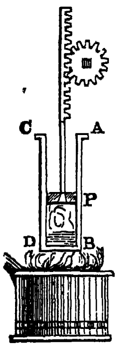

Fig. 6.

But Papin halted there. His proposed modes of procuring a vacuum by removing the fire was a step in retrogression from Savery's practice, which was to pour water over the receiver, and operate by surface condensation. In Savery's engine, however, there was the waste of steam consumed in re-heating the receivers and the upper stratum of water, every time it was admitted for the purpose of forcing up the water. It was reserved for Newcomen and Cawley of Dartford to combine the good points of Savery and Papin:—a separate boiler and furnace, and a separate cylinder and piston, with a distinct water-pump connected with the piston through the medium of a beam; a means of rapid condensation by injecting water into the cylinder in direct contact with the steam to be condensed, and a system of self-acting valves, which were opened and closed by the reciprocations of the beam, without the usual agency of an attendant. The history of the discovery of the two last-named features is thus concisely given by Dr Desaguliers:—"They were surprised to see the engine go several strokes and very quick together, when after a search they found a hole in the piston which let the cold water in to condense the steam in the inside of the cylinder, whereas before they had always done it on the outside. They used before to work with a buoy in the cylinder enclosed in a pipe, which buoy rose when the steam was strong, and opened the injection-pipe and made a stroke, whereby they were capable of only giving six, eight, or ten strokes in a minute, till a boy named Humphrey Potter, who attended the engine, added what he called a *scoggan*, by which the beam of the engine always opened and shut its own valves, and then it would go (entirely without the attendance of a man) fifteen or sixteen strokes in a minute. But this being perplexed with catches and strings, Mr Henry Beighton, in an engine he had built at Newcastle-on-Tyne in 1788, took them all away, the beam itself supplying all much better." Thus, for more than half a century, the engine remained in general use without any material change.

Newcomen, Potter, and Beighton had rendered the atmospheric steam-engine an independent self-acting mechanical power of so great perfection in its principle of action, and its minor details, as to be very generally introduced as a substitute for the power of animals in draining mines and collieries, and to confer very great advantages in those important and primary sources of national industry and wealth. The saving of money from this change was so great as to be continually opening up new avenues of mining enterprize, by the rapid progress of which the capabilities of the engine were soon put to the severest trial. The cylinders, which had been originally of 12 and 16 inches diameter, were gradually increased to 60 inches. Along with this dimension, the other parts required to be increased in a still higher proportion; and at last the structure became so gigantic as to demand an amount of science and practical skill which was rare in that period. The man suited to the emergency at last arose in the father of civil engineering, the justly celebrated Smeaton, who brought to bear on this subject endowments and accomplishments seldom united. He conferred upon the atmospheric steam-engine all the extent and variety of application of which it was capable, and all the perfection of proportion and execution which the state of the mechanical arts could then afford. The most magnificent of Smeaton's works in this department is his great Chasewater engine, of which the details are also given in his reports, and which abound in ingenious contrivances and judicious arrangement. This engine was of 150 horse-power, turning out 880 hogsheads of water per hour, by the heat of $16\frac{1}{2}$ bushels of coal. The cylinder A B, fig. 7, is 72 inches in diameter, the stroke 10 feet 6 inches. The great lever or beam of the engine D D consists of twenty large bulks of timber, the four nearest the centre being each a foot square, and the whole firmly joggled together with heart of oak, and bolted with iron, forming a very elegant but ponderous beam. The beams F F upon which the cylinder rests are kept in their place by being entered into the side-walls of the house, and are joggled and framed together similarly to the great lever; G is the boiler, H the furnace, I B the steam-pipe, J the injection-pipe, K the injection cistern, fed by a pump L, which is wrought by the great lever, M the waste-pipe for the condensed steam. On the left edge of the figure is the spear or rod of the great

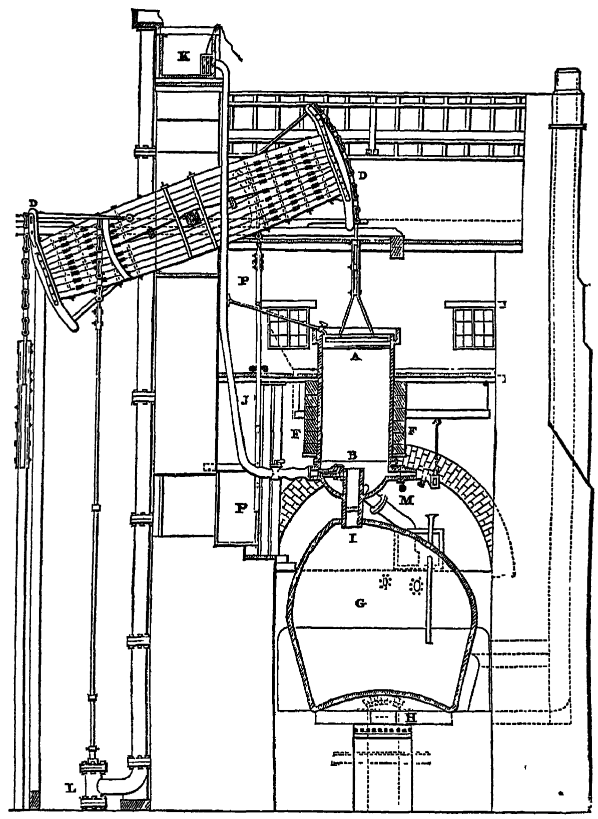

Fig. 7.

draining-pump, wrought by the engine; P P is the plug-tree, suspended from the main beam and carrying plugs, which in their upward and downward progress act on the levers which open and shut the regulator and injection-cocks. The date of this engine is 1775. Its working gear, which is very simple and good, is represented on a larger scale in fig. 8, for those who are conscientious enough to study it.

A collateral scintillation of invention was exhibited by Jacob Leupold in 1725, who inverted the ordinary Newcomen's engine, causing the engine to do its work against the atmosphere. He introduced comparatively high pressure steam below a piston, and raised it against the pressure of the atmosphere, plus the active resistance of the column of water forced up by a pump. His machine (figs. 9 and 10) was a true water-pumping high-pressure steam-engine, and might be efficiently used without any alteration at the present day, only the modern machines do the work with less fuel. Two pumps T V for raising water are directly worked by steam by connecting the handles G H of these

pumps with the pistons of two high-pressure cylinders C D in such a manner that, when the pistons are raised by the

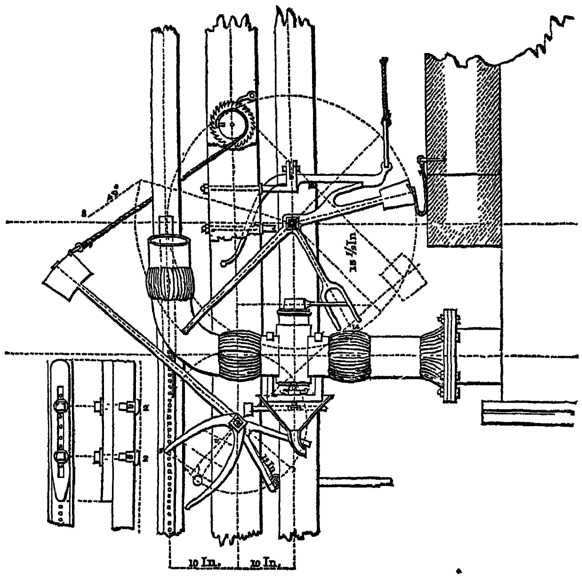

Fig. 8.

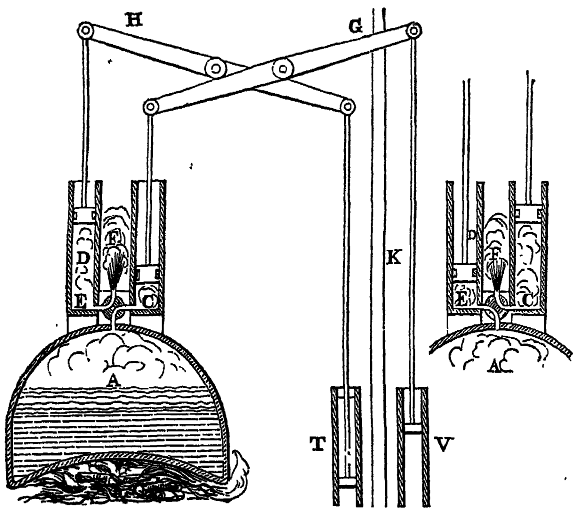
steam, the water is forced up in the pump-pipe K. In fig. 9, at A C, the steam is entering the cylinder C, and push-



Figs. 9 and 10.

ing up the end of the lever G, so as to force the water; and in fig. 10 the steam is shown entering the cylinder D to work it. This change is effected by turning round the disc A F into the position which reverses the passages. Thus, while the steam is entering the cylinder C (fig. 9) through A C, the steam from the cylinder D is escaping through E F into the open air; and in fig. 10 the steam is passing into the cylinder D through A E, and out of the cylinder C through C F. The action of this four-way stop-cock is very simple and beautiful, and deserves to be carefully studied. By continually turning it in one direction, communications are simultaneously effected between the boiler and each of the cylinders alternately, and between each cylinder and the open air.

Hitherto the fire-engine, even in Smeaton's hands, was so imperfect, that it wasted a large quantity of fuel and of steam in doing what was useless, viz., heating the cylinder, which was cooled alternately in each stroke by the cold water injected into it. In Long Benton colliery engine, out of 63 cubic feet of steam 32 were thus wasted, and the remaining 31 feet alone performed useful work. There remained, therefore, one-half of the power of the steam and expense of the fuel to be saved by future improvements, provided the useless heating and cooling of the cylinder could be avoided. The vacuum formed below the cylinder was also far from being perfect. In this state James Watt found the atmospheric fire-engine in the hands of Smeaton, and produced from it the pure steam-engine, which he left to us in its present state of high improvement. He was the man who turned the scale of expense in favour of the fire-engine, when it was a more costly power than horses, except when fuel was extremely cheap. In his hands it ceased to be an atmospheric engine, and became wholly a steam-engine, capable of being applied to any purpose, on a much larger scale, and at much less expense than the power of horses. He reflected that, "in order to make the best use of the steam, it was necessary, first, that the cylinder should be maintained always as hot as the steam which entered it; and secondly, that when the steam was condensed, the water of which it was composed, and the injection itself, should be cooled down to 100°, or lower where that was possible." The means of accomplishing these objects occurred to Mr Watt in 1765:—The separate condenser, distinct from but in connection with the steam-cylinder, into which the steam from the cylinder would flow, and in which all the operations of condensation could be performed by surrounding it with cold water, or by injection, or both. The water which would necessarily accumulate in the condenser, Mr Watt proposed to remove by means of a pump. "It next occurred to me," says Mr Watt, "that the mouth of the cylinder, being open, the air which entered to act on the piston would cool the cylinder, and condense some steam on again filling it. I therefore proposed to put an air-tight cover upon the cylinder, with a hole and stuffing-box for the piston rod to slide through, and to admit steam above the piston to act upon it instead of the atmosphere. There still remained another source of the destruction of steam, the cooling of the cylinder by the external air, which would produce an internal condensation whenever steam entered it, and which would be repeated every stroke. This I proposed to remedy by an external cylinder containing steam, surrounded by another of wood, or of some other substance which would conduct heat slowly.

"When once the idea of the separate condensation was started, all these improvements followed as corollaries in quick succession; so that, in the course of one or two days, the invention was thus far complete in my mind, and I immediately set about an experiment to verify it practically. I took a large brass syringe A, $1\frac{3}{4}$ inches diameter and 10 inches long, made a cover and bottom to it of tin-plate, with a pipe S to convey steam to both ends of the cylinder from the boiler; another pipe E to convey steam from the upper end to the condenser (for to save apparatus I inverted the cylinder). I drilled a hole longitudinally through the axis of the stem of P the piston, and fixed a valve at its lower end, to permit the water which was produced by the condensed steam on first filling the cylinder to issue. The condenser used upon this occasion consisted of two pipes *a b*, *c d* of thin tin-plate, 10 or 12 inches long and about $\frac{1}{6}$th-inch diameter, standing perpendicular and communicating at top with a short horizontal pipe *h* of large diameter, having an aperture on its upper side which was shut by a valve opening upwards. These pipes were joined at bottom to another perpendicular pipe *p* of about an inch diameter, which served for the air and water pump, and both the condensing pipes and the air-pump were placed in a small cistern C filled with cold water.

"The steam-pipe was adjusted to a small boiler B.

When steam was produced it was admitted into the cylinder, and soon issued through the perforation of the

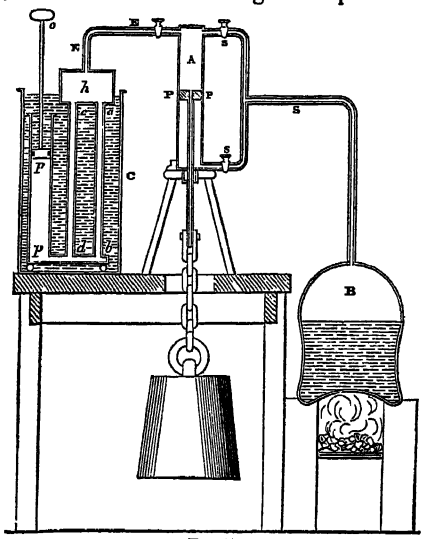


Fig. 11.

rod, and at the valve of the condenser. When it was judged that the air was expelled, the steam-cock was shut, and the air-pump piston-rod was drawn up, which leaving the small pipes of the condenser in a state of vacuum, the steam entered them and was condensed. The piston of the cylinder immediately arose, and lifted a weight of about 18 lbs. which was hung to the lower end of the piston-rod. The exhaustion-cock was shut, the steam was re-admitted into the cylinder, and the operation was repeated; the quantity of steam consumed, and the weights it could raise were observed; and excepting the non-application of the steam case and external covering, the invention was complete in so far as regarded the savings of steam and fuel. A large model with an outer cylinder and wooden case (fig. 12) was immediately constructed, and the experiments made with it served to verify the expectations I had formed, and to place the advantage of the invention beyond the reach of doubt." Mr Watt patented his inventions in the steam-engine in 1768.

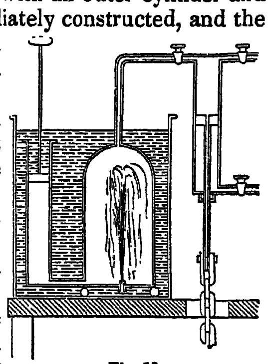

Fig. 12.

In recapitulation, it appears that the invention of the steam-engine as a useful and permanent machine originated with the Marquis of Worcester, that he employed high-pressed steam in close vessels pressing directly upon water contained in them, and forcing it to considerable elevations above the level of the engine. Second, Captain Savery created a vacuum within the vessels by means of cold water applied externally, so as to lift the water from below the level of the engine, as well as to force it above the level. Third, Papin proposed the use of a cylinder and piston separate and distinct from but connected with the work to be done, but showed no practicable application of the proposal. Fourth, Newcomen and Cawley successfully embodied Papin's idea of the independent cylinder and piston connected by a beam to the pumps for raising water, and they greatly accelerated the action and increased the efficiency of the machine by internal condensation, or the injection of cold water within the cylinder. Fifth, James Watt added the separate condenser—a chamber distinct from but auxiliary to the working cylinder, in which internal condensation was effected without necessarily cooling the cylinder and wasting steam in re-heating it, which was unavoidable in Newcomen's engine. We have, then, the boiler or generator, with its appendages; the cylinder or applicator, with its appendages; and the refrigerator or condenser, with its appendages—the function to be discharged by the first of these being altogether the reverse of the last; the first producing steam by heat from water, the last producing water from steam by cooling. Papin's scheme was possible but impracticable; Newcomen's system was practicable but wasteful; Watt's system was practical, economical, and complete.

Mr Watt's first engines are in general form represented by fig. 13, in which A represents the cylinder of his earlier

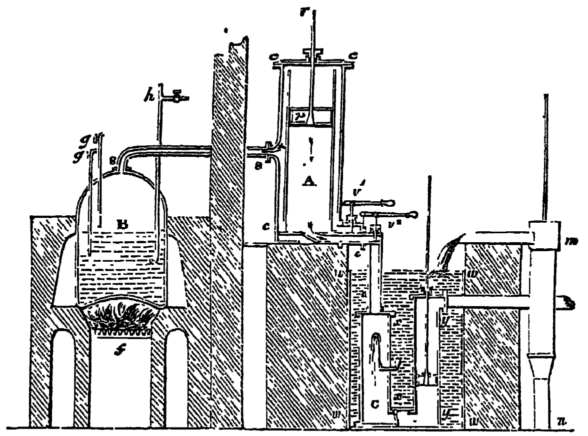

Fig. 13.

engine, B the boiler, and C the condenser, each with its various appendages. The appendages of the boiler B are, of course *f*, the furnace; *g g* small pipes for showing the height of the water in the boiler; *h* a pipe for supplying the boiler with water as it passes off in the form of steam; *s s* a pipe for conveying the steam to the cylinder. The appendages of the cylinder are—*p* the piston, fitting accurately the inside of the cylinder, and surrounded with hemp-packing, soaked with tallow and oil, so as to be steam-tight; the jacket or casing *c c c c*, which prevents the cold air of the atmosphere from entering into and cooling the cylinder at the expense of afterwards heating it by the steam; and instead of allowing such air to enter at the top of the cylinder A and press down the piston, as in Newcomen's engine, the hot steam is substituted, which, being of an elasticity equal to the force of the atmosphere, presses it towards the bottom of the cylinder. On this being accomplished, the handle of the valve v^1 is raised so as to admit the steam below as well as above the piston, which equilibrium of upward and downward pressure allows the piston again to rise, in consequence of a counter weight connected with the top of the piston-rod *r*, and this opening, of what is called the steam-valve v^1, continues until the piston again reaches the top of the cylinder, when it is closed. The eduction valve v^2, which is at that moment opened, permits the steam to escape suddenly into the condenser, when it becomes water, and leaves the space below the cylinder vacuous, so as to give free space for the piston to be carried down into the cylinder by the pressure of the steam upon the top of the piston. These, the casing, piston, piston-rod, steam-valve, eduction-valve, and communicating passages are appendages of the second great member of the machine, viz., the cylinder, by which the power of the steam is applied to give the required motion to whatever solid machinery may be placed in connection with the piston-rod. The appendages of the condenser C of Mr Watt are as follows:—First of all, a large cistern *w* of cold water is provided, and furnished continually with fresh supplies of cold water either from a

History and Descriptive Account.

running stream or by means of a pump in or wrought by the engine itself; in this is placed the condensing chamber *c x x*, wholly surrounded by cold water, but perfectly empty, excepting that a small jet of cold water from the exterior is admitted through a regulated aperture to play in the inside, by which injection it has always been observed that the condensation of the steam is more efficient than when a casing of metal intervenes between the cold water and the steam. The eduction-pipe *e e e* conducts the steam out of the cylinder by the valve v^2 into the condenser *x x*, where it is reduced back into the water from which it had been originally generated. Now, it must be obvious on a little consideration, that the water which is injected into the condenser must rapidly accumulate there, becoming at the same time warmed by mixing with the steam, and so would impede the progress of condensation by ultimately filling up the interior of the condensing chamber, which should be kept vacuous; and further, that the steam itself, becoming reconverted into water, would soon accumulate in the condenser and choke it up. Hence a principal appendage of the condenser is a large pump, which is essential to its long-continued efficient action, and which withdraws a portion of the accumulated warm water from the interior of the condenser, and keeps it vacuous; and because there is generally air in the water, and because, also, air is very apt to insinuate itself by many chinks or crevices into the condenser, this clearing pump must be capable of pumping out air as well as water. This appendage of the condenser, represented in the preceding figure by *y y*, is generally termed the "air-pump," a name which but imperfectly expresses its functions.

Fire being placed under the boiler, its heat, communicated to the water, rapidly expands that water, and rarifies it into steam, by the addition of more than five times the heat which would raise its temperature from the freezing to the boiling point. This combination of heat and water, forming the steam, rushes along the steam-pipe into the cylinder casing, and is admitted into the interior of the machine, filling all its chambers and pipes with steam; but that portion of the steam which is in communication with the condenser, being instantly chilled by the jet of cold water and the cold sides of the vessels in the cold well, is condensed, and then the valve v^2 being closed so as to admit no more steam into the condenser, and the valve v^1 being closed so as to admit no more steam into the lower part of the cylinder below the piston, there remains the elastic force of the steam above pressing it towards the bottom of the cylinder with a force proportioned to the pressure of the steam and the extent of the cylinder. Thus, a moving power is generated in the cylinder by the steam which may be conveyed through the piston-rod *r*, and applied through various mechanism of application to the performance of the required work. The steam which has thus pressed down the piston is now admitted below to neutralize the force of that which remains; and having thus done its duty, is again annihilated by the opening of the communication into the condenser, into which it rushes; and being almost instantly deprived of the heat which gave it power and magnitude, there remains nothing except the few spoonfuls of water from which all that volume of steam had arisen, now lying inert at the bottom of the cylinder. This dead water is not yet cold. It is evident that in the primary generation of steam in the boiler, the supply of water must be rapidly diminished by this boiling off, and this water must somehow be supplied. Now, here lies an opportunity for economy; this waste, instead of being supplied by cold water, may be better replenished with the water of the condenser, which is highly heated in condensing the steam from the cylinder.

Mr Watt's engine was first used as a substitute for the engine of Newcomen in pumping up water or draining mines. In 1788 it had attained the form represented in fig. 14, as placed within the walls of a building, the anterior portion of which is omitted, to show the machine. On the left stands the boiler outside the building; and on the right also outside the house, is the large pump, by which the water is raised and the work of the engine performed. Nearly in the middle stands the cylinder, with its appendages, and below these are the well and condensing apparatus.

Beginning with the apparatus for generating steam. It is the boiler of what is called the wagon shape, set in a furnace of brickwork immediately over the fire, which rests on the fire-bars at *p*, over a deep ash-pit; the flame passes under the concave bottom of the boiler to the further end, and there, instead of proceeding at once up the chimney, returns by O on the left side of the boiler, through the brick channel or flue, giving out additional heat to the water, and after passing across the front of the boiler, proceeds along the right hand flue *o* in the chimney. The draught of the chimney is regulated by the damper *r*, which is lowered into the flue or raised out of it in any degree by the attendant, and so permits the gases to rush with

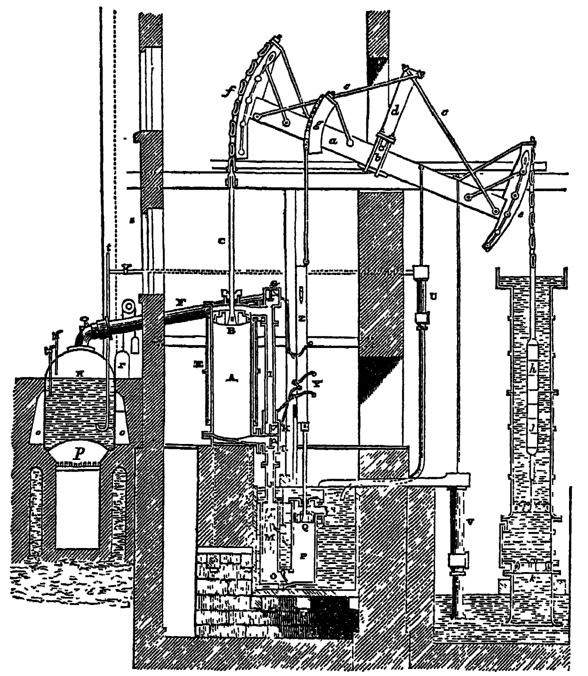

Fig. 14.

greater or less ease up the chimney. A tube *t*, regulated by a stop-cock, comes from a small pump U, on the right hand side of the cylinder, which raises the warm water discharged by the air-pump, and sends it into the boiler, so as to replenish its waste; this pipe and pump being generally named the feed-pipe and tube. The two little tubes proceeding from the water in the boiler are open at both ends, and have external stop-cocks, which are always shut, except when the attendant wishes to ascertain the height of the water in the boiler. He then opens these guage-cocks, and observing whether water or steam issues from them, forms his judgment accordingly. F is the steam-pipe which carries the steam from the boiler to the cylinder.

The second great member of the machine, the working-cylinder A, is placed in the engine-house. It contains the moving piston B, which communicates the force impressed on it by the steam, through the piston-rod *c*, and the chain *f* to the end of the great lever or working-beam *f a e*, which is forced up and down around the fixed centre or iron gudgeon *b*, and so raises or depresses the other end of the lever on the right hand side of the figure, and thus

gives the required motion to *hj* the piston and rods in the barrel of the great pump, in which the work of raising water to a height or from a mine is the useful labour or duty to be performed by the engine. Returning to the cylinder at A, we have now to examine the mechanism by which the steam is admitted alternately above and below the piston, through the openings or ports which may be observed on the right hand side of the cylinder at top and bottom. F is the steam-pipe which brings steam from the boiler to the top of the valve-passages, and the pipe I conducts it down to the bottom valves and port at K, and the pipe J forming the eduction-pipe, conducts the steam into the refrigerating apparatus, where it is finally condensed. In commencing to work the machine, the duty of the attendant is to allow the steam to pass freely into all the pipes, passages, and ports F, G, I, J, &c., filling the cylinder A, the condenser M, and passing out at an aperture O, closed by a valve, called the blow-off valve, by means of which operation the whole of the parts being filled with steam, are rendered vacuous from air, and this preparatory process is called blowing through. At G is a steam nozzle and valve, or regulator, which allows the steam to enter the cylinder at the upper part whenever it is opened, by raising the metallic cover or valve from the opening of the nozzle immediately below, which it exactly fits. At K is a similar contrivance, called the equilibrium valve and nozzle, which admits steam through the pipe I into the bottom part of the cylinder, and the third, or exhaustion valve and nozzle or aperture, allows the final egress of the steam into the condenser. After the engine has been wholly filled with steam, the piston B, being at the top of the cylinder, the injection-cock N is suddenly opened, and the cold jet of water playing amongst the steam condenses it instantaneously, forming a vacuum into which the steam from the cylinder instantly rushes, and is in like manner annihilated, leaving the cylinder below the piston equally vacuous; and, of course, the steam from the boiler, on being admitted by the valve G to the upper side of the piston, instantly presses it down into the vacuum below with a force proportional to the perfection of that vacuum and to the pressure of the steam. Thus, the engine makes its first stroke, and raises the water of the great pump on the right of the figure, and the weight of the chain, rod, and bucket, and also a counterpoise *h*, added for restoring the beam to its former position, which it does in the following manner. The equilibrium valve K is opened, and the steam getting admission below the piston, as well as above it, ceases to urge it in either direction, and being thus in equilibrio, the piston would remain passively in its place at the bottom of the cylinder; but the counterpoise *h*, and the weight of the pump, rods, and bucket in the large pump on the outside, draw down the outer end of the great lever or working-beam *f a e*, and so raise the anterior end *f* and the piston B to the top of the cylinder. The equilibrium valve is then closed at K, and the eduction-valve L is opened, so as to allow the steam below the piston to rush down into the condenser and leave a vacuum under the piston, into which it is immediately forced down by the pressure of the steam above A, as at first, and raising water at the other end of the beam through a second stroke; and thus, by the continual opening and shutting of the valves by the attendant, the engine performs its work. But we have still to consider the mechanism by which the machine shuts and opens its own valves; for this purpose we have given in fig. 15 two separate and enlarged drawings of one of the valves and its working gear; *l i l* is a part of the air-pump rod, formed of wood, called the plug-frame or plug-tree, on which are two projecting plugs of wood to work the upper and lower valves. One of these plugs is seen at *i*. As the plugtree moves up and down, the plugs strike the handles or working gear of the valves, and open or shut them at the proper instant. The valve D E is called a conical valve, because the small cover D which closes the opening of the nozzle is slightly tapered downwards, so as the more readily to fit its seat, from which it is lifted by a small-toothed rack and pinion *c*, moved by a spindle from without, and communicating by rods with the valve gear at *r*, or at *z* and *y* in figure 14. When the plug frame *l i l* descends, the valve D is closed by the plug *i*, and the valve K is shut, and the valve L in fig. 14 opened by the plug *y*.

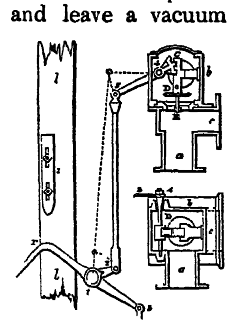

Fig 15.

Returning to figure 14, where the condensing apparatus and its appendages are placed almost immediately under the cylinder, and to the right of it. The eduction-pipe J conducts the steam into the condensing chamber M, which is in the middle of the cold well, wholly surrounded by cold water, and through the regulated aperture N a jet of cold water, pressed in by the atmosphere, is allowed to play in the inside of it amongst the steam. P the air-pump is also placed in the cold well, surrounded by water; Q the piston or bucket of the air-pump, is worked up and down by the piston-rod Q Y Z *g* from the great lever. The valve R closes when the piston descends, and opens on its ascent, allowing water and air to pass into the air-pump, but preventing their return; and the upper valve of the air-pump S allows the escape of water and air outwards, but prevents their return; this valve S leads to the hot well T, from which the feed-pump U supplies water for the boiler.

The great advantage of Mr Watt's form consists in avoiding the excessive waste of steam formerly occasioned by condensing in the cylinder itself. The cylinder now is always hot, and therefore perfectly dry. By the time Mr Watt had completed these improvements, his experiments on steam had given him a pretty accurate knowledge of its density; and he found that the quantity of steam employed did not much exceed what would fill the cylinder, so that very little was unavoidably wasted. But before he could bring the engine to this degree of perfection, he had many difficulties to overcome. He enclosed the cylinder in another containing steam, and that in a wooden case at a small distance from it, which effectually prevented all condensation in the inner cylinder from external influence; and the condensation by the outer cylinder was very small.

In order to regulate the power of the engines when working light loads, Mr Watt introduced the variety which he called the *expansive engine*, the principle of which had first occurred to him in 1769, and was applied by him about 1776. "The steam-valve is always allowed to open fully; the pins of the plug-frame are regulated so that that valve shall shut the moment the piston has descended a certain portion, suppose one-fourth, one-third, or one-half of the length of the cylinder. Thus far the cylinder is occupied by steam as elastic as common air. In pressing the piston farther down, it behoves the steam to expand and its elasticity to diminish. It is plain that this can be done in any degree we please, and that the adjustment can be varied in a minute by shifting the plug-pins.

"In the meantime, the pressure on the piston is continually changing, and consequently the accelerating force. The motion, therefore, will no longer be uniformly accelerated. It will approach much faster to uniformity; nay, it may be retarded, because, although the pressure on the piston at the beginning of the stroke may exceed the resistance of the load, yet, when the piston is near the bottom, the resistance may exceed the pressure."

Hitherto we have considered the condensing steam-engine of Watt as applied to work the large pumps used to

draw water from mines, or to supply reservoirs from a lower level. This, indeed, was the most obvious and immediate application of the steam-engine, which was at first introduced as a substitute for the atmospheric pumping-engine of Newcomen. But it had always been matter of regret that one-half of the motion was unaccompanied by any work. It was a very obvious thing to Mr Watt, that as the steam admitted above the piston pressed it down, so steam admitted below the piston would press it up with the same force, provided a vacuum was made on its upper side. This was easily done, by connecting the lower end of the cylinder with the boiler, and the upper end with the condenser. The steam-engine of revolution of Mr Watt was an invention subsequent to the mining steam-engine, or "water commanding machine." Previously to the time of Watt, indeed, there had been a few attempts to produce a revolving motion by steam, such as the case where the engines of Savery and Newcomen drew up water to turn a wheel. There had also been many attempts to apply the old pumping-engine directly to this purpose. Jonathan Hulls, Keane, Fitzgerald, Mr Oxley, John Stewart, and Matthew Wasbrough, had all contrived some means of producing a revolving motion from the reciprocation of the great beam; but Watt's engine alone was capable of being rendered an efficient and economical motive-power for driving machinery of continual motion. The earliest record of the invention was in 1774. The Albion Mill

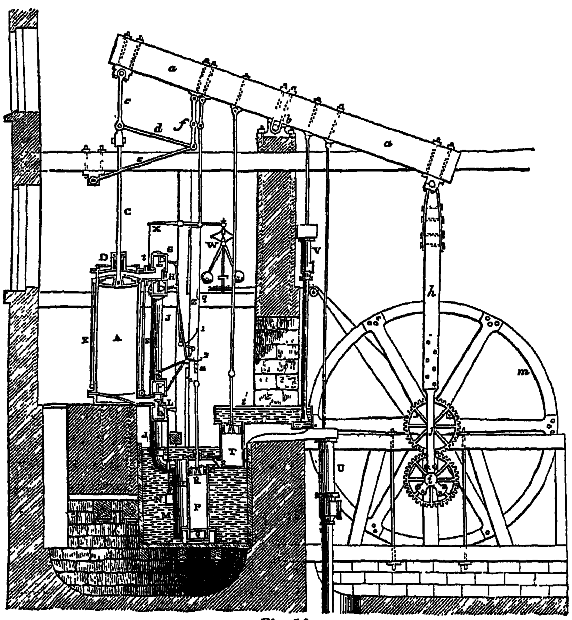

Fig. 16.

engine (figs. 16 and 17) were amongst the earliest rotative engines made for sale.

The steam-pipe F conveys steam from the boiler n to the cross-pipe or upper steam-nozzle G, and by the perpendicular steam-pipe I, to the lower steam-nozzle K. In the nozzle G is a valve, which, when open, admits steam into the cylinder above the piston B (fig. 16), through the horizontal square pipe at its top; and in the lower steam-nozzle K there is another valve, which, when open, admits steam into the cylinder below the piston. In the upper exhaustion-nozzle H is a valve, which, when open, admits steam to pass from the cylinder above the piston into the exhaustion-pipe J, which conveys it to the condensing vessel M, where it meets the jet of the injection from the cock M, and is reduced to water; and in the lower exhaustion-nozzle L there is also a valve, which, when open, admits steam to pass out of the cylinder below the piston, by the eduction-pipe into the condenser M.

"The piston being at the top of its stroke, the valves G and L are to be opened, and the fly-wheel M turned by hand about the eighth of a revolution, or more, in

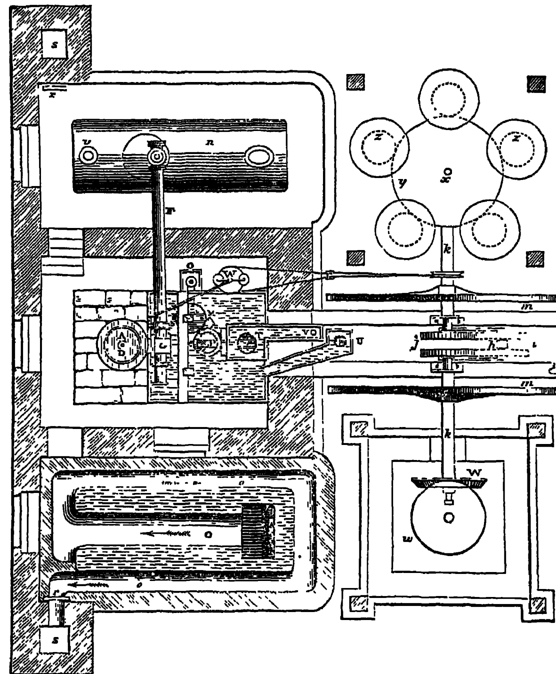

Fig. 17.

the direction in which it is intended to move; the steam which is then in the cylinder will pass by L into the condenser, when, meeting the jet of water from the injection-cock, it will be converted into water, and the cylinder thus becoming exhausted, the steam, entering the cylinder by the valve G, will press upon the piston, and cause it to descend, while, by its action upon the working-beam through the piston-rod, &c., it pulls down the cylinder out of the beam and raises up the outer end and the connecting-rod h, which causes the planet-wheel i to tend to revolve round the sun-wheel j; but the former of these wheels being fixed upon the connecting-rod, so that it cannot turn upon its own axis, and its teeth being engaged in those of the sun-wheel, the latter, and the fly-wheel, upon whose axle or shaft it is fixed, are made to revolve in the desired direction, and give motion to the millwork.

"As the piston descends, the plug-tree Z also descends, and a clamp or slider q, fixed upon the side of the plug-tree, presses upon the handle 1 of the upper Y shaft, or axis, and thereby shuts the valves G and L; and the same operation, by disengaging a detent, permits a weight suspended to the arm of the lower Y shaft to turn the shaft upon its axis, and thereby to open the valves K and H. Just before the opening of these valves, the piston had reached the lowest part of its stroke, and the cylinder above the piston was filled with steam; but as soon as H is opened, that steam rushes, by the eduction-pipe J, into the condenser, and leaves the cylinder empty above the piston. The steam from the boiler entering by I and K, acts upon the lower side of the piston, and forces it to return to the top of the cylinder. When the piston is very near the upper limit of its stroke, another slider A raises the handle Q, and in so doing disengages the catch, which permits the upper Y shaft to revolve upon its own axis and open the valves G and L, and the downward stroke recommences, as has been related.

When the piston descends, the buckets R, T of the air-pump p and hot-water pump T also descend. The water which is contained in these pumps passes through the valves

History and Descriptive Account.

of their buckets, and is drawn up and discharged by them through the lander or trough *t* by the next descending stroke of the piston. Part of this water is raised up by the pump N for the supply of the boiler, and the rest runs to waste.

The history of the steam-engine in a great measure ends with the history of Mr Watt's labours. There remain, of course, important improvements in points more nearly of detail; and it would be unfair to ignore the doings of Watt, and others, in the article of boilers. For a consideration of these and other points arising for discussion, the reader is referred to the succeeding portions of this treatise.

The names of many individuals who have in earlier times distinguished themselves by ingenuity directed to the steam-engine have been omitted in this notice, not because we consider their labours either undeserving of notice or uninteresting to the general reader, but because they have not contributed towards the production of the modern steam-engine, and because an account of their works would rather serve to illustrate the possible varieties of the machine and the fertility of the human mind in mechanical devices, than either to conduct the reader along the stream of historical succession, or render him better acquainted with the nature and mechanical peculiarities of the steam-engine itself.

For the important purpose of converting reciprocating rectilineal into rotary motion, Mr Watt had early designed the application of the crank. A crank is an elementary machine, which has been used from the earliest times for converting a revolving into a rectilineal motion, or the reverse. A crank is merely a handle to a wheel, by which it may be turned round. In fig. 18, let *ax* be an axis of a wheel *bcd*, and *a*RP the usual bent (or crooked) handle by which it is turned round by the man, whose arm first pushes it from him, and then draws it towards him, and so continually turns the wheel round, then the part *a*R radiating from the centre, is called the crank, the axis *ax* is called the crank-axle, and the straight part PR is called the crank-pin.

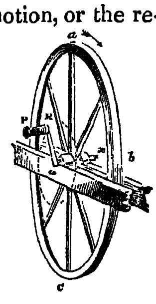

Fig. 18.

The idea of the crank had very early occurred to Mr Watt; "but my attention," says he, "being fully employed in making and erecting engines for raising water, it remained *in petto* until about the year 1778 or 1779, when Mr Wasbrough erected one of his ratchet-wheel engines at Birmingham, the frequent breakages and irregularities of which recalled the subject to my mind, and I proceeded to make a model of my method, which answered my expectations; but having neglected to take out a patent, the invention was communicated by a workman employed to make the model to some of the people about Mr Wasbrough's engine, and a patent was taken out by them for the application of the crank to steam-engines. This fact the said workman confessed, and the engineer who directed the works acknowledged it, but said, nevertheless, the same idea had occurred to him prior to his hearing of mine, and that he had even made a model of it before that time, which might be a fact, as the application of a single crank was sufficiently obvious. In these circumstances I thought it better to endeavour to accomplish the same end by other means, than to enter into litigation, and if successful, by demolishing the patent, to lay the matter open to every body. Accordingly, in 1781, I invented and took out a patent for several methods of producing rotative motions from reciprocating ones, amongst which was the method of the sun and planet wheels, above described."

Oliver Evans, of Philadelphia, United States, devoted himself to the development of the non-condensing, high-pressure steam-engine, in which the condenser was superseded, and the steam was treated as in Leupold's engine, and exhausted into the atmosphere. Before 1785 he had erected and made experiments upon a high-pressure engine, which seems to have been in all essential respects similar to our own. Indeed, it appears that the Americans have taken the form and arrangements of their engines from Evans, as implicitly as in this country we have adopted those of Watt. The history of Evans consists almost entirely of the romance of real life. Sanguine and energetic, he continually encountered difficulties only to overcome them, and to encounter renewed disaster and disappointment, till he at length died of a broken heart. To him may be attributed the rapid advancement of America, at the commencement of the present century, in all that relates to the introduction of the steam-engine in its multifarious applications, and especially in steam navigation. He had awakened in that nation a lively sense of the advantages they were likely to derive from the power of steam, and placed in their hands an instrument well fitted for their use, and which they were not slow to adopt and apply.

Cylinder-Valves and their Mechanism.

SECTION II.—CYLINDER-VALVES AND THEIR MECHANISM—HISTORICAL AND DESCRIPTIVE ACCOUNT.

The modern non-condensing steam-engine is in principle the same as Leupold's engine; and if the latter be supposed to be consolidated into one cylinder, double-acting, analogous to the conversion of the single-acting condensing engine by Mr Watt into double action, its operation would be represented by the figure 19, which comprises an automatic valve, or four-way cock, opened and closed by the reciprocating movements of the beam. A vertical rod, II^2, being suspended from the lever, with two plugs by which the handle H of the valve is raised; in that position the steam enters at S, and passes up the superior passage into the top of the cylinder, forcing the piston down, while the steam, acting below the piston, finds free egress along the inferior passage B, through the valve, and escapes by the eduction-pipe E into the open air. Just before the piston gets to the bottom of the stroke, the plug I strikes the handle H into the position H^2, when the direction of the passages is reversed; the steam enters below the piston, and escapes from above. The four-way cock was superseded by Murray's "slide-valve," now in ordinary use, by means of which the distribution of the steam was more simply effected. In this case all the four passages are united in a square box called a valve-box, or valve-chest, as in fig. 20; S, E, A, B being the steam, eduction, upper and lower passages. Into this box is introduced a small valve or cover D (fig. 21), which is of such a size as at one time to leave open only one of the three openings on the right; so that, by covering two of the openings A and E, as in fig. 22, the steam from S can only find its way through B into the lower part of the engine, while the steam already in the upper part of the cylinder can find its way, below the valve D, into the eduction-pipe E, so as to escape into the air. The valve is next shown in fig. 23, in its middle position, where all the three passages are closed, preparatory to reversing the direction of the steam, as in the third position when it slides from the upper port A, as is shown in fig. 24, so as to allow the steam to

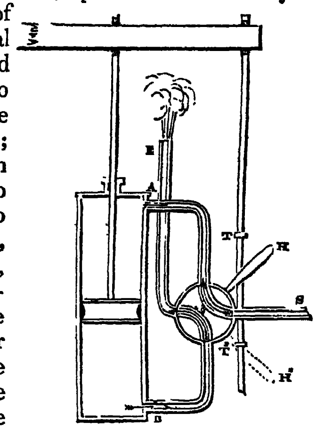

Fig. 19.

enter above the piston and press it down, while the steam formerly below the piston escapes into the air through the

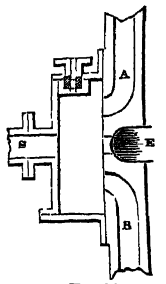

Fig. 20.

Fig. 21.

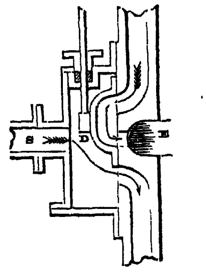

Fig. 22.

passage B, under the valve D, by the eduction-pipe E. This valve, named from its figure the D valve, is also

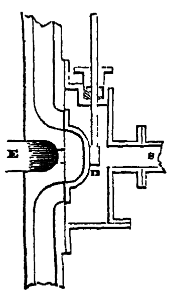

Fig. 23.

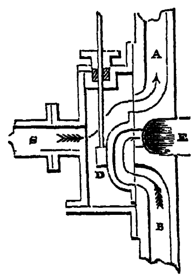

Fig. 24.

worked by the machine itself, either by some of its moving parts striking plugs on a rod which is fixed to the valve, or by some of the other apparatus, which will afterwards be described.

Another form is that called the long slide or long D valve, the invention of Mr Murdoch, which gives the advantage of shutting off the steam close to its ingress into the cylinder, and so saving what in the common short D slide is lost in the passage from A and B to the ends of the cylinder. It is formed thus:—The valve-chest extends along the side of the cylinder. It is shown in fig. 25 without the valve. In fig. 26 the long D slide valve is shown separately. It is a sort of pipe, extending along the whole length of the cylinder. Towards the ends, this pipe is almost semi-circular, with two narrow flat plates capable of covering the openings or ports of the cylinder. This pipe is left open, and perfectly clear from the one end to the other, so that the steam may traverse it freely lengthwise. The steam-pipe is

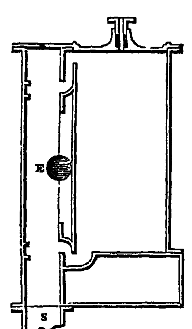

Fig. 25.

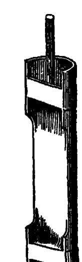

Fig. 26.

represented as entering the valve-chest from below at S, and the eduction-pipe in the middle as at E. In this valve-chest are placed packing-boxes, as they are called, immediately opposite the ports of the cylinder. They contain soft, elastic hemp, soaked in oily matter, the object of which is to press against the truly cylindrical and polished outside of the slide-valve when it its place, and make steam-tight partitions in the valve-chest, to prevent communication between the middle and the two ends.

In the figs. 27 and 28, the valve is shown in the working position. In fig. 28, the steam from S rises up along the centre of the slide, and enters the upper port A, while the

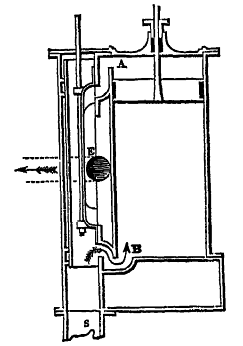

Fig. 27.

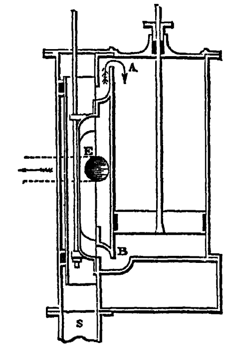

Fig. 28.

steam in the under part of the cylinder has free egress through B to the eduction-pipe E. In fig. 27, the steam has free access to the lower port B, while the steam already above the piston has free egress through the upper port A to the eduction-pipe E. In this species of slide, there is scarcely any loss of steam in the passages, as it is cut off close to the cylinder.

Instead of the long D-slide, which is very heavy, on a large scale, two short slides, similar to its two ends, and connected together by bars, have been used in the following form. Fig. 29 is a section of the slide; fig. 30 a face view; and fig. 31 a section of the cylinder with the valves

Fig. 29.

Fig. 30.

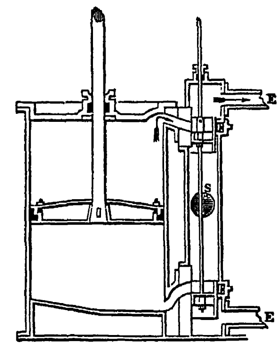

Fig. 31.

in their places. In this case, however, there are two eduction-pipes E, E instead of one, as formerly, and the steam-pipe S enters between the valves.

A cylindrical slide-valve of the following form has been used in a considerable number of engines, and works well. The valve-chest is an upright cylindrical pipe P Q, the inside of which is bored truly cylindrical, and is exactly fitted by two metallic cylindrical plugs, which are ground so smooth in their places as to be steam-tight. It will be apparent from the figure that these two plugs, being raised and depressed by the valve-rod which connects them, will effect the same purpose as the former valve. (Fig. 32.)

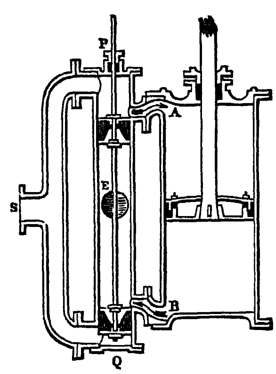

Fig. 32.

The conical-valve, spindle-valve, or button-valve, as it is variously designated, is a species introduced by Mr Watt, and improved by his assistant Mr Murdoch, from whom the steam-engine of Watt has received many valuable ap-

Cylinder-Valves and their Mechanism.

pendages and much of its practical perfection. It has been applied in two forms. Mr Watt's own form, the earlier one, is given in the following figures. For a single engine four valves are required. One of them is represented separately in figures 33, 34, which are vertical sections through the valve, at right angles to each other. The valve is shown open in fig. 33, and shut in 34. S is the entrance of the steam, A the port, V the conical valve, and N the seat or nozzle which it covers. On a cursory glance, it is evident that when the conical cover V of the aperture N is up, as in the first diagram, the steam has free entrance; and when it is closed, the steam will merely press the valve down into its seat, without obtaining an escape from the nozzle.

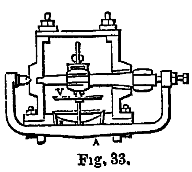

Fig. 33.

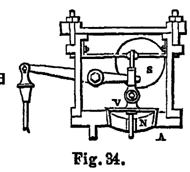

Fig. 34.

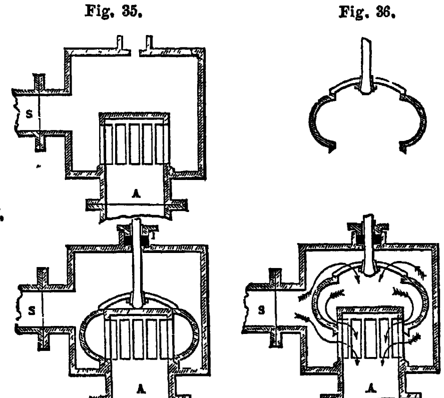
The last valve which may here be described is the crown-valve, or equilibrium-valve, which is in use on the Cornish engine, and has also been introduced into rotative engines. Its value consists in effecting a large opening, and requiring little force to work it, while large valves of the common sort are heavy, or are so much pressed in one direction by the steam as to require great force to work them.

The crown-valve is so named from its resemblance to a diadem. Conceive a chamber, fig. 35, out of which an aperture A leads into the cylinder, and into which a pipe S brings steam. The aperture A is surrounded by an upright ring or collar rising a few inches into the chamber, which ring is on all sides perforated by slits of considerable size, but closed at the top. Figure 36 represents the crown or cover of this valve, which is also a ring attached to a steel rod or spindle, by which it is raised or depressed. All round at the top and bottom, the collar in the chamber and the crown-valve are ground so as accurately to fit each other. Fig. 37 shows the valve on its seat and closed on all sides, so that no steam can find admittance; and fig. 38 represents it open or raised up from its seat, with steam

Fig. 35. Fig. 36.

Fig. 37. Fig. 38.



entering freely on every side. There are two ways in which valves are worked by the steam-engine itself. The first of these is by the agency of some part of the engine that happens to move up and down, or performs a reciprocating motion, and the other is by the agency of some part which revolves. The following is a simple method, which has been applied to the short D slide, already described. In fig. 39, ABP is the cylinder, P the piston, acting on the end L of the great lever LL^2, raising and depressing it alternately; while the other end L^2, united by the connecting-rod L^2R to the crank of the fly-wheel, turns it round. The manner in which the steam-valves are moved, is by the long vertical bar or plug-rod TT, suspended from the lever LL^2, so as to move up and down with it. This bar TT carries two projecting plugs of wood ss^2 upon it, which strike alternately up and down upon the handle ll^2 at the bottom and

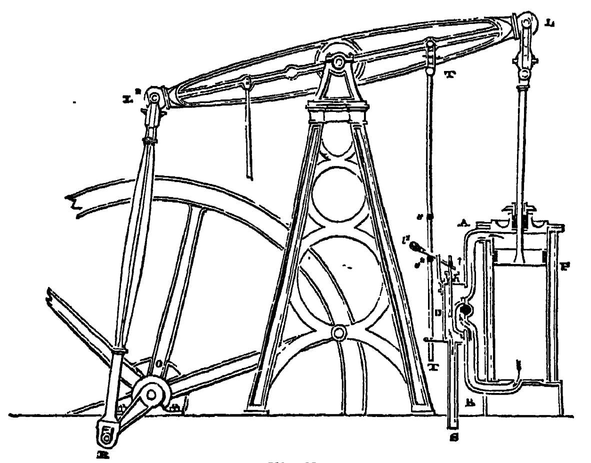


Fig. 39.

top of the stroke, and so produce the reciprocating motion of the slide-valve D; and by admitting the steam on alternate sides of the piston, and discharging it at the opposite ports, produce the continuous motion of the engine. In the figure, the steam is supposed to be forcing down the piston; but when the piston gets near the bottom, the plug s will have come in contact with the valve-rod ll^2, and will have forced it and the slide-valve D into the opposite position, and so permitted the steam formerly above the piston to pass into the open air, while the steam on the other side presses up the piston, so as to bring the plug s^2 in contact with the lever, pressing it up, and the valve D down into its first position, and so on alternately. This method of moving the valves, by a plug-frame, rising and falling with the strokes of the piston, has been principally adopted for pumping engines that have no revolving motion.

In the second system of valve apparatus, by which the steam-engine is rendered automatic, the steam-valves are worked by the revolving of one of the shafts or wheels. Of the various methods in which this has been done, the following are some examples. On the axis *o* of the crank (at the bottom of the right side of fig. 40), which is turned

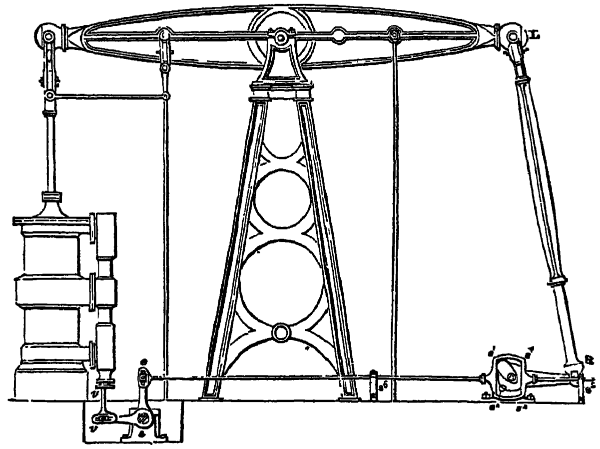

Fig. 40.

round by the rod L R during each alternate ascent and descent of the piston, is placed a cam or projection. A square frame s^1 s^2 s^3 s^4 encloses this cam. As the axis turns round, the cam comes into such positions as to bear upon the sides s^1 s^2 and s^3 s^4 of the frame successively, and so pushes the frame towards the right and left alternately. *s e v* is a bell

Cylinder-Valves and their Mechanism.

crank, which the horizontal rod ss^1 attached to the frame moves on its centre *e*, and so shifts the point *v* and the valve-rod *v v* up and down alternately, together with the valves. The different positions into which the frame is forced by the cam are sketched in figs. 41, 42, and 43.

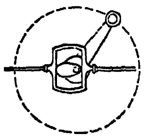

Fig. 41.

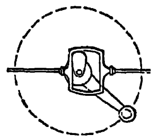

Fig. 42.

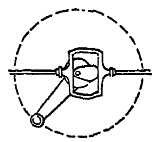

Fig. 43.

But that modification of this principle which is in by far the most general use, is in the form called "the eccentric;" which is a circular disc, or ring of metal, placed upon the shaft or axis, turned by the crank. In fig. 44, *o* is the centre of the shaft or axis, to which revolution is given by the crank R of the steam-engine. On this axis the circular disc E E E is placed, but eccentric to it, so that its centre *d* moves round the axis. The distance of the centre *d* of the disc from the centre *o* of the axis is called the eccentricity, and it is equal to half the throw or range of the motion of the valves to be moved by the eccentric. The rod, fig. 45, is called the eccentric rod, and is attached to a hoop, or circle, that exactly fits the eccentric disc. The various positions which the eccentric will take during the revolution of the engine is shown in figs. 46 to 49.

Fig. 44.

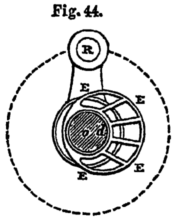

Fig. 45.

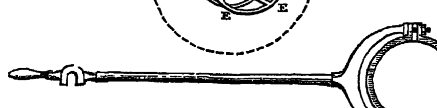

Fig. 46.

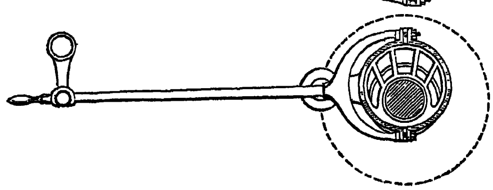

Fig. 47.

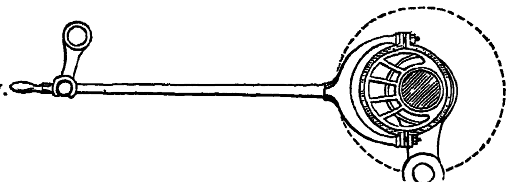

Fig. 48.

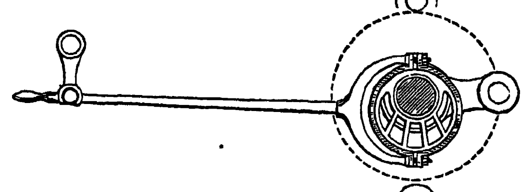

Fig. 49.

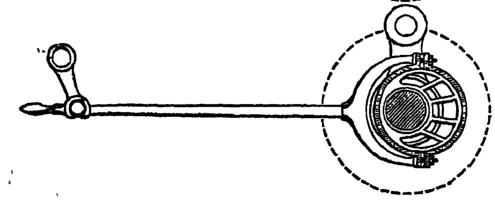

In the application of valve-gear to railway locomotives, it appeared that the gearing must be capable of being readily reversed. In the early engines of the Killingworth Railway, before 1820, the valves were moved by means of a "square box or tumbler, which was superseded by a loose eccentric, fitting the driving-axle (fig. 50), a motion which

Cylinder-Valves and their Mechanism.

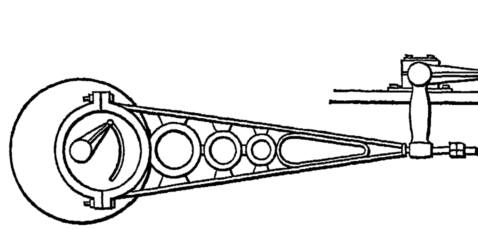

Fig. 50.

exactly answered the purpose, and was employed till the revolutionary year in railway history, 1829. A lever was fixed upon, and revolved with the driving-axle, formed with a stud, which entered and slid freely in a concentric groove cut in the body of the eccentric. The stud found its way to one end of the groove, and determined the position of the eccentric on the axle, for the fore or back gear. The small end of the eccentric rod was permitted some longitudinal play in the eye of the intermediate lever, adjustable by nuts. With an adjustable eccentric, of sufficient throw, and the adjustable limits of the travel of valve, the valve was quickly opened and closed, and its movement was equally good for both directions. The motion so derived was obviously similar to that of the ancient tappet frame, or the more modern cam. Loose eccentric gear was employed by Hackworth, and in the original inside cylinder engines of the Liverpool and Manchester Railway. The two eccentrics were cast in two pieces, and bolted together into one mass, capable of sliding laterally on the axle between the cranks. No play was permitted between the eccentric rods and the valve-levers: a necessary precaution in high-speed engines. The eccentrics were engaged in fore and back gear, by two snugs or catches fixed on the axle, behind each crank; the locking of the eccentrics being accomplished by a forcible lateral movement. Separate mechanism was employed to control the small ends of the eccentric-rods, formed with gabs to disengage them when it was necessary to work the valves by "hand-gear," which was occasionally required at starting, as in Bury's valve-gear, fig. 51. But the system of loose eccentrics was, for

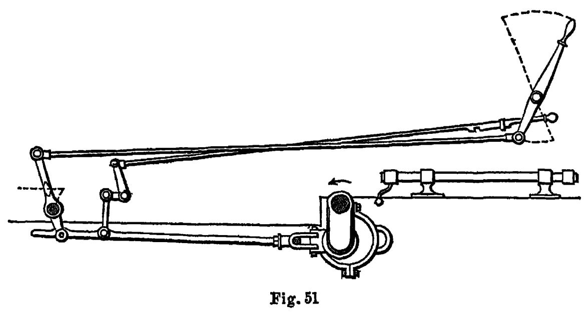

Fig. 51

locomotives, cumbrous, complicated, abrupt, and easily deranged. It was, therefore, readily abandoned for a simpler and firmer plan. Two fast eccentrics were substituted for the loose ones, one to each cylinder. This was partially a reversion to the primitive plan of the fixed cam; and the same difficulty of working equally well in fore and back gear was encountered. Mechanism suitable for working each valve with one fixed eccentric, affording the required lead both ways, was invented by J. and C. Carmichael, of Dundee, in 1818, and has been variously applied by them. For locomotives (fig. 52), the eccentric rod was finished with a double fork, to gear with the pivots of a double spanner on the traverse shaft of the valve, and was

grvooed to receive a roller on the end of the reversing lever, by which it was placed in fore or back gear, with the

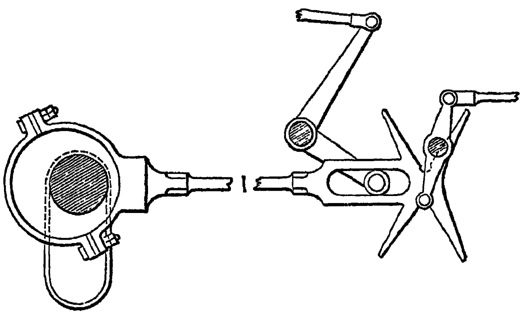

Fig. 52.

lower or upper spanner. The spread of the forks enabled them to engage the pivots of the spanner in all positions of the valve, and to bring them home to the gabs. This motion, duly proportioned, preserved the lead of the valve both ways—a matter of fact which for many years proved a *pons asinorum* for ingenious youths. It was a real advance upon the system of the loose eccentric, as one handle sufficed for working the gear, and all the parts were solidly put together.

The inconvenience of combining in one eccentric the functions of two, was removed by the adoption of four fixed eccentrics, of which the authorship is uncertain. Two were provided for each cylinder, for working respectively in fore and back gear. Each eccentric had its own fork; and though the plan entailed the use of four eccentrics, and additional bearings, the increased workmanship was compensated by precision and certainty of action. The first application of four eccentrics to locomotives was made by the Hawthorns of Newcastle, in 1837. It has been ascertained, however, that some time previously, an ingenious mechanic, in private circumstances, residing at Newcastle, had contrived and constructed an efficient model of valve-gear for locomotives, in which four eccentrics were employed, in the manner afterwards wrought out in practice. In all the forms of double-eccentric gear, it was necessary to effect simultaneously the disengagement of one pair of eccentrics, and the engagement of the other. Various plans of reversing were adopted. Stephenson employed two transverse shafts (fig. 53), the principal of which was worked by

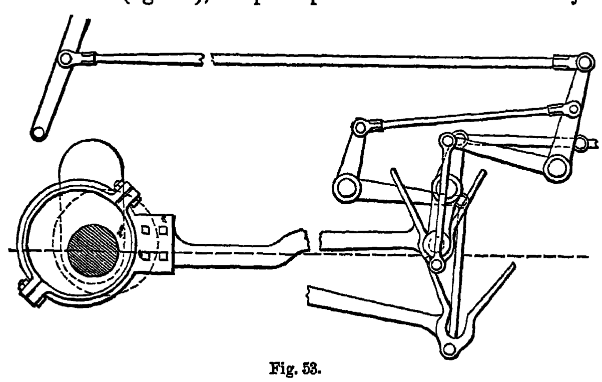

Fig. 53.

the reversing handle, and commanded the four gabs; the secondary shaft was linked to, and worked by, the principal shaft, and it had charge of the back gabs. All the forks geared from below, and one movement of the reversing handle elevated one pair and lowered the other. Thus, the manipulation was simple and easy, as the reciprocal action of the gear balanced the weight of one pair of rods with that of the other. To consolidate the gearing by dispensing with the second shaft, Buddicom employed a system for the outside-cylinder engines of the Paris and Rouen Railway, in which the forks were opposed, and worked by one lever on the reversing shaft, which was placed below, and left clear head-room under the boiler.

In these plans an intermediate traverse shaft was necessary to transmit the motion to the valves, as the valve-spindles could not, according to the prevailing arrangement of the steam-chest over the cylinder, be in the same horizontal plane with the driving-axle. A modification was introduced, however, by which the valve-chests were removed from the top and placed between the cylinders, uniting into one capacious chest, with vertical valve faces, which brought the valve-spindles to the level of the driving-axle, to dismiss the intermediate shaft, and to work the valves directly. The forks were transferred to the valve-rods, and the eccentric rod-ends formed with plain pins, and linked. This motion, as it was the most direct, and involved the fewest parts, was the best of all that had yet appeared.

EXPANSION VALVES.

The conical valves of Watt, operated by tappets, which opened and closed them at any desirable point of the stroke of the piston, afforded ample range for expansive-working; and equal facilities were afforded by the use of cams. But when slide-valves and eccentric motion came in, the benefits of expansive-working and a clear exhaustion of steam were sacrificed to the simplicity and smoothness of action of the new mechanism of distribution. The essential proportions of the primitive slide-valves, and the steam-ports over which they travelled, are shown in section in fig. 54, in which it is apparent that the length of the valve was a very little greater than the extent of the ports *a*, *a*, so as barely to lap one-sixteenth inch over these openings, just as an assurance that the steam

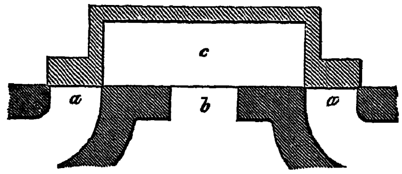

Fig. 54.

should not enter at both ends of the cylinder at the same time; the body of the valve was made just so long that the walls of the cavity *c* just closed the steam-ports *a*, *a*, on the inside, when the valve stood midway. Engineers desired chiefly to insure timely and free admission of steam, overlooking the much greater necessity that existed for an early and liberal exhaustion; this valve, with such properties, was in common use until 1838. The steam-passage was opened to the exhaust immediately after it was closed for admission, and both events took place at the termination of the slider. Thus, no time was allowed for exhaustion previously to the beginning of the succeeding stroke; and so little were the defects of this valve understood in locomotives, where the highest speeds of piston were practised, that when, in 1836, according to Mr Edward Woods, short-stroke passenger-engines were introduced on the Liverpool and Manchester Railway, to run at high speed, their greater consumption of fuel was ascribed to the supposed mechanical disadvantage of the short stroke. Mr John Gray, then locomotive-foreman at Liverpool, appears to have been the first to have suspected the cause of the excessive consumption of fuel; and after having made a few preliminary experiments on the valves of the stationary engine, and satisfied himself that the evils complained of could be traced to defective exhaustion, he lengthened the valves of one of the locomotives, which had originally a "lap" over the steam-port at each end, of only $\frac{1}{8}$ inch to $\frac{3}{8}$ inch. The effect was, that the eccentric being shifted and advanced on the shaft, so as to cause the valve, with the additional lap, to be just open at the beginning of the stroke, the inside was open at least $\frac{3}{8}$ inch to the exhaust, whereas, previously, it was not open at all. The consumption of

Expansion Valves.

fuel was, in consequence of the timely and more efficient exhaust, reduced about one-fourth. Further experience led the way to the adoption by Mr John Dewrance of 1 inch of lap at each end of the valve, with a travel of $4\frac{1}{4}$ inches, as depicted in fig. 55. By the use of the long valve, which just opened for steam at the beginning of the stroke, and stood 1 inch open for the exhaust, the steam was cut off

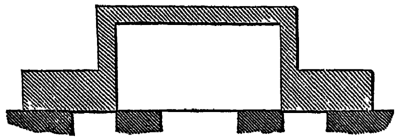

Fig. 55.

at 79 per cent. of the stroke, expanded in the cylinder to 95 per cent., or 5 per cent. from the end of the steam-stroke, and at this point it was exhausted. The waste steam which had previously been choked up in the cylinder, owing to the difficulty of escape, and so causing excessive back-pressure on the piston, was freely released, less steam was thus consumed, and other natural advantages accrued.

The necessity and advantage of lap on the valve was thus established in railway practice, both as to its facilities for affording a free exhaust, and for working steam expansively. Without lap there could be no expansion; and though it was introduced primarily for the purpose of an efficient release, its advantages as a means of working expansively became likewise apparent. It was quickly adopted on other lines of railway, as a specially good thing for high-speed engines, and by slow degrees circulated also in stationary and marine practice, in which, certainly, pistons moved at a more moderate velocity. In order to vary the degree of expansive-working of steam, according to circumstances, two classes of mechanism have been employed for slide-valves—first, those mechanisms which operate upon single valves by varying their travel; second, those in which two valves are employed, one of which is specially designed for varying the expansion. Increase of expansion, it must be observed, is obtained simply by causing the valve to cut off the steam earlier in the course of the stroke. In mechanisms of the first-class, the travel is varied by means of mechanism external to the valve-chest, of which the merit of the first application was made by Mr John Gray, on the Liverpool and Manchester Railway in 1839. In his plan, the pin at the end of the eccentric-rod slides in a segmented lever, curved to the radius of the rod, the upper end of the lever being linked to the valve-rod; thus the travel of the valve could be varied by raising or lowering the eccentric-rod end in the segmented lever. The celebrated "link-motion" was originally introduced in 1843, by Robert Stephenson and Co., on locomotives, and is now universally applied to them; it is also extensively applied in marine and winding engines. It is shown at fig. 56, as applied by that firm to locomotives,

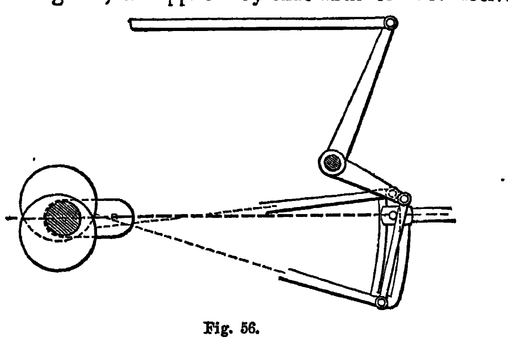

Fig. 56.

and is specially adapted for situations where the engine requires to be quickly and easily reversed, whilst its capacity for advantageously working by variable expansion, in varying the travel of the valve, is unquestionable. The two eccentrics, fore and aft, usually provided, have the ends of their rods connected by a slotted link, the slot of which embraces the end of the valve-spindle from which the valve is worked. The link is commanded by a reversing lever, and may be raised or lowered, so as to bring the valve and spindle into gear with, and receive the motion of, the fore or the back eccentric; and, while the link would partake of the two motions jointly of the two eccentrics, its horizontal motion would be smallest at the centre of its length, and would be extended towards the extremities. By shifting the block or end of the valve-spindle towards the centre, the travel of the valve is reduced, and variable expansion obtained.

Historical notice of Steam-Boilers.

Variable-expansion gear of the second-class, with two or more valves, has been applied in many different forms. The use of a secondary valve, in addition to the principal valve for expansive-working, is now limited to stationary engines. For locomotives, it has often been tried and abandoned, except in the United States, where, however, the link-motion with a single valve is steadily superseding the double-valves.

SECT. III.—HISTORICAL NOTICE OF STEAM-BOILERS.

During the first period of the history of the steam-engine, the danger of bursting the boiler, and the difficulty of making it strong enough to resist the internal force acting towards explosion, and also of making the joints tight against the leakage of highly elastic steam, formed the chief obstacles to the introduction of steam as a mechanical mover. The first important point in preparing a steam-boiler is to secure strength without unnecessary expense. The globular or spherical shape was very early adopted as one of greatest capacity, as a shape in which, the pressure at every point being equal, there remained no force tending to produce flexure, or destroy the equilibrium of strength and strain at any point. A fire was lighted below the boiler, and the steam confined until the heat had raised it to the required pressure. This form was accordingly adopted by Hero, Savery, and others, as already noticed.

It was soon found that a spherical boiler, when set upon an open fire, required an enormous consumption of fuel to raise a small quantity of steam, the heat being copiously communicated not only to the water in the boiler, but also in very great quantity to the surrounding objects, besides being rapidly carried off by the air. To surround the spherical boiler with non-conducting substances, and to keep the flame throughout its whole extent in contact with the boiler, so as to prevent radiation to surrounding objects, and also to diminish the size of the fire by making it wind round the boiler, were the first steps towards improvement; and we accordingly find in the work of Dr Desaguliers the form of boiler (fig. 57), which is built into a brick casing, with the fireplace below, and the flue winding round the boiler on its way to the chimney.

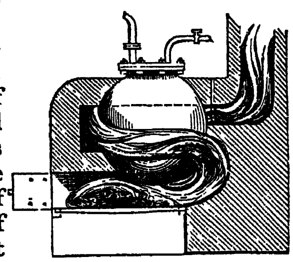

Fig. 57.

The form next in simplicity to the spherical boiler is the cylindrical. From the facility with which a cylinder is made, it was introduced at a very early period. It stood upright like a bottle, as in fig. 58, the fire being placed at the bottom, and the flue winding round that part of the sides covered with water. This form of boiler was found, however, to be weak in the bottom part.

For the prevention of these two evils, the cylindrical form of boiler was very soon modified and improved by two opposite expedients, one applied at the top and the other at the bottom of the cylinder. The top being made hemispherical, possessed all the advantages of a spherical

Historical notice of Steam-Boilers.

boiler; and the bottom being arched upwards, so as to present a large concave dome to the impact of the flame.

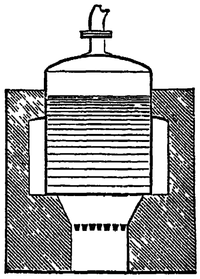

Fig. 58.

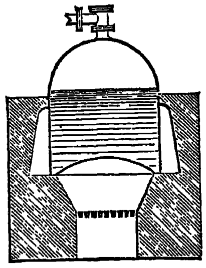

Fig. 59.

This dome being sustained by the cylindrical belt round its spring, a very strong and extensive surface was obtained, as in fig. 59.

In this cylindro-spherical boiler it was found that the action of the flame on the upright round sides produced but a very slight effect in raising heat. It was therefore desirable that the flame should be brought somewhat under the sides by inclining them a little outwards. From the form the boiler then assumed, and which has since become very common, it has not inaptly been named the hay-stack boiler, fig. 60. The same effect was next obtained in many of the boilers of Newcomen in the way represented in fig. 61, so that the flame in the flues impinged upon a surface

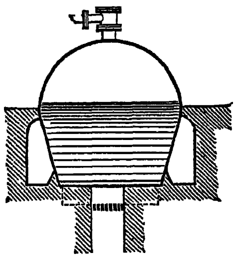

Fig. 60.

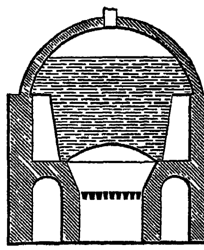

Fig. 61.

directly over them, the flues in this case forming a recess in the sides of the boiler, instead of being built around it by the brick-work alone.

In process of time, boilers of much larger size came to be required, and the spherical shape was found cumbrous and too capacious; that is to say, contained an enormous mass of water, which it required much time and fuel to heat to the boiling point before any steam could be raised. The diameter, also, of the boiler was so great when much steam was required, that the enormous dome became weakened. To make a stronger boiler, and one which should at the same time cover a large fire, the waggon-boiler (fig. 62), so named from its form, was introduced by Mr Watt. It was made of considerable length, and its transverse section resembles that of the old cylindrical boiler. In this form the boiler was long made by Messrs Boulton and Watt. It was afterwards improved by hollowing the sides (see figs. 63 and

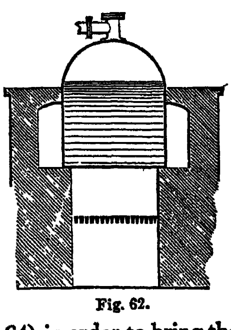

Fig. 62.

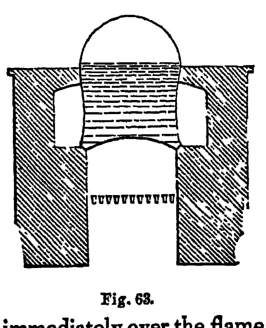

Fig. 63.

64) in order to bring them more immediately over the flame. These forms of boiler, although very convenient, are weak; they are very different from the spherical or cylindro-spherical boilers in strength and safety, and it is necessary to place in them strong iron stays, which are essential to

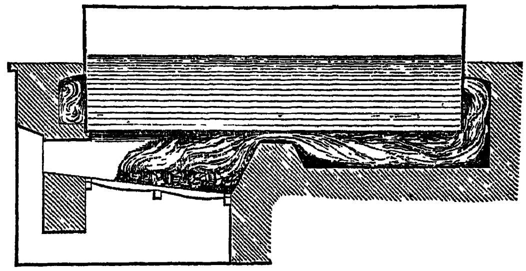

Fig. 64.

strength and security in boilers having large surfaces, concave outwardly, or perfectly flat. To avoid the use of stays, and to secure great strength without any other metal than the shell of the boiler itself, is the object of the cylindrical boiler with two hemispherical ends (fig. 65), laid

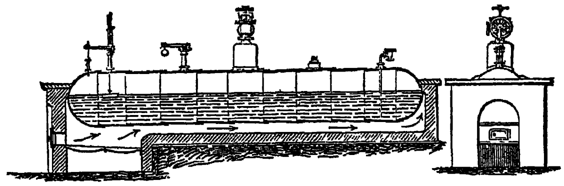

Fig. 65.

with its axis nearly horizontal, and below it, at one end, is placed the fire, enclosed by brick, as usual. The flame traverses the bottom of the boiler, beating directly upon its under horizontal surface, till it reaches the end furthest from the fire. The flame and hot air then, in some examples, return along the one side of the cylinder, being confined in a brick flue, and passing along in front of the end which is over the fire, traverses the other side towards the chimney, which it enters after having thus traversed the length of the boiler three times, and applied its heat successively to every point of the cylinder, which is covered with water. This is a boiler that requires no stays, and is valuable where room is not important. It contains much water, requires much heat to raise its temperature after being cooled at night, and is very bulky.

The spherical, cylindrical, and waggon shaped may properly be denominated the simple boilers. But some hundred kinds of boilers have been invented for different purposes; almost all of them designed to save either bulk, weight, or fuel. For these purposes one great object of improvements in boilers has been to increase as much as possible the extent of heating surface without increasing the general dimensions. Thus Boulton and Watt have inserted a flue in the middle of the large waggon-boiler in the manner shown in figs. 66 and 67, so that, after the flame has passed along the bottom of the boiler to the further end, it returns along the flue in the middle of the water to the front, and then makes an entire circuit of the outside of the boiler before entering the chimney. The same plan has been employed in cylindrical-boilers, the flame and hot air being made to traverse a hollow tube or cylinder in the interior of the boiler; sometimes several such flues have been used.

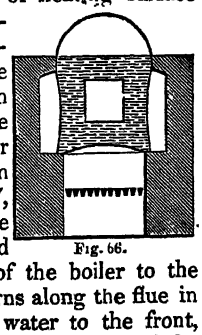

Fig. 66.

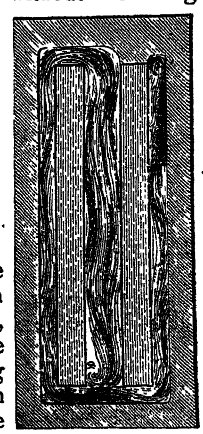

Fig. 67.

Historical notice of Steam-Boilers.

In these boilers, a large surface is still exposed to the cold air; and the brick-work, in which the fire is placed, radiates off a considerable portion of heat, which is lost. To remedy this evil, the furnace has been so contrived that the fire is in the inside of the boiler. This was probably done for the first time by Smeaton, who succeeded in producing almost as high a proportion of steam from fuel as engineers of a more modern date. His portable engine-boiler is represented in figs. 68, 69. The interior of this

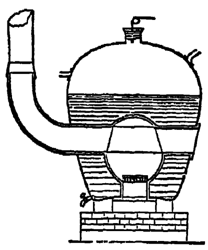

Fig. 68.

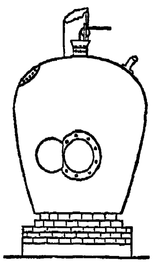

Fig. 69.

hay-cock boiler contains a hollow ball of cast-iron, in which the fuel is burned. Air enters by an aperture at the bottom; a large cast-iron pipe leads through the water to the door, and another pipe, in the opposite direction, passes through the water, conducting the products of combustion to the chimney, immediately round which are introduced the fresh supplies of cold water for replenishing the boiler. But a much better boiler than this, and one which indeed might bear comparison with many boilers of the present day, is given by Mr Farey as the invention of an unknown author. In the centre of a large old-fashioned hay-stack boiler, figs. 70, 71, is placed a large round furnace, from

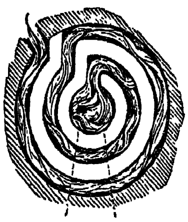

Fig. 70.

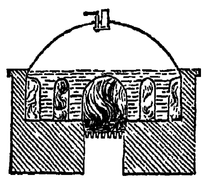

Fig. 71.

which there passes a simple rectangular flue, winding round and round the boiler in spiral circuits till it reaches the outside, and thence passes to the chimney. In the same way, it has often been provided, that the furnace should be in the interior of a cylindrical boiler, by placing another cylindrical tube, of large dimensions, in the interior of the outer-case, as in fig. 72, to serve at once as furnace and flue.

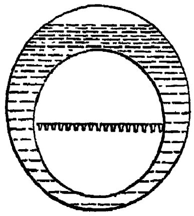

Fig. 72.

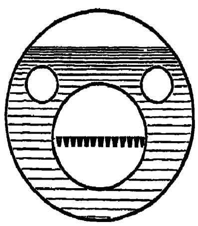

Fig. 73.

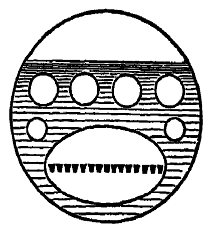

Fig. 74.

This was probably first done by Trevithick, the advocate of high-pressure engines in this country.

To the great central flue there have been sometimes added lateral flues on each side, for the return of the products of combustion, fig. 73. Thus, again, this internal flue has been made elliptical, fig. 74, a weak, and therefore dangerous, form. It is one of the faults of the boilers that have their fires in the internal tubes, that the ash-pit and interior of the furnace over the fuel are so confined as to prevent that perfect combustion of fuel which may be obtained by a deep ash-pit, a large expanse of fire-grate, and a deep and wide furnace. These evils may, in some measure, be obviated by an internal flue of large dimensions, or by the following species of boiler, figs. 75, 76, where

Historical notice of Steam-Boilers.

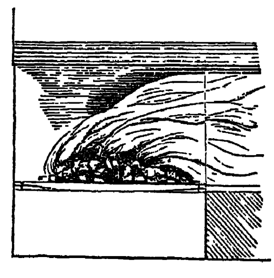

Fig. 75.

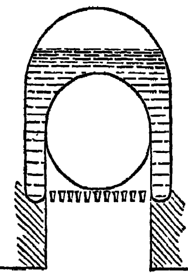

Fig. 76.

the fire is still surrounded by water, and gives ample room for the most perfect combustion. In this species of boiler, the tube opens out at the front, so as to leave a semi-cylinder above the fire, and two vertical spaces, or "water-legs," as they are called, which cover the fire on both sides; thus obstructing the heat that would otherwise pass away into the brick-building, and, at the same time, covering a large and wide space of furnace-bars, a deep ash-pit, and so insuring adequate combustion. The internal surface of this boiler has been still further increased, by substituting for this single tube a number of smaller ones, which in some cases are not more than two inches in diameter, as in figs. 77, 78. After passing through all these tubes,

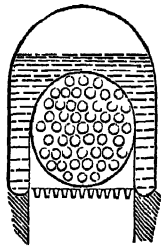

Fig. 77.

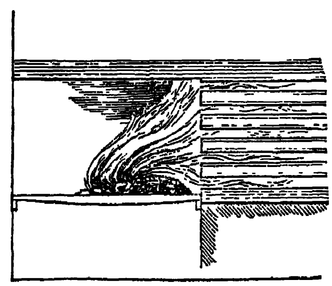

Fig. 78.

the flame and hot gases again return along the bottom and sides on the right of the boiler, and pass back on the other side to the chimney. The Butterly boiler (figs. 79, 80),

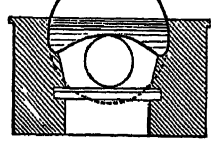

Fig. 79.

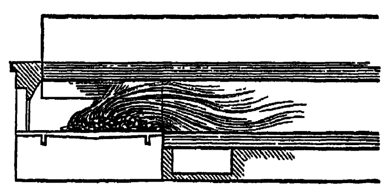

Fig. 80.

and similar to this, has been much used in Lancashire. It has the large internal flue, but wants the fire-legs, and, in this respect, is inferior to the former.

Definition of the Organs of the Engine proper.

Definition of the Parts of Boilers.

PART II.—THE MODERN STEAM-ENGINE.

SECTION I.—THE MECHANICAL ORGANS OF THE MODERN STEAM-ENGINE—THEIR DYNAMICAL ACTION.

CHAP. I.—ENUMERATION AND DEFINITION OF THE ORGANS OF THE ENGINE PROPER.

The steam is conducted to the engine through the *steam-pipe*, in which the *stop-valve* is placed; also the *throttle-valve*, or *regulator*, for adjusting the supply of steam to the cylinder; the supply may be regulated by hand or by a *governor*. The steam-pipe sometimes contains also the *cut-off* or *expansion-valve*, for cutting off the steam at any part of the stroke, and may be controlled by the governor.

The *cylinder* may be single or double-acting. When single-acting, or operating in one direction only under the steam pressure, the *piston* is made to return in the opposite direction by the action of a weight or *counterpoise*. In a double-acting cylinder, the steam is admitted on the piston at both ends alternately. The steam passes into the cylinder through *steam-passages*, or *steam-ways*, or *ports*, the entrances to which are sometimes called specifically the *ports*, sometimes *nozzles*, opened and closed by the *induction* and *eduction-valves*. When these are in one, it is called a *slide-valve*, which is placed in the *valve-chest*.

In *non-condensing engines*, conventionally called *high-pressure engines*, the *waste steam* discharged from the cylinder escapes into the atmosphere through an *exhaust-pipe*, or *blast-pipe* as in locomotives. The *cylinder-cover* has a *stuffing-box* to pass the *piston-rod*, which, if tubular, is called a *trunk*. A *grease-cock* is fixed to the cylinder, or the cover, for the lubrication of the piston. An *escape-valve*, held by a spring, may be placed at each end of the cylinder, or *blow-through*, or *cylinder-cocks*, for the escape of water collected in the cylinder, either by condensation or by the *priming* of liquid water from the boiler. To prevent condensation in the cylinder, it is cased in a *jacket*, filled with steam from the boiler, or hot air; and the jacket is covered with *clothing*, or *cleading*, of felt and wood.

Double-cylinder engines have two cylinders, the steam being admitted from the boiler to the first cylinder, and filling the second by expansion from the first. The *condenser* is a steam and air-tight vessel, into which the steam from the cylinder is discharged and condensed by a shower of cold water from the overheated *injection-valve*. In land engines the *injection-water* is supplied from the *cold well* surrounding the condenser, which is filled by the *cold water pump*. In marine engines the water enters direct from the sea. In the *surface condenser* the steam is condensed within tubes, or other passages, surrounded by cold water or air. The *blow-through* valves connect the cylinder with the condenser, and there is a *snifting-valve* opening to the atmosphere; through these valves steam may be blown to expel air from the cylinder and condenser before the engine is set to work. The *vacuum-guage* on the condenser shows how much the pressure in the condenser falls below the atmospheric pressure. Residual steam, air, and water are extracted from the condenser by the *air-pump*, and discharged into the *hot well*, from which the boiler is supplied with water. The surplus is discharged into a pond to cool, in land engines; in marine engines it is delivered into the sea.

The *cross-head* of the piston-rod is guided by a *parallel motion*, to move in a straight line; except in *trunk-engines*, guided by the stuffing-box; *oscillating-engines*, in which the cylinders oscillate on *trunnions*, and the piston-rod is connected direct to the crank; Mr Hunt's *Z-crank-engines*, *disc-engines*, and *rotatory-engines*. The reciprocations of the piston are either transmitted through a *beam*, and a *connecting-rod*, to the *crank*, and the *crank-shaft*, for double-acting *rotative-engines*; or the beam may be dispensed with, and the piston-rod coupled to the connecting-rod, forming a *direct-action* engine. The *fly-wheel* on the crank or main shaft equalizes the motion. The mechanism to work the valves is called the *valve-gearing*, or *valve-motion*.

A *pair* of engines work together on the same shaft; they have a *pair* of cylinders, a *pair* of pistons, a *pair* of cranks. Engines are properly in *pairs*, when they are designed simply to equalize the action of the power.

CHAP. II.—ENUMERATION AND DEFINITION OF THE PARTS AND APPENDAGES OF BOILERS.

The *shell* of the boiler, or outer part, commonly of iron, is spherical, cylindrical, or flat in figure, or a combination of these forms. The *steam-chest*, or *dome*, on the upper side of the boiler, is a reservoir, whence the steam is supplied to the engine by the *steam-pipe*, which is fitted with a *stop-valve*. The *furnace* is the chamber for the combustion of the fuel; when within the shell, it is called a *fire-box*. The *flues*, or conduits for the products, are either *external* or *internal* to the boiler; cylindrical metal flues are *flue-tubes*, and they are fixed at the ends into *tube-plates*. The *man-hole* is the entrance to the boiler for inspection, &c. *Mud-holes* are placed at or near the bottom for the discharge of sediment, &c. The water is supplied by the *feed-apparatus;* its level is indicated by a *float*. The boiler is emptied by the *blowoff-cock;* the surface of the water is cleared by the *scum-cock*. *Brine-pumps* may be used instead of *blowoff-cocks* to draw off the brine from marine boilers. *Sediment-collectors* receive the solid impurities floating in the water. Surplus steam escapes by the *safety-valves*. *Vacuum-valves* admit air into the boiler, when the pressure is less than that of the atmosphere, to prevent collapse. *Fusible plugs* are inserted in the boiler, over the fire, which melt and give vent to the steam when the pressure and temperature in the boiler become excessive and dangerous. The pressure is indicated by the *pressure-gauge*. The *water-gauge* shows the level of the water: it may be a *glass-tube*, or it may be *guage-cocks*. The boiler is strengthened by *stays*, which may consist of *rods*, *bolts*, or *gussets*. The boiler is covered with *clothing* or *cleading*.

The *fire-grate* carries the fuel, and consists of *fire-bars* or *grate-bars*, supported by *cross-bearers* or *bar-frames*. The *mouth-piece* is the entrance to the furnace, and rests on the *dead-plate;* the *fire-door* is fitted to and hung by it.

The *heating-surface* is the surface of the boiler exposed to the flame and hot gases from the furnace. The *boiler-room*, or internal capacity of the boiler, is divided into the *water-room*, occupied by water; and the *steam-room*, occupied by steam.

CHAP. III.—THE CRANK AND FLY-WHEEL.

The introductory historical account of the steam-engine —in particular the engine of Watt—prepares the way for a more systematic investigation of the modern steam-engine, with its manifold adaptations to the demands of engineering practice. The cylinder and piston, the crank and the main shaft, are the primary elements of steam-engines; the cylinder to contain the steam, the others to receive and transmit its energy. The following chapter is to be devoted to a consideration of the movements and action of the mechanical organs of the steam-engine, geometrically con-

The Crank and Fly-Wheel.

sidered, prior to the study of the behaviour and performance of the steam within the cylinder.

The Crank and Fly-wheel.—One of the most important appendages of the steam-engine is the crank, by means of which the force of steam, although at first producing motion only upwards and downwards in the straight line of the axis of the cylinder, is nevertheless rendered capable of exerting that force equally well in a circular direction. When the steam-engine is only employed for some such purpose as pumping up water no crank is necessary; but as some of the most usual and valuable applications of the steam-engine are those where it turns wheels of mills, of cotton machinery, of steam-vessels, or locomotive engines, the crank, by which this is accomplished in an admirable and simple manner, which has superseded every other plan of transmission, is entitled to very minute consideration. On examining in detail the action of the crank, it is to be observed that the force exerted by the steam is neither constant in direction nor in action. If the steam be admitted first below the piston, it forces it to the top of the cylinder; it is then cut off, preparatory to its being admitted above the piston; and in the interval it has no motive action. When admitted above the piston, it forces it to the bottom of the cylinder; and again there is a cessation in its action during the change in the position of the valve. Now it is evident that this recurring cessation of action between the alternating impulses would interrupt the continuous revolution in the wheel, but for the power of the wheel itself to continue the motion, by what is termed the momentum of its mass. When the steam, during a stroke of the machine, is acting most powerfully on the piston, part of its power is spent in accelerating the wheel; and when, at the end of the stroke, it ceases for a time to act, the wheel gives out the power which it had gained, and continues its motion until the next stroke gives it a fresh accession of power. A wheel of this kind, when attached to an axle for equalizing motion, is termed a fly-wheel; and to obtain the full benefit of its equalizing power it is made of large diameter, that its rim may move rapidly, and it is made of great weight, being formed of iron, that it may acquire momentum to render the motion as uniform as possible.

From the circumstance that at one period the steam possesses no power of turning the crank, it has been imagined that some considerable loss of the power of the steam takes place during its transmission through the crank. This is a grave error. Figs. 81 to 84 represent the crank in different positions. In figs. 81, 84, the connecting rod and crank are in the same straight line, technically called the position "on the centre," or passing the line of centres, in which the action of the the steam neither tends to turn the crank in the one direction nor the other. Again at M and N (figs. 82, 83), where the crank is acted upon at right angles by the connecting-rod, it is plain that the whole force transferred through the rod is acting to turn the crank; while in the intermediate positions there are two efforts, one acting on the centre of the crank, and another to turn it round. For examining the proportion of these forces to each other, we may use the two following diagrams. Fig. 85 represents the circle of the crank, the arrows showing the direction in which the crank-rod would require to act, in order that all its force should be undivided, and produce alone the single effect of causing revolution.

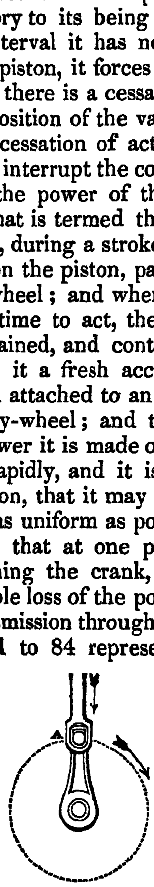

Fig. 81.

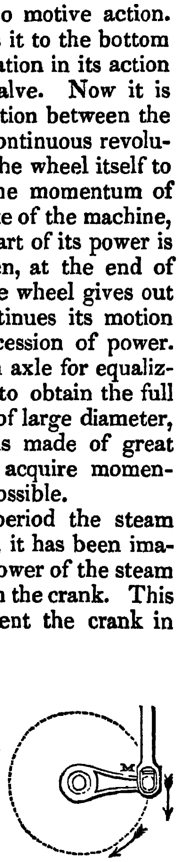

Fig. 82.

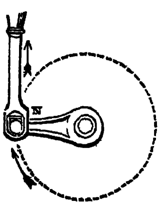

Fig. 83.

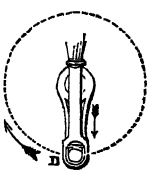

Fig. 84.

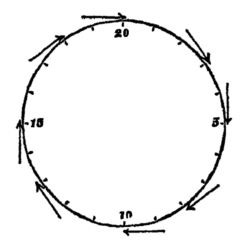

Fig. 85.

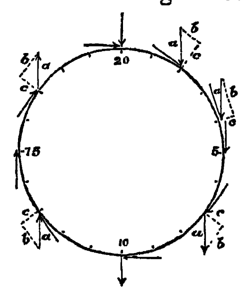

Fig. 86.

Fig. 86 indicates the deviation which the actual motion of the crank exhibits from this hypothetical condition. The arrow *a* indicates the direction of the action of the connecting-rod, which at divisions 10 and 20 is acting only towards the centre of the circle, with no effect in producing revolution. At divisions 5 and 15 the whole effect takes place in producing revolution only. Through the first half of the circle the pressure of the rod acts wholly downwards, and through the latter half of the circle wholly upwards. The circumference of the circle being divided into twenty equal parts, the analysis of the force is given in the figure at several of these points. At the second division, *a* represents the direction of action of the crank-rod; *b* is parallel to the direction of the circumference (or tangent) of the circle at that point, while the line *c* is directed to the centre; *a* indicating the direction of the whole force of the connecting-rod, *b* representing the effect produced in the direction of the tangent to turn it round, and *c* the effect of the force of the connecting-rod acting to produce pressure on the centre of the crank; but as the centre of the crank is fixed and prevented from moving, none of the moving power of the crank is given out in producing motion towards the centre, but only in producing motion in the circumference. At the fourth division of the circumference, it may be observed that the effect of the connecting-rod is differently distributed. The whole force *a* is now more nearly in the direction of *b*, and *c* is comparatively small; showing that, as we approach the end of the first quarter's revolution, the force of the connecting-rod is producing much less pressure in the centre of the crank, and pressing in a higher proportion in the direction of the revolving effect, until at last the connecting-rod being at right angles to the crank, its whole pressure acting to turn round the crank, none of it is directed towards the centre. After passing the quadrantal point 5, the crank-rod still presses downwards, as shown by the arrow *a* at point 7; but, of its two effective pressures, one represented by *b* still acts in turning round the crank, while another, represented by *c*, instead of acting towards the centre, as in the upper quadrant, now produces a pressure which would draw the crank away from the centre; but as the crank is fixed, none of the motive-power is employed in producing any motion of the crank away from its centre. Similar alternating effects are produced through the other quadrants; so that while the pressure of the steam, acting through the connecting-rod upon the extremity of the crank, is divided into two effects, one of these is prevented from expending the moving force of the engine by the fixedness of the crank-centre, and the whole motive-power is given out only at the circumference of the crank-circle in turning it round, but in a proportion of pressure that is continually varying from 0 to a maximum, and from a maximum to 0, through every successive quadrant of the circle. In order to simplify the inquiry, it proceeds, meantime, on the assumption that the pressure transmitted through the connecting-rod is constant. In general practice, with expansive-working and other circumstances, it varies, and the influence of this

The Crank and Fly-Wheel.

variation will be another subject for consideration. The variation of pressure circumferentially on the crank of a steam-engine may be conveniently represented by curves. Let the circumference of the circle described by the crank be represented by the straight line A X (fig. 87), and

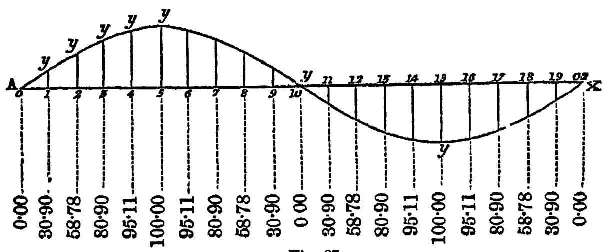

Fig. 87.

divided into any number of equal parts; let straight lines $y^1 y^2 y^3$, &c., be drawn to represent the amount of pressure converted into the direction of the motion of the crank, according to the line *b* in fig. 118, being the amounts represented in the line of figures, then the curved line A, *y y y x*, passing through the summit of all these lines, will represent the variation in the power of the crank at each instant of time, each ordinate $y^1 y^2 y^3$ being the pressure, and the area of the whole figure will represent the whole motive-power, having a maximum at y^5 and y^{15}, and a point of change of direction from pressure one way to pressure the opposite way at y^{10}.

Now, one method of equalizing the rotative pressure on the crank has been proposed, and is very generally adopted,—viz., to make two steam-engines act on the same axis by means of two cranks at right angles to each other, so that when the one ceases to exert force the other may be at its point of greatest force.

Thus, in figs. 88 to 91, two cranks are represented as coming from two cylinders, and attached to the same axis, so that when the one of them is at 0 the other is at 5, when the first is at 5 the second is at 10, and so on; so that while either is on the line of cessation of force, the other is at the point of maximum.

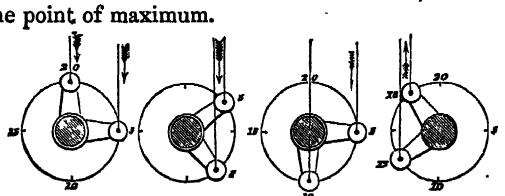

Fig. 88. Fig. 89. Fig. 90. Fig. 91.

The joint effect of two such cranks may be represented by curves in the following way:—Let the circumference of each crank-circle be represented by the lines A X, and $A^2 X^2$ (figs. 92, 93), as formerly, each semi-circumference being divided into eight parts, and let the pressure be calculated from a table of sines, where each will be found as the sine of the arch of the circumference to which it corresponds; the numbers thus obtained being set off on the base lines, the varying quantity of force, but without regarding the reversion of direction. If, now, we place these curves together, as in fig. 94, their whole ordinates taken across from the one curve to the other, will represent the amount of the sum of the forces and its variation; and if we place all these ordinates from a fourth axis, we shall have represented by the new curve (fig. 95) the variations of the sum of the forces of the two cranks.

When a lever intervenes between the crank-rod and the piston-rod, new irregularities are introduced. The variation in the direction of the connecting-link, and in the position of the lever-ends from a straight line, introduces modifications of these effects of a serious nature, but not of a large amount. It is worthy the attention of practical men to consider these variations, and the manner in which they affect the uniformity of the pressure. They affect it by way of increase at the beginning and end of the stroke. By proper arrangements these very obliquities may be ren-

dered very considerable improvements in the working of the engine. It should also be observed that the stroke of the piston and crank will not remain of the same length. The agency of the crank in transmitting a force parallel to the piston-rod has been represented by the curve of sines, as in fig. 96. But if we represent in a similar way the pressures produced by the obliquity of the connecting-rod, we shall find the form become that given in the following figures. Fig. 97 represents the variation of pressure with a connecting-rod of four times the length of the crank; fig. 98 with a connecting-rod of double the length of the crank; and fig. 99 with a connecting-rod equal to the length of the crank. It is obvious that with the shortening of the connecting-rod, the irregularity of the motion becomes very great. Two maxima rapidly succeed each other, and these are wide apart from the next pair. Thus two violent pressures succeed at a short interval, and a long pause intervenes when the force is very small.

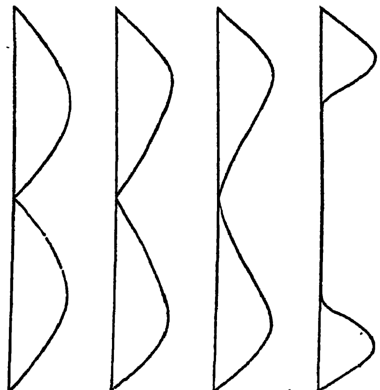

Fig. 96. Fig. 97. Fig. 98. Fig. 99.

Instead of using two cranks for applying the force of two steam-engines to the same axis of revolution, two engines have been used with their cylinders laid at right angles to each other, and having their connecting-rods applied to the same cranks.

CHAP. IV.—THE CONNECTING-ROD AND PARALLEL MOTION—THE GOVERNOR.

In considering the agency of the crank in modifying the force and velocity of steam, so as to connect its direction, and distribute its force in the manner required to produce a rotative motion in the machinery from the original reciprocating motion of the piston in the cylinder, we have hitherto avoided the introduction of another important element, by which a further variation of force and of motion is produced. The connecting-rod is a rigid bar of metal, which conveys the motion of the piston from the piston-rod to the crank, either immediately or through the interposition of the lever or beam; and as the connecting-rod, in doing so, takes various directions, different from those either of the piston-rod or of the crank, there is an obliquity of pressure

The Connecting-Rod and Parallel Motion.

produced at both extremities of the connecting-rod, which gives rise to a variation of force and of direction which must be practically provided for, and carefully appreciated in quantity, in so far as it may affect the ultimate operation of the machine.

There are two ways in which the motion of the piston-rod is most commonly transferred to the crank,—either immediately through the connecting-rod, as in fig. 100, or

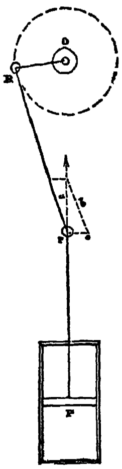

Fig. 100.

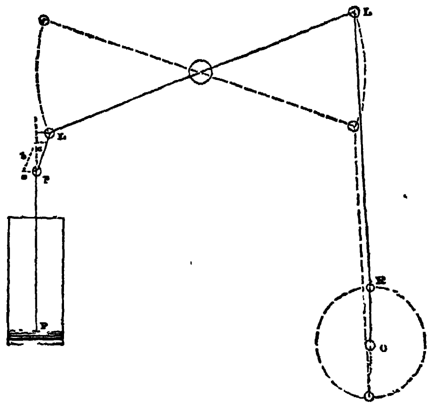

Fig. 101.

through the medium of the great lever, as in fig. 101, both ends of that lever describing circles around its middle fulcrum as a centre, and the head of the piston-rod being connected with the one end of the lever by means of an iron strap or connecting-link. From inspection of the figure it becomes plain that the connecting-rod or link is never, except at two points, in the same straight line with the piston-rod, so as to propagate its remodified force to the crank, but that in these oblique positions it would produce a lateral motion in the end of the piston-rod, which would not only be a waste of power in producing motion in a place where it is useless, but would have the effect of continually bending the piston-rod in opposite sides, so as either to break it or materially to impair its working. In the first of these figures, P p being the direction of the piston-rod, p R that of the crank, the force in the piston-rod in the direction $p\,a$ becomes resolved into two parts p R and $p\,c$, p R being effective in the direction of the crank-rod, and $p\,c$ tending only to give lateral motion to the piston-rod, or else to bend it or break it across. And so also in the second figure there is a similar separation of pressure. To prevent these oblique pressures from wasting the power of the steam, by producing lateral, useless, or injurious motions, is the object of a series of contrivances called parallel motions or parallel guides. The most notable of these we owe to Mr Watt.

Let it be supposed that we desire to prevent the top of the piston-rod p (fig. 102) from being moved by the obliquity of the connecting-rod pR, either towards the right or the left, then it is accomplished in the following way:—A fixed support s is found on one side of the piston-rod, and another on the other s^1, at equal distances from it, and two parallel bars $g\,s$ and $g^1\,s^1$ are placed between the piston-rod and these points, so that it may be steadied between them. These parallel bars are made so as to revolve freely round the points s, s^1, as centres, each of the ends g g^1 describing the circles g, g^3, g^1, g^2; from which it is evident that, if these rods were directly

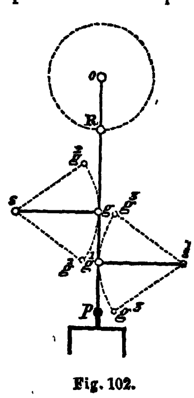

Fig. 102.

attached to the piston-rod at g and g^1, they should have the effect of keeping the point p in the straight line $o\,g\,g^1\,p$. As these bars $s\,g$ and $s\,g^1$ must describe circles round s and s^1, they would, in the positions $s\,g^2$, $s^1\,g^3$, deviate altogether from the straight line of the piston-rod; but as the one will act nearly as much in the one direction as the other in the opposite, it occurred to Mr Watt that, by connecting their extremities with a link $g\,g^1$, and attaching the piston-rod, not to the ends of the guide-bars, but to the middle of this link, the point p might be prevented from deviating to any appreciable extent from the straight line. This is accordingly produced in a very simple way. The following figures, 103, 104, 105, show the effect of these links in various positions.

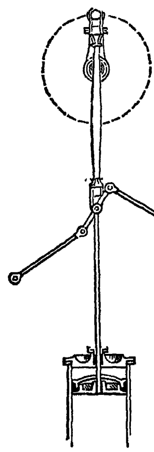

Fig. 103.

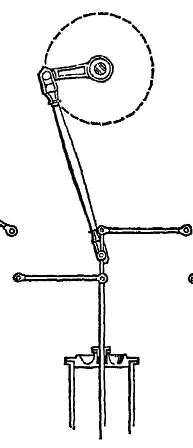

Fig. 104.

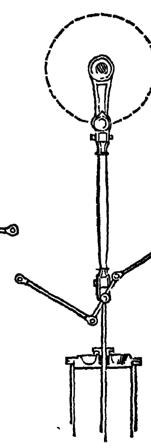

Fig. 105.

This elegant and simple contrivance is not, however, absolutely perfect. At the best, only a part of the line which it describes makes an approximation to a straight line, of scarcely sufficient length, and beyond which the stroke of the piston cannot be increased without being seriously deranged. Nor can this be remedied but by constructing the apparatus on a scale so large as to be highly objectionable. Thus, in the above arrangement, the point p is not kept perfectly in a straight line, but is, on the contrary, compelled to deviate from it so as to describe a looped curve. The nature of this deviation will become very evident if we suppose the parallel motion to be altogether detached from the piston-rod, and the motion of the parallel bar and link carried to its extreme, as in the following figures, 106, 107. A pencil being used to trace the motion

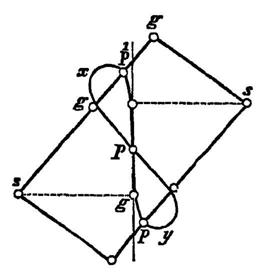

Fig. 106.

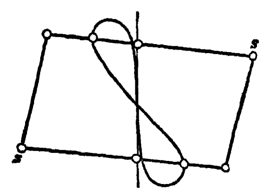

Fig. 107.

of the middle point, p will describe, not a straight line, but a curve $p\,x\,y$. When we carry the rods up to the position represented in fig. 106, where the bar $g\,s$ comes into the straight line with the link $g\,g$, the point p deviates from the straight line by turning to p^1; and this is reversed in the opposite extreme. In figure 107 the deviation is much greater when the link $g\,g$ comes into the same line with the other bar $g\,s$, and is also reversed in the position at the bottom of the figure. By the time the links have been re-

The Connecting-Rod and Parallel Motion.

The Connecting-Rod and Parallel Motion.

turned to their primitive position, they have described the curve $x\,p\,y$.

It is important to diminish this deviation, which increases more rapidly than the square of the length of the stroke. Having ascertained the greatest deviation at the end of the stroke, and also at $\frac{1}{8}$th part of the stroke from the middle, bring the centres s and s nearer each other by a quantity equal to the deviation at the said eighth part, and the greatest deviation will now be reduced to less than one quarter of its former amount; the curve will now become a line of the sixth (eighth ?) order.

The parallel motion of one point having thus been secured, it is easy to transfer it to any other point. This is most commonly done by a pointed parallelogram. Thus, to transfer it to a point in connection with $s\,g$ prolonged to t (figs. 108 to 110), take a second link $t\,q$, equal to $g\,g$,

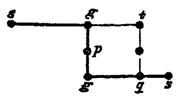

Fig. 108.

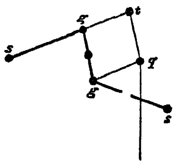

Fig. 109.

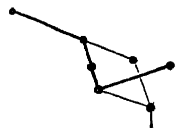

Fig. 110.

and a second bar, called the parallel bar $g\,q$, equal to $g\,t$, the corner q of the parallelogram will give a motion $t\,q$ similar to p. Figs. 111, 112, show the parallel motion

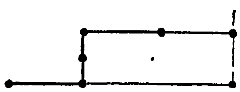

Fig. 111.

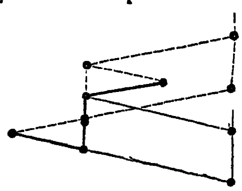

Fig. 112.

transferred to a point still farther from the original point.

Another form of Mr Watt's invention consists in placing two bars in the same direction, with such a difference in their length as may afford the means of compensation. Suppose that the point p (fig. 113) is to be guided to move

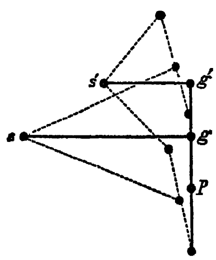

Fig. 113.

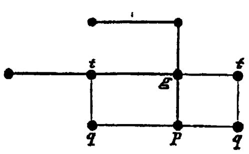

Fig. 114.

in the straight line $p\,g\,g'$; $s\,s'$ are points on the same side of the required direction of motion, and $s\,g$, $s'\,g'$, are the differential bars connected by a link $g'g$, which is prolonged to p. The dotted lines of the figures show the bars in different positions. The point p does not describe a straight line, but a curve, like figs. 106, 107. The motion of the point p may be transferred to a distance, as in the former instance, by a jointed parallelogram $g\,p\,t\,q$ (fig. 114). All these parallel motions may be inverted, and, indeed, generally are inverted, in steamboat engines. For practical examples of them the reader may consult the plates.

All these motions, as well as the first, being imperfect, various plans have from time to time been adopted for remedying the evil. In American steam-engines, Watt's parallel motion has been to a great extent abandoned, because in them long strokes and long cranks are preferred; and because, in such cases, the deviations of the point p—that is to say, of the piston-rod from a straight line—would, with Watt's method, become excessive. Watt and his assistants and followers were perfectly aware of this, and hence were led to construct beams, and connecting-rods, and parallel motions, of very great length, so as to diminish the evil as far as possible. This has, of course, the effect of rendering the whole engine both bulky and expensive, and is, therefore, in many cases inexpedient. The American engineers, therefore, use the sliding parallel motion; that is, they have substituted for the radius bars of the parallel motion of Mr Watt a sliding-bar or groove, in which the top of the piston-rod is guided. The head of the piston-rod p (figs. 115, 116) is enclosed between two flat surfaces, or between two parallel iron bars, which are kept in the vertical position by means of stiff framing; on these it slides, or, to diminish the friction, wheels may be added; but there are reasons why such wheels do not, in practice, work very well, and the plain slide is therefore preferred. In fig. 115 we have represented this motion as applied to

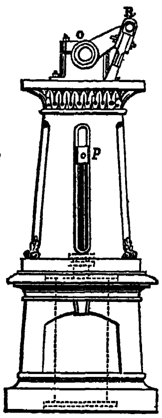

Fig. 115.

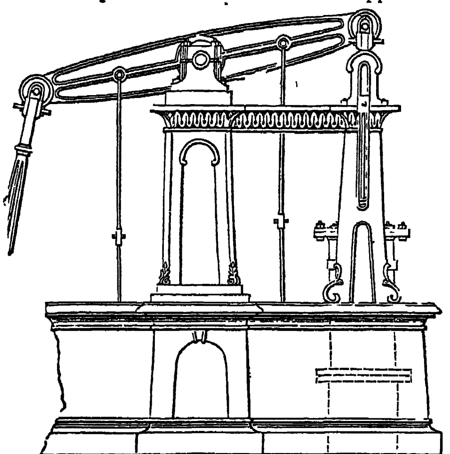

Fig. 116.

an engine of the simplest form; and in fig. 116, to a beam engine. In locomotives and some classes of marine engines, the guide-bars are universally employed.

Another species of parallel motion was, we think, first adopted in America; but it has also been used in this country. It is the engine with vibrating pillar. The pillar, which supports the beam or lever, instead of being fixed in an upright position, has a joint at the bottom, as will be seen in fig. 117, on which it, and the beam, and the

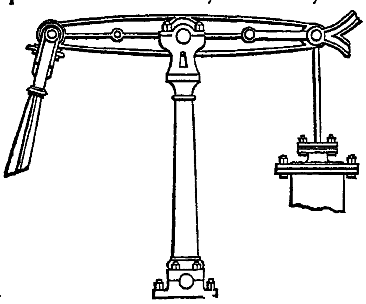

Fig. 117.

crank-rod perform a joggling motion backwards and forwards during each stroke. The motion is of the following nature:—The point s (fig. 118) is fixed; so is s'; $s\,g$ and $s'\,g'$ are moveable bars; $p\,g$ is $\frac{1}{2}$ of $p\,g'$. The point g describes a circle round s, and g' round s'; hence p describes the curve $p\,s\,p'$ of the sixth order. The oscillation of the moving mass of the engine in alternate directions, with a sudden jolt at the end of the stroke, renders this a bad engine when made

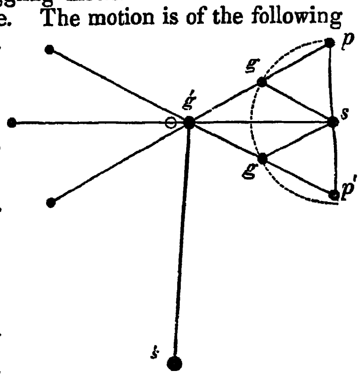

Fig. 118.

The Connecting-Rod and Parallel Motion.

on a large scale; and it is obvious that the deviation of the piston-rod from the straight line is very great.

But the principle which furnishes the most perfect parallel motion is one which, although not new, we have never seen applied to practice. It is well known that the locus of the extremity of a straight line, the middle of which moves in a circle, the other end being confined to one straight line, is also another straight line at right angles to the former. Let a straight bar $x\,y$ (fig. 119) be placed with one end y confined in an horizontal groove $a\,s$, and let a pin in the middle g be allowed to slide in circular groove $y\,g\,x$, then the end x will always describe a straight

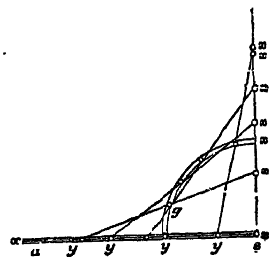

Fig. 119.

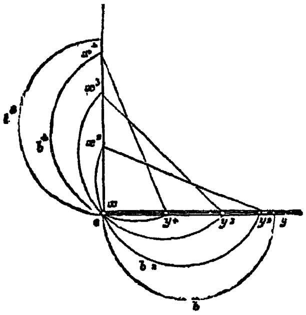

Fig. 120.

line $s\,x$ perpendicular to the first. Or it may be thus modified:—If the arc of a semi-circle have one of its extremities placed in a given straight line, while it moves along a given fixed point, the other extremity of the arc will describe another straight line at right angles to the former. Let a semi-circular round bar $y\,b\,x$ (fig. 120) be allowed to slide through a fixed centre at s, the one end y sliding in a groove, or along a bar $s\,y$, then the point x will describe the perpendicular $s\,x^4$, a perfect straight line.

To put this in practice in a form which shall not deviate widely from received forms of construction, is not difficult. The semi-circular groove and the semi-circular bar are not good constructive expedients. But if we take a radius bar $s\,g$ (figs. 121, 122, 123), fixed at a centre s, so that its end

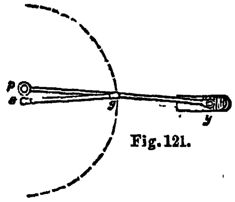

Fig. 121.

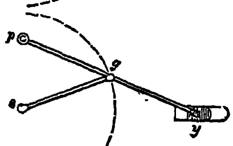

Fig. 122.

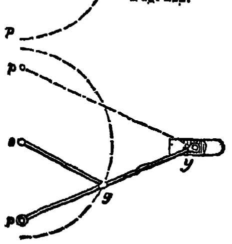

Fig. 123.

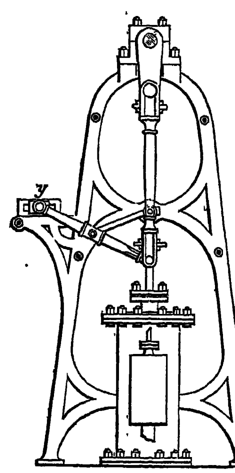

Fig. 124.

g describes a circle freely round it; and if we take a rigid bar $p\,y$ of double the length of $s\,g$, and united to it at g, then the middle of $p\,y$ being thus constrained to move in the circle round s, we have only to permit y to slide freely in an horizontal groove, and the point p being carried up and down, will describe the straight line $p\,s\,p$. Fig. 124 shows the application of this motion to the simple engine, and fig. 125 to the beam engine.

The Connecting-Rod and Parallel Motion.

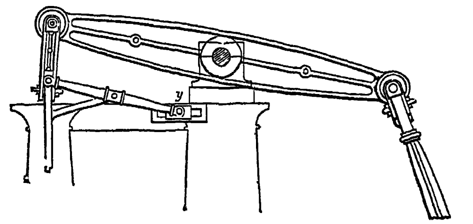

Fig. 125.

Such is the mechanism which the obliquity of the direction between the connecting-rod, or link, renders necessary to prevent any of the motion, propagated through them, from being expended in producing oblique transverse motion in the top of the piston-rod. Still, however, the motion of the piston-rod is modified by transference in an oblique direction, and we have now to consider the nature of that modification. With an indefinitely long connecting-rod, of which the angularity is inconsiderable, the relation of the motion of the crank and the piston is represented by the annexed diagram (fig. 126), in which $a\,c$ is the stroke of the piston, and $a\,b\,c$ the half revolution of the crank-pin simultaneously described. Let the path of the crank-pin be divided into equal parts at the points 1, 2, 3, 4, and draw verticals from the points of division to the line $a\,c$; then, as the angular speed of the crank is uniform, and the divisions of the circular path $a\,b\,c$ are equal, the line $a\,c$ will be divided by the perpendiculars already drawn into segments representing spaces described by the piston in equal times; and therefore, also, the varying average velocity of the piston in the same spaces. Whence it is obvious, that the speed of the piston, during one stroke, begins and ends at nothing at the extreme or dead points a, c; that it accelerates towards b, the position, at half stroke, when it reaches a maximum, and that beyond this point it is retarded till it gains the end of its stroke. The two halves of the stroke are described in equal times; and in these halves the variation of the velocity of the piston are exact counterparts.

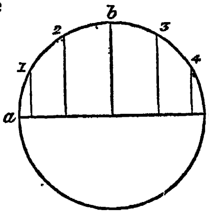

Fig. 126.

The obliquity of the connecting-rod destroys the symmetry here observed. In a stroke of the piston there are three cardinal points—the commencement, the middle, and the termination of the stroke. According to the preceding diagram, these three points are arrived at by the piston simultaneously with the horizontal and vertical positions of the crank. But the angularity of the connecting-rod at half-stroke of the piston virtually shortens its length, and the crank-pin is by as much short of its midway position. As the crank is presumed to move with a uniform angular velocity, it follows that the piston describes the two halves of its stroke with different average velocities, and in unequal times. In an engine, for example, with a stroke of 22 inches, and a connecting-rod $5\frac{1}{2}$ feet long, or six times the length of the crank, we find from the annexed diagram (fig. 127) of the relative positions of the piston and the crank, that, at half-stroke of the piston, the connecting-rod $a\,b$ falls short of the vertical centre line of the crank by the amount $o\,r$, fully 1 inch. Dividing the stroke of the piston into three equal parts, the connecting-rod being in the relative positions, $c\,d$, $e\,f$, the distances of the points d, f, from the centre line, are $o\,s$, $o\,t$, respectively $4\frac{1}{2}$ and $2\frac{3}{4}$ inches. The corresponding angular positions of the crank are, for the half-stroke of the piston, 6° with the vertical, and for the one-third of the stroke respectively 26°

The Governor.

and 15°. The sum of 26° and 15°, or 41°, is the angular motion of the crank during the middle third of the stroke,

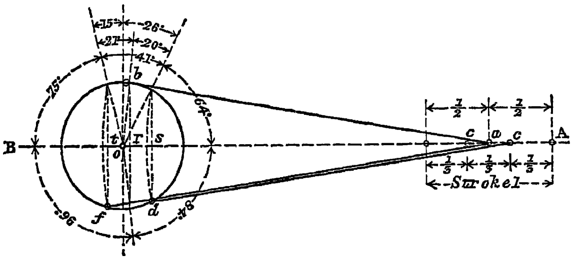

Fig. 127.

and the complements of these 75° and 64° are the angular motions for the extreme thirds. The average speeds of the piston, therefore, in describing the successive thirds of its stroke in the direction AB, are inversely as 64, 41, 75, or directly, as 6, 9, 5, nearly; and the two halves of the whole stroke are described with average speeds inversely as 84 to 96, or directly, as 8 to 7. The shorter the connecting-rod, the greater is the irregularity so introduced into the motion of the piston. The general effect, therefore, of the connecting-rod on the motion of the piston is, that the piston anticipates the position which it would occupy if the connecting-rod were "indefinitely" long at any point throughout the whole of the front stroke, which is described towards the crank; and that throughout the back stroke the piston is in the same degree behind the position due to the crank alone.

The Governor.—The governor is an appendage to a steam-engine of much value in regulating all its applications to the production of uniform revolving motion. It is merely a modification of an apparatus similar to the pendulum, and by which Huyghens once attempted to regulate a time-keeper instead of the common pendulum. If we suppose the axis Ax (fig. 128) to revolve along with the ball B, hung by a thread from x, and also with two pieces of iron xC, xC, bent so as to form cheeks, of a form called the cycloidal curve; then, when the string Bx comes in contact with those cheeks, the ball will perform each revolution in the same time as it would make two oscillations if merely swinging as a common pendulum; that is, if there be 39·1 inches from the centre of B to x, the pendulum will revolve once in two seconds. If, however, the ball B be suspended from x by a straight bar, such as Bx in fig. 129, the line Bx, in deviating from Ax, will describe the circular arch AB instead of a cycloid as formerly, and the time of oscillation will vary as the ball recedes from A, the revolutions being more rapid at b than at B. If, in the position B, the perpendicular height xC be 39·14 inches, then will the revolution be performed in two seconds, or at the rate of 30 per minute; while at b they will be performed in less time, and between B and A more slowly. The height Cx for any required number of revolutions is equal to the length of a simple pendulum, which will give double the number of vibrations in the same time.

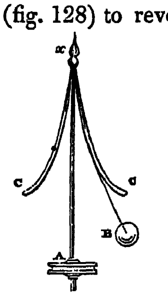

Fig. 128.

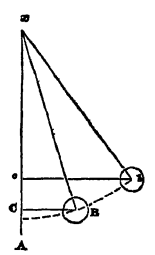

Fig. 129.

The regulation of the engine by the rate of the admission of steam to the cylinder is effected in the following manner:—The balls BB (fig. 130), showing Watt's original governor, are suspended by rigid bars from the fixed point or centre x. These bars, being prolonged to kk, are joined by links ky and ky to a moveable socket y, which can slide up and down the axis. The straight lever yp is acted on at one end by y, and at the other it draws up or pushes down the handle of a circular disc v, so as either to close or open it to different degrees; this disc, called the throttle-valve, is placed within or in connection with the steam-pipe that supplies the cylinder, so that if the engine should at any time move too slowly from having too much work to do, the balls will collapse, raise up y, and open v to the fullest extent, as at 4 in the small sectional figure to the right, 3 being the mean position; while, on the other hand, should the engine, from its work being taken off, go too quickly, the balls would fly off from the axis, bring down y, and close the valve to 2; or if it had happened, as by an accident, that the load was suddenly withdrawn, close the valve altogether, as at 1 in the side figure. Instead, however, of the bars being always, as here, prolonged above x, they have frequently the points $k\,k$ placed below x, and the socket y below these again, as in several of the plates and woodcut illustrations.

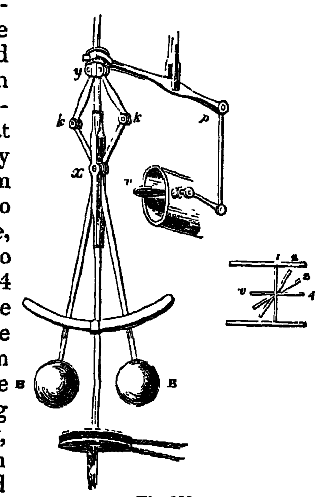

Fig. 130.

Distribution and Behaviour of Steam in the Steam-Engine.

SECTION II.—THE DISTRIBUTION AND BEHAVIOUR OF STEAM IN THE STEAM-ENGINE.

CHAP. I.—INTRODUCTORY.

It is within the cylinder that the power of steam is exerted and its work consummated, and our next business is to study the behaviour of steam in the cylinder, and to discover the conditions upon which its good working properties may most efficiently be turned to advantage.

Steam, as it is commonly employed, is drawn directly from the boiler, and is in the condition of maximum density for the pressure and temperature, under which it is generated and delivered over to the cylinder. The slightest reduction of temperature, or abstraction of heat, does, therefore, unavoidably incur the condensation of a portion of the steam. It is this peculiarity of ordinary or saturated steam—its sensitiveness to cold and susceptibility of condensation—which defeats the ordinary expedients for increasing its efficiency; and it is essential that the nature and extent of this distinction should be understood and appreciated, in order to show how it may be prevented.

From the detailed description already accorded to Watt's engines, it may be gathered that steam operates in the cylinder in a twofold manner—first, it is admitted freely from the boiler into the cylinder, following the piston, and exerting pressure upon it throughout a greater or less portion of the whole stroke; second, the communication from the boiler to the cylinder being cut off, the volume of steam thus enclosed within the cylinder continues, though isolated, to press upon the piston and to follow it to the end of the stroke, or at least for so far as the steam is therein confined—that is to say, the steam is "worked expansively." The energy resident in the steam, and of which only a part is utilised in following the piston direct from the boiler, is further utilised in virtue of the inherent elasticity of the body of steam cut off into the cylinder. Strictly speaking, the whole process is one of expansive action, as the steam admitted direct from the boiler flows into the cylinder by its elastic or expansive force, the boiler constituting the fulcrum, or "point d'appui," of

Distribution and Behaviour of Steam in the Steam-Engine.

action. The process is continued on a more limited scale within the cylinder, after the steam is shut off, the steam continuing, in virtue of the same elastic force, its expansive action against the piston, the end of the cylinders constituting the fulcrum. The boiler, of course, exercises independently its function of generating fresh steam to replace that which is expelled.

Although, however, there is no generic distinction between the admission of steam direct from the boiler to the cylinder, and the subsequent continuation of duty under the name of expansive working—seeing that it is but elastic action in both cases—yet it is convenient in practice to draw a line of demarcation between the period of the stroke during which steam is admitted into the cylinder and the period during which it is simply expanded therein. The different conditions of the pressure or elastic force during these two periods is usually quite apparent in the indications of the internal pressure which, by means of suitable instruments, may readily be observed and registered, where proper proportions subsist in the mechanism employed for the distribution of the steam; but in certain conditions the distinction is obliterated, and the steady uniform pressure with which the entering steam ought to take its place in the cylinder merges frequently in the descending pressure characteristic of simply expanding steam. This descending pressure, indicated while yet the communication between the boiler and the cylinder is not finally cut off, is the result of what is expressively called "wire-drawing" the steam, the current of steam into the cylinder being partially intercepted at the "port" or entrance, by the nearly-closed valve or slide, and thus wire-drawn, "throttled," or spun into steam of reduced density and pressure. Thus, then, in consequence of what is technically considered an imperfection of mechanism, interrupting the flow of steam before it is fairly shut off, the process of "expansive working,"—an economising process and nominally initiated when the cylinder is fully closed,—may be anticipated at an earlier part of the stroke.

In describing the cycle of events known as the "distribution," or the ordering of the steam admitted to and subsequently discharged from the cylinder, it should be noted, by way of recapitulation—speaking of engines as ordinarily formed—that with the cylinder is associated the valve-chest or steam-chest, into which the steam from the boiler enters previously to its passing into the cylinder,—an ante-room where the steam waits in readiness to enter the cylinder when admitted. The form and position of the chest or chamber varies indefinitely with the design of the engine. From this chest three passages are formed, one leading to each end of the cylinder, and the third passage leading to the condenser or to the atmosphere, or otherwise for the exit of the steam from the cylinder. The orifices of these three passages or thoroughfares are known as ports, and are usually brought together and placed parallel, terminating in a flat surface on the side of the cylinder, on which the valve reciprocates. The function of the valve is to distribute the steam, for which purpose it is impressed with a simple reciprocating motion, by which it alternately covers and uncovers each port leading to the cylinder, admitting the steam from the chest, suppressing or cutting it off, and ultimately releasing it from the cylinder by opening a means of exit by the third port already mentioned. The reciprocating motion of the valve is derived from an eccentric, in the simpler forms of mechanism, fixed on the driving-axle, and revolving with it. The linear motion derived to the valve from the eccentric is, on a smaller scale, exactly similar to that of the piston in connection with the crank.

That the steam may gain admission to the interior of the cylinder at the commencement of each stroke, the eccentric is so set on the axle, in advance of the crank, as to have the valve moved sufficiently aside at that juncture, that the steam-port may be uncovered by a small amount known as "lead," at the beginning of the stroke. When the piston has described a portion of the stroke, the valve returns in obedience to the return of the eccentric, and closes the port, thereby shutting off the further supply of steam to the cylinder behind the advancing piston; and confining what has been admitted, during an additional portion of the stroke. As the valve continues in its retrograde motion, it uncovers the steam-port on the inside, while the piston is still some distance from the end of the stroke, and opens the way out of the cylinder for the steam within, from which accordingly it emerges, and rushes into the condenser or the atmosphere. This external communication continues open, not only to the end of the "steam-stroke" through which the course of the piston has been traced, but also during the greater part of the "return-stroke," while the steam from the valve-chest is busy on the other face of the piston. Shortly before the completion of the return-stroke, the valve, in the regular course of the motion prescribed for it by the eccentric, closes the port to the atmosphere, and, finally, at a very small distance from the end of the return-stroke, the port is again opened, and the valve obtains the necessary lead in timely preparation for the entrance of steam from the valve-chest, before the commencement of the next steam-stroke, and the development of the full steam-pressure on the piston for another cycle of duty.

The periodical and cotemporaneous operations of the piston, the valve, and the steam, just described for one end of the cylinder and one face of the piston, take place independently for the other face of the piston; so that, two performances are proceeding together in one cylinder, and the engine is thence denominated double-acting. Four distinct events take place in consecutive order with respect to each end of the cylinder—first, the admission of the steam at or just before the beginning of the stroke; second, the suppression of the steam; third, the release or exhaust of the steam; and finally, the lock-up, or compression of the exhaust steam, prior to the opening of the port for admission. These four events together constitute the "distribution" for the cylinder, and their durations, measured in parts of the stroke, are the "periods of the distribution." By the aid of the indicator, which, as its name implies, is a sort of stethoscope for the observation of what transpires within the cylinder—a simple instrument for receiving and registering the tension of the steam—a minute and accurate picture of the operations within is transferred by pencil to paper, affording valuable and indeed indispensable data for the measurement of the power and efficiency of the steam in the cylinder. But before proceeding with this part of the inquiry, the movement and action of the slide-valve, in its relation to that of the piston, had better be explained by the process of geometrical illustration.

CHAP. II.—GEOMETRICAL ILLUSTRATION OF THE ACTION OF THE SLIDE-VALVE.

Geometrical Illustration of the Action of the Slide-Valve.

As the path of the crank-pin is represented by a circle, and the stroke of the piston by a straight line, equal to the diameter of that circle, so also the path of the eccentric is represented by a circle, and the travel of the slide-valve by a straight line, equal to the diameter of the eccentric circle—assuming, for the sake of illustration, that the valve is actuated in direct connection with the eccentric. If, then, two circles be described on a common centre O (fig. 131), for the crank-path and the eccentric-path respectively, their diameters AB, *ab*, are the stroke of the piston, and the travel of the valve. When the piston is at one end of the stroke at A′, the valve is opening the port at *a*″, and is just as much in advance of its middle position over the ports as is needed to

Geometrical Illustration of the Action of the Slide-Valve.

draw the lap clear off the edge of the port at a', in addition to the lead or opening of the port at the beginning of the

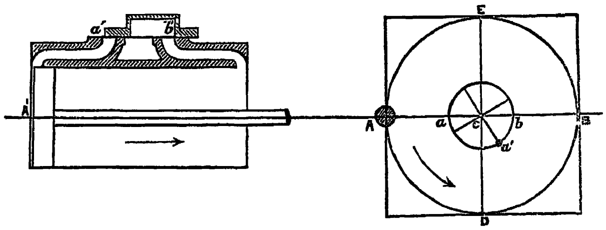

Fig. 131.

stroke. The position of the eccentric, then, (represented by its own revolving-centre), must be at the point a'', which is in advance of its position at half-throw, in the line DE, by as much as the lap *plus* the lead. As the axle revolves, the valve is further opened by the retiring eccentric, till it falls into the line AB, when the crank is getting on to half-throw. When the crank has attained to half-throw, in the position CD, the eccentric is on its way returning, and the motion of the valve is reversed on the way to close the port. The port is actually closed sometime before the valve and the eccentric return to their midway position—the former over the ports, and the latter in the line CE,—in virtue of the lap on the valve. Further, when the valve and the eccentric do arrive at their middle positions, half-travel and half-throw, the edge of the cavity of the valve coincides with the inner edge of the steam-port, and the opening of the port to the exhaust-passage, through the medium of the cavity, is forthwith established by the progressive motion of the valve. All that has just been described of the operation of the eccentric on the valve is effected before the crank completes a half-revolution, that is, before the crank-pin arrives at the point B, and, consequently, before the piston completes its stroke. The valve, indeed, makes another change before this; it opens the other port at b', for the other end of the cylinder, the lap having been completely withdrawn, and an additional movement for the lead effected, just as the stroke is completed.

The successive positions occupied by the valve during a revolution of the crank may be graphically represented, as in fig. 132, where AB and ab, being the circles of the crank

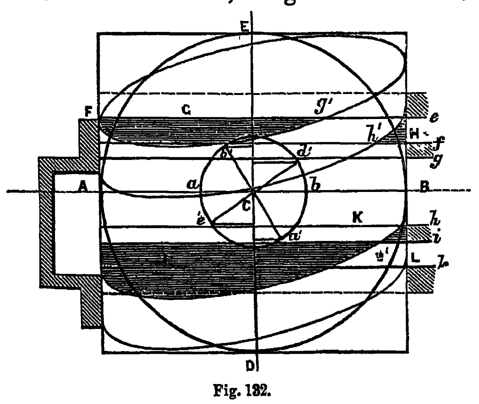

Fig. 132.

and the eccentric respectively, are divided into any equal number of parts, of which the points A, a', are respectively the positions of the crank and the eccentric at the beginning of the stroke; the other points, B, b', D, d', E, e', show the simultaneous positions of the crank and eccentric at intervals of one-fourth of a revolution. Draw the lines e, f, g, h, i, k, parallel to the centre line AB, spaced apart at intervals, equal to the exhaust and steam-ports and the intervening bridges; ef and ik being the steam-ports, and gh the exhaust-port. Place the valve on the perpendicular at A, in the right position with respect to the parallels e, f, k, for the commencement of the stroke, showing the requisite lead at F, and set off its positions on the face of the diagram, according with the positions of the crank. The elliptic lines, traced so as to connect these positions, represent the linear motion of the valve relative to the ports and to the crank, and, with the aid of a little shading, they clearly show the successive periods and changes of the distribution, subject, of course, to correction for the angularity of the connecting-rod. The shaded space G shows the period of admission, terminating at g'; and the shaded space H, the period of exhaustion, commencing at h'. The shaded space I shows the exhaustion for the alternate end of the cylinder, K the compression, and L the short period of pre-admission of steam for the following stroke.

The Indicator-Diagram.

On the same system, diagrams of motions may be constructed for any other proportions, or other species of valve, whether double or superposed valves, conical valves, moved by cams, or with conditions otherwise varied. The link-motion, as a variable expansion gear, operates by varying the travel of the valve; the extra expansion, and diminished period of admission, being affected by the shortening of the travel:—the result being precisely the same as if an eccentric of correspondingly smaller throw were substituted for an eccentric of greater throw.

CHAP. III.—THE INDICATOR-DIAGRAM—THE GENERAL BEHAVIOUR OF STEAM IN THE CYLINDER.

Proceeding to the investigation of the behaviour of steam in the cylinder, it may be noted that the action is fundamentally the same with condensing as with non-condensing engines; the difference being chiefly in degree. The receptacle into which the steam from the cylinder is discharged, is, in one case, the artificial atmosphere of the condenser, which causes an absolute pressure of 1 lb. per square inch, less or more; in the other case, the natural atmosphere, having a higher absolute pressure of 14·7 lb., or, in round numbers, 15 lb. per square inch. The action of steam is developed, in its most simple form, in the non-condensing engine, in which the question of the vacuum has no part; and the writer will, therefore, open the inquiry with a summary of his experimental analysis of the behaviour of steam in non-condensing engines, chiefly of the locomotive class, first published in 1851, in *Railway Machinery*.

In illustration of the function and utility of the indicator, by means of which most of the writer's observations were conducted, examples of indicator-diagrams, obtained by the writer from one of the cylinders of a locomotive, are illustrated in fig. 133. The base line A B is the line of

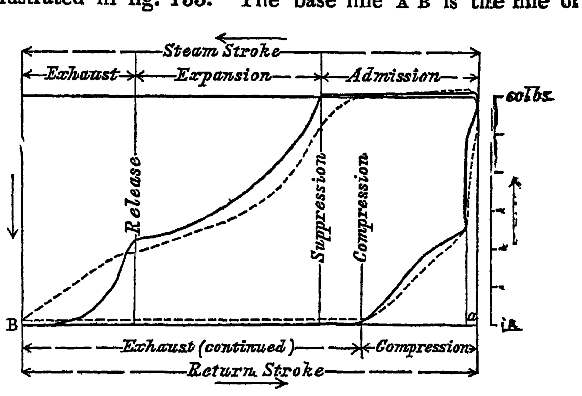

Fig. 133.

atmospheric pressure, and represents the stroke of the piston; and the rectangular space above it may be supposed to be the interior of the cylinder. The heavily lined figure is a diagram of the indicated action of the steam, when the piston moved in the cylinder at an average slow speed of

Behaviour of Steam in the Cylinder.

40 feet per minute, and shows, by its angularity, how the steam is controlled by the valve, and the precise points of the stroke at which the changes of the distribution take place. The piston is represented as having started from the right hand end of the cylinder, under a uniform pressure of 61 lb. steam above the atmosphere, traced from the upper right hand corner, till it reaches the point of suppression. The admission being terminated, the period of expansion is commenced, the pressure declines as the piston advances before the expanding steam, and continues to do so till the piston reaches the point of release. At this point the piston enters on its third and last stage of progress toward the end of the steam-stroke; the steam, primarily admitted at 61 lb. above the atmosphere, and attenuated to 23 lb. pressure previously to being released, quickly discharges itself into the atmosphere, in virtue of its remaining elasticity, and is entirely evacuated before the end of the stroke, as indicated by the quick and total decline of the steam-line during the period of exhaust towards the point B. The evacuation is, however, only relative, not absolute, as steam of atmospheric pressure remains in the cylinder, though not obviously sensible in the indicator-diagram; during the return stroke, therefore, the valve ought to maintain the exhausted end of the cylinder continuously open, to allow the steam of one atmosphere to escape before the returning piston, and the benefit of this provision is proved by the diagram, in which it appears that during the continuation of the exhaust the steam of latent pressure remains at the zero point of the scale. At the instant of closing or compression, however, when there is no longer an exit for the latent steam before the piston, the diagram-line slopes upwards towards the right hand side, and the steam is compressed against the end of the cylinder. While the volume of the compressed steam is being thus forcibly reduced, the density is increased, the pressure is raised, until the accumulation of back-pressure so induced is merged into the superior pressure of the steam admitted by anticipation for the business of the next steam-stroke. The point at which this irruption of pressure occurs is indicated by the small compartment *a* in the figure, representing the "period of pre-admission;" instantly the pressure mounts to the maximum initial pressure of 61 lb., in readiness for the succeeding steam-stroke.

The behaviour of the steam in the cylinder may thus, with the aid of the indicator-diagram, be clearly traced through the cycle of changes. The period of admission, in the example just described is, it appears, about one-third of the whole stroke; that of expansion is something more, and a simple inspection of the diagram shows that, in this instance, one-half of the work of the steam is performed by simple expansion while shut up in the cylinder. Even the period of exhaust supplies its quota of effect, inasmuch as the evacuation is a work of time, and the extra positive pressure so yielded is represented by the small triangular space between the point of release and the end of the stroke. The force developed by compression is properly designated resistance, as it is opposed to the motion of the piston, and must be classed with the slight opposition also made by the entering steam during its pre-admission for the steam-stroke.

But the important inquiry remains to be urged, How is the behaviour of the steam affected by the speed of the piston? If the piston move slowly, there is plenty of time for the steam to go about its mechanical duties. While the steam is admitted, it follows up the piston at full pressure; while the exhaust is open, it thoroughly evacuates itself. But at higher speed, the time for each evolution is proportionally shortened; and it remains to be considered, in what way this acceleration of duty is discharged. The dotted-line diagram, fig. 133, illustrates the behaviour of the steam in the same cylinder, under the altered circumstance of a higher speed of piston, averaging 310 feet per minute, other circumstances being the same. The steam enters at an initial pressure of 62 lb. per square inch, but suffers a slight reduction of pressure as the piston recedes before it —a circumstance which may at once be attributed to the accelerating speed of the piston in the cylinder, specifically due to the nature of the crank-motion, and the consequently greater difficulty of following it. The difficulty, however, is not considerable, and it is only when the piston nears the point of suppression, and the port is nearly closed by the valve, that the pressure rapidly falls in the diagram towards the suppression-line. This is a case of simple wire-drawing, as the opening of the port, previously wide enough to admit all the steam that could find its way into the cylinder, against the frictional resistance and bends of the passage, is now reduced to the minimum width consistent with this condition, and a further contraction and final closing necessarily occasions an accelerated fall of the pressure. The pressure at the instant of suppression, or cut off, under these circumstances, is 54 lb. above the atmosphere. The curve descends during the period of expansion, and cuts the line of release at a pressure of 19 lb., and on reaching the end of the stroke it attains a minimum of 2 lb. pressure. The curve of expansion, it appears, runs into those of the admission and the exhaust without any of the abruptness which distinguishes the slow diagram; the fact being that, before the steam was nominally cut off, expansion, technically so called, had begun—a result implied in wire-drawing—and there was therefore not the same liability to sudden change of pressure on entering the period of simple expansion. At the termination of the period of expansion, the curve crosses the exhaust line nearly at right angles, and barely reaches the minimum pressure at the termination of the stroke. The comparative delay so evinced in the accomplishment of the exhaust, is plainly a consequence of the shorter time allowed for this purpose by the greater speed of the piston; and, accordingly, we perceive a material accession to the area of the diagram, or the useful effect of the steam, in the very circumstance that it exhausts less freely. On the other hand, a drawback on this additional effect exists in the sustained back-pressure of 2 lb. per square inch, as indicated during the return stroke, referable to the same cause, imperfect exhaustion. The exhaust-line runs into the compression-line with a slight bend; and it is observable, that before the pre-admission takes place, the compressed steam attains to a higher pressure than that found by the slow diagram, a circumstance referable to condensation of steam in the cylinder at the low speed, which will be fully considered. But, though the curve of high speed is in advance of that of the low speed at the instant of admission of fresh steam, it falls behind at the commencement of the stroke; at this point the pressure does not get beyond 51 lb. above the atmosphere, and only attains the maximum, 62 lb., when the piston has described half an inch of the steam-stroke. This deficiency is attributable chiefly to the shortness of time allowed for the re-establishment of the working pressure, and indicates the need for more lead of the valve.

Behaviour of Steam in the Cylinder during admission.

CHAP. IV.—THE BEHAVIOUR OF STEAM IN THE CYLINDER DURING ADMISSION.

In the flow of steam from the boiler to the cylinder it meets with hindrances to its passage which usually operate to cause a considerable reduction of pressure when it reaches the cylinder, even if all the passages be thrown wide open. The actual charge of steam transmitted through an irregular passage of considerable length, and of a given sectional area, is, in all cases, less than what can be passed through an aperture, of a very short length, as in a thin plate of the

Behaviour of Steam in the Cylinder during admission.

same sectional area, owing to the bends and lateral friction of the long passage. It, therefore, frequently happens, that the opening of the port allowed by the valve, though it may be much less than the total area of the port, is sufficiently large to pass all the steam that can force its way along the passage. This fact is constantly exemplified in practice; it is known that opening the port beyond a certain amount, in all cases less than the area of the port itself, ceases to be advantageous in facilitating the passage of the steam into the cylinder. Similarly, the opening of the regulator, or "throttle-valve," beyond a small fraction of the sectional area of the steam-pipe, does not add to the available pressure at the valve-chest. When the steam is not dry, or contains water in suspension, the labour of moving in passages is greatly increased, owing to the quantity of dead inelastic weight to be dragged along, and the reduction of pressure is consequently much more than with dry steam.

Directing attention, for the present, to the behaviour of steam within the cylinder, it is to be premised that, notwithstanding the objections that have been urged against the ordinary slide-valve, worked by eccentric-motion, for want of sufficient celerity of action, there is no material wire-drawing of steam by the closing valve, when the period of admission exceeds two-thirds of the stroke, unless at very high speeds of piston, exceeding 500 to 600 feet per minute. When the steam is cut off at shorter periods, however, the travel of the valve being less, and therefore also its velocity of motion, the wire-drawing increases at high speeds, though at low speeds it does not. For example, the indicator-diagrams, fig. 134, were taken from a locomo-

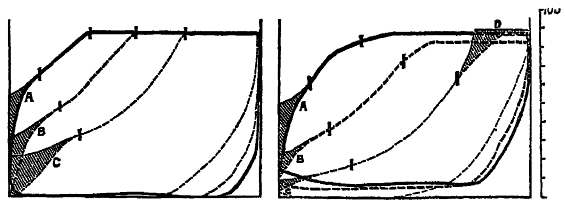

Fig. 134.

tive-cylinder, 18 inches diameter, 24 inches stroke; steam-ports, 13 inches by 2 inches; exhaust-port, 13 by $3\frac{1}{2}$ inches; lap of valve outside, $1\frac{1}{4}$ inch; inside, $\frac{1}{16}$ inch. Each figure shows three diagrams for periods of admission, respectively 16, $11\frac{3}{4}$, and 7 inches of the stroke, the terminations of which, and of the expansions, are pointed off on the figures; for the first figure the speed of piston was 240 feet per minute; for the second, 770 feet per minute. The wire-drawing at the lower speed was obviously nothing; at the higher speed, the pressure fell 3 lb., 12 lb., and 25 lb., below the initial pressure before the steam was cut off. This shows that the wire-drawing increased very much in proportion as the steam was cut off earlier—doubtless explained by the fact, that, in the three cases, the travel of the valves was, respectively, $4\frac{3}{4}$, $3\frac{15}{16}$, $3\frac{7}{16}$, inches; and the maximum opening of the port was $1\frac{3}{32}$, $\frac{11}{16}$ nearly, and $\frac{1}{2}$ inch. It was found, however, that, in the third case, with the shortest admission, the steam line was practically straight and parallel to the atmospheric line, at speeds of piston up to 450 feet per minute. In inferiorly arranged engines, with short lap and short travel of valve, wire-drawing is considerably greater than in the example just illustrated. With the same sizes of cylinders, a $\frac{5}{8}$ inch lap wire-draws considerably more than 1 inch lap of valve.

Long lap, in conjunction with wide ports, reduces the wire-drawing to a minimum. The more dry the steam is, the more susceptible it is of apparent wire-drawing, as indicated in the cylinder, because dry steam enters the cylinder more freely than wet steam, and attains a higher initial pressure.

As to the quantity of lead of the valve needful to insure ample and timely admission of steam into the cylinder at the commencement of the stroke, one-fifth of the length of the steam-port is sufficient. When the lead is excessive, the steam is admitted so readily as to be momentarily compressed, and to cause, in some cases, an unfavourable pulsatory action of the steam. The total absence of lead likewise occasions an unsteady pulsatory pressure in the cylinder. If lead is deficient, or wanting, the maximum pressure of steam in the cylinder is not attained until after a portion of the stroke is travelled by the piston.

Behaviour of Steam in the Cylinder during expansion.

CHAP. V.—THE BEHAVIOUR OF STEAM IN THE CYLINDER DURING EXPANSION.

When steam is admitted into the cylinder, while the latter is comparatively cold, or colder than the steam, a very sensible condensation of the steam takes place during admission, in the process of heating the cylinder to the temperature of the steam, which continues to a certain extent during the period of expansion. A portion of this heat, though but a small part, passes off and is lost; the remainder is retained by the cylinder until it is re-absorbed by the precipitated steam during the expansion of the remaining steam, if it be long enough continued—that is, until the temperature of the latter falls below that of the cylinder. This is a destructive process, occasioning an absolute loss of steam, and the amount of steam thus injuriously precipitated, and but partially revived, increases rapidly in proportion as the steam is earlier cut off and expansion extended. In the cylinders of ordinary steam-engines, the extra consumption and waste of steam devoted to the heating of the cylinder in the first part of the stroke is above 12 per cent. of the whole steam consumed for a period of admission of one-third of the stroke. In exposed locomotive cylinders, the loss has been proved to amount to nearly 40 per cent. of the whole steam consumed, when cut off at an eighth of the stroke.

This important species of loss is inseparable from the attempt to work steam expansively where there is no provision for the heating of the cylinder, and maintaining it at a suitably high temperature, equal, at least, to the initial temperature of the steam. The magnitude of the loss is so great as to defeat all such attempts at economy of fuel and steam by expansive-working, and it affords a sufficient explanation of the fact, in engineering practice, that expansive-working has been found to be expensive working, and that, in many cases, an absolutely greater quantity of fuel has been consumed in extended expansive-working, while less power is actually developed.

With respect to the ratio of pressure to expansion of steam in cylinders, observed in ordinary practice, it may be sufficient to remark in this place, that the quantity or weight of steam in the cylinder is the same throughout the process of expansion, estimated in terms of the pressure and the volume of the steam, as saturated at different points of the stroke, when the steam is dry, and the temperature of the cylinder is properly maintained; and that, consequently, the pressure of expanding steam in a cylinder, under such circumstances, may be determined with sufficient accuracy, for any degree of expansion, in terms of the ascertained density of saturated steam. On the contrary, in cylinders imperfectly heated, when the steam is partially precipitated during admission, and during the first part of the expansion, the expanding pressure at first declines more rapidly than would be due to the maintenance of a constant quantity of steam, and, afterwards less rapidly, rising above the expanding line of pressure, proper for a constant weight of steam, equal to that contained in the cylinder at the commencement of expansion. This want of conformity is exemplified in a diagram taken from an outside-cylinder locomotive, with a stroke of 24 inches, at a low speed (fig. 135), in which the dotted lines show the expansion-curve which

Behaviour of Steam in the Cylinder during exhaustion.

would have been described with a constant weight of steam. This process of successive condensation and re-evaporation is distinctly indicated: for, no sooner is the steam cut off at A, than condensation is made visible by the vertical sinking of the expansion-curve below the standard or normal curve, until the temperatures of the steam and the material of the cylinder become equal, when, as the pressure continues to fall, and the temperature of the steam with it, the curve rises and crosses the normal curve at C, in virtue of a partial re-evaporation of the steam previously precipitated, caused by the cylinder itself, which, at first colder than the steam, and heated by it in the first stage of the expansion, is then relatively hotter, and partially restores the heat of which it had previously robbed the steam. The process of restoration of heat goes on to the end of the expansion, as farther proved by the increasing excess of the indicated above the normal pressure at the point D, amounting to above 10 lb. per square inch at the point of exhaustion.

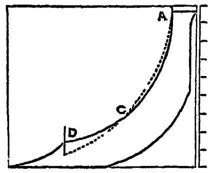

Fig. 135.

That the condensing power of an unprotected cylinder is something very considerable, is rendered very obvious by an indicator-diagram (fig. 136), taken from the same cylinder, in full gear, at a low speed, shortly after starting with a train. It shows that the pressure could not be maintained in the cylinder, as condensation in heating the cylinder proceeded faster than steam could be supplied through the opening of the port. Had the cylinder been hot, the pressure would have been fully maintained, according to the dotted line.

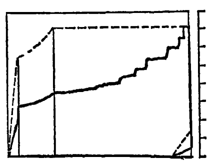

Fig. 136.

CHAP. VI.—THE BEHAVIOUR OF STEAM IN THE CYLINDER DURING EXHAUSTION.

In no part of the distribution is the advantage of time more apparent than during the period of exhaust. It is plain, by reference to figs. 133 and 134, that the steam does not discharge itself instantaneously from the cylinder at the point of release, as the piston, in all the diagrams, has visibly to go some distance before the pressure falls to a minimum. In fig. 133, at the lower speed, the piston moves $3\frac{1}{2}$ inches from the point at which the steam is released to the point at which the pressure falls to the atmospheric line. At the higher speed, the steam only reaches the minimum pressure of 2 lb., when the piston has attained to the end of the stroke, through 5 inches of the cylinder. These are elementary proofs of the benefit of time for insuring a good exhaust.

As the velocity of steam, escaping uninterruptedly, would practically suffice to evacuate the cylinder in good time, to prevent the evil of back-pressure, there is no doubt that the back-pressure which does actually arise is owing to the circumstantial hindrance of mixed water, strictures, bends, and friction. The retarded motion of the piston towards the end of the stroke, in virtue of the action of the crank, is peculiarly favourable for the exhaustion of the steam, as it allows time for its escape before the piston returns upon it. At the higher speeds, however, the escaping steam may be overtaken, and driven before the piston into the atmosphere, should its remaining elasticity prove insufficient, and then an opposing back-pressure is established. The wider the lead for the exhaust, the less is the back-pressure, on account of the increased facility for escape. For the usual speeds of pistons of stationary engines, about 300 feet per minute, the back-pressure is practically unimportant, if the cylinder be properly heated and the steam dry. On the contrary, the back-pressure is very great when the steam is condensed within the cylinder, or if it be loaded with water by priming. Fig. 137 shows, in contrast, the evil of condensation in a cylinder, in causing back-pressure. In the one case, the steam admitted at 80 lb. pressure above the atmosphere is cut off at one-sixth of the stroke, and exhausted at half-stroke, yet it is so loaded with water, when discharged, that it incurs a back-pressure of 12 lb. per inch in being expelled by the piston, moving at an average speed of 430 feet per minute. In the other case, illustrated in the same figure, the steam was admitted in a much greater volume, though half the stroke, at a speed of piston of 580 feet per minute, whilst the exhaust-pressure fell to about $2\frac{1}{2}$ lb. per square inch. The cylinder had been previously heated by hard work, the steam was comparatively dry, and the opposing pressure was, consequently, almost entirely removed.

Behaviour of Steam in the Cylinder during exhaustion.

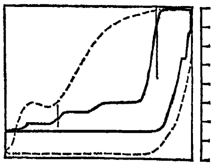

Fig. 137.

The ordinary effect of the priming of muddy water from a locomotive boiler is illustrated by fig. 138, in which are shown indicator-diagrams, taken from the cylinder immediately previous and subsequent to blowing off the boiler when the water had been unusually impure, at the same speed of piston, about 600 feet per minute. The full line was described before, and the dot-line after the boiler was supplied with clean water; and other circumstances being the same, the back-pressure fell from 9 lb. to about $1\frac{1}{2}$ lb. per square inch above the atmosphere. In some cases, the priming of water into the cylinder has been found to reduce the effective pressure more than a half.

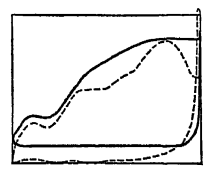

Fig. 138.

The blast-pipe of locomotives should be larger in sectional area than the steam-passages in the cylinder, in order to discharge the steam with facility. The orifice of the blast-pipe should not be less, and it need not be greater than the smallest part of the passage from the cylinder; if smaller, it increases back-pressure.

Summary of data as to Back-pressure.—If the steam working in steam-engines could escape freely, without resistance, the back-pressure would be simply the pressure of the atmosphere, in non-condensing engines; and, in condensing engines, it would be the pressure corresponding to the temperature in the condenser—what Professor Rankine calls the "pressure of condensation." The mean back-pressure, however, always—sometimes considerably—exceeds the pressure of condensation. One cause of this, in condensing engines, is the presence of air mixed with the steam, which causes the pressure in the condenser, and also the back-pressure, to be greater than the pressure of condensation of the steam. The ordinary temperature in the condenser, in proper working order, is about 104° Fahr., for which the pressure is 1·06 lb. per square inch; whilst the actual pressure in the best condensers of ordinary engines may be scarcely ever less than 2 lb. on the square inch.

The principal cause, however, of increased back-pressure is resistance to the escape of the steam from the cylinder, amounting to from 1 to 3 lb. per inch greater than the pressure in the condenser. Professor Rankine thus summarises the ordinary results of observation on the back-pressure in condensing engines:—

	Mean Back-pressure.
Ratio of expansion from $1\frac{1}{2}$ to 3.........	5 lb. per square inch.
Ditto.....................4 to 7.........	$4\frac{1}{2}$ to $3\frac{1}{2}$ lb. „
Ditto...................8 to 15.........	$3\frac{1}{2}$ to 3 lb. „

There is no doubt that, practically, in condensing engines, the back-pressure increases with the speed of the engine, and also with the density of the exhausted steam, and with

Relative Pressure of Steam in the Boiler, &c.

the size of the exhaust-ports. In non-condensing locomotive-engines, Mr D. K. Clark, in *Railway Machinery*, has found that the excess of back-pressure above the atmospheric pressure varies nearly as the square of the speed;—as the pressure of the exhaust-steam at the commencement of the exhaust;—and inversely as the square of the area of the orifice of the blast-pipe; that it is less, the greater the ratio of expansion; that it is less, the longer the time during which the exhaustion of the steam lasts; and that it is increased by the presence of liquid water amongst the steam.

CHAP. VII.—RELATIVE PRESSURES OF STEAM IN THE BOILER, THE VALVE-CHEST, AND THE CYLINDER.

As in the cylinder, so in the intermediate thoroughfares between that and the boiler, the movements of steam are affected by the conditions of dryness, as well as by the size and form of the passages. In well-protected cylinders, with dry steam, and ports $\frac{1}{15}$th of the area of the piston, the fall of pressure, or wire-drawing, in the cylinder-passages is about 16 per cent. of the pressure in the valve-chest, at a speed of piston of 600 feet per minute; and with a port $\frac{1}{10}$th the area of the piston, the fall of pressure does not exceed 10 per cent. at any speed. An example of the relative indicated pressures in the valve-chest and the cylinder of a locomotive is shown in fig. 139, when the former is represented to have oscillated above 5 lb. per square inch.

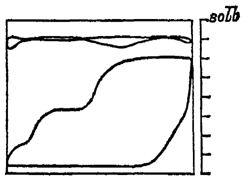

Fig. 139.

In imperfectly protected cylinders, when the steam is not dry, the fall of pressure varies from 20 to 40 per cent. The fall of pressure in passing through pipes less than $\frac{1}{16}$th of the piston in area, may be from one-third to one-fourth; in a pipe of $\frac{1}{10}$th the piston, the fall is inconsiderable. If the steam be highly dried, a pipe of ordinary length, $\frac{1}{13}$th the area of piston, is sufficient to transmit the steam undiminished in pressure.

The greatest useful opening of the regulator does not exceed $\frac{1}{20}$th the area of the piston. A greater opening is not found to add to the facility of transmission.

SECTION III.—MEASUREMENT OF POWER—HORSE-POWER.

CHAP. I.—MEASUREMENT OF WORK DONE IN THE CYLINDER FROM THE INDICATOR-DIAGRAM—FRICTION-BRAKES.

Definition of Work.—Work is an exertion of pressure through space. The unit by which quantities of work are measurable is the labour necessary to raise one pound weight through the height of one foot—that is, a foot-pound. The rate at which work is done is expressed in horse-power, and one horse-power is equivalent to work done at the rate of 33,000 lb. raised through one foot in one minute of time, or 33,000 foot-pounds—that is, one horse-power is expressed by the performance of 33,000 units of work per minute. The rather odd number 33,000 was adopted by the fathers of steam-engines, for the measure of power, because it was actually the measure of the performance of an average working-horse, under favourable circumstances; and though it was a useful and convenient measure at the time of its adoption, when horses rivalled steam-engines, the number 33,000 is only now retained because it is inconvenient to alter what has continued for so long a period to be the standard measure of power.

The indicator-diagram represents the active pressure and the back-pressure per square inch exerted by the steam on one face of the piston. During one stroke of the piston, therefore, if the steam-pressure be supposed to be exerted uniformly throughout the stroke, and if there be no back-pressure, the work done would be simply expressed by the product of the whole pressure on the piston in lbs. into the stroke in feet. The diagram expressing such an uniform exertion of force would necessarily be rectangular, and the product of its length in feet by its weight in lbs., measured by scale, would be an expression of its area, and would express the work done for one stroke per square inch of piston. If an uniform back-pressure were indicated, it would form a deduction from the useful pressure; and the difference of height representing power and resistance on the diagram, would be the effective pressure, which, multiplied by the length, would express, as before, the useful area of the diagram, or the useful work done per square inch of piston.

Measurement of Work done in the Cylinder.

But, in practice, the lines of positive-pressure and back-pressure on the diagram are not straight but curved. These conditions involve a preliminary process of reduction before the area of the diagram can be estimated, and the work for one stroke determined. Let the diagram be divided vertically into a sufficient number of parts by a series of parallels, drawn at equal distances across the figure transversely to the atmospheric line, representing the stroke of the piston; measure the mean effective pressure in each section by the scale, take the sum of the pressures thus found, and divide by the number of divisions of the diagram. The quotient is the effective mean pressure per unit of surface for the whole diagram. Multiply the effective mean pressure per unit of surface thus found by the area of the piston in the same units of surface, say square inches, and by the length of stroke in feet, and the resulting product expresses the whole effective work done upon the whole surface of the piston for one stroke. Reduce, in a similar manner, a second indicator-diagram for the other face of the piston, and take the mean of the two expressions of work done; or assume for a double-acting engine that the same quantity of work is done in the alternate stroke, multiply by the number of single strokes of the piston per minute, and divide by 33,000; the resulting quotient expresses the indicator horse-power of the engine.

If there be two or more cylinders to the engine, the power must be found in the same way for each cylinder, and the whole added into one sum, to express the entire indicator-power. But the simplest way in dealing with two or more cylinders, of equal diameters and strokes, working on a common main-shaft, is, first, to find from indicator-diagrams the average effective mean pressure on the whole surface of the piston, for all the cylinders; second, to multiply that by the length of the stroke, and by 2, and by the number of revolutions of the shaft per minute, and by the number of cylinders; third, to divide this product by 33,000. The quotient is the indicator horse-power.

On the contrary, should the cylinders be various in their functions, as in compound engines, in which a non-condensing and a condensing cylinder are combined, or should they be differently connected to the main-shaft, or have different diameters or lengths of stroke, it is better to find the power for each cylinder singly, and subsequently to sum the powers together, to find the whole. There is an advantage in this method of procedure, that the contribution of each cylinder, or class of cylinder, to the aggregate of power may be distinguished.

The friction-dynamometer measures the useful work done by a prime mover, by causing the whole of that work to be expended in overcoming the friction of a brake. The magnitude of the work done may be measured by a weight or a spring, as in Prony's dynamometer, in which the moving shaft or pulley is embraced by friction-blocks commanded by a lever weighted at the end.

Horse-Power of Engines.

CHAP. II.—HORSE-POWER OF ENGINES.

Horse-power is the term employed to express the capacity, magnitude, or power of an engine. It sprung from the actual measure of horse-power originally adopted by Mr Watt—namely, the performance of work at the rate of 33,000 foot-pounds or units of work per hour; or the raising of 33,000 pounds, 1 foot high, per hour. From the desire to give over-measure, just as the hundredweight rose from the original 100 lb. weight to 112 lb., as well as from the scanty means of exactly gauging the real power of engines, the horse-power rose to two, three, four, or five times that of actual horse-power; and thus, commercially, real or actual horse-power was altogether disregarded, and was replaced by what is called "nominal horse-power," the estimation of which is based simply upon the dimensions of the cylinder. "Nominal horse-power" is not, then, in any sense, horse-power, but is a commercial unit of capacity or power of performance, to fix the magnitude of the engine, and the price which is to be paid for it. But, even nominal power is not estimated by any uniform standard; individual manufacturers and others adopt different measures, and a uniform and universally recognised measure of power is a desideratum.

Different rules are applied to condensing and to non-condensing engines, the effect of which is to give a larger allowance of capacity to the former than to the latter. For condensing engines, the following are a few of the rules in use:—

Boulton and Watt's Rule.—Assume the speed of the piston to be 128 feet per minute, multiplied by the cube root of the length of stroke in feet; and the mean effective pressure to be 7 lb. per square inch. Then, nominal horse-power $= \frac{\sqrt[3]{\text{stroke in feet}} \times \text{diameter}^2 \text{ in inches}}{60}$. This rule is much in use in the south of England, and to some extent in Manchester.

Manchester Rule.—The common rule is to allow 23 square inches of piston per nominal horse-power; or, nominal horse-power $= \frac{\text{area of piston in inches}}{23}$. Occasionally, 30 is used for the divisor.

Leeds Rule.—This rule is taken in terms of circular inches of piston, or the simple square of the diameter, allowing 30 per nominal horse-power; thus, nominal horse-power $= \frac{\text{diameter}^2 \text{ in inches}}{30}$. This is, practically, almost identical with the Manchester rule, as 30 circular inches are equal to 24 square inches.

For non-condensing engines, the usual rules are as follow:—

Manchester Rule.—Ten square inches of piston are allowed per nominal horse-power; or, nominal horse-power $= \frac{\text{area of piston in inches}}{10}$.

Leeds Rule.—Sixteen circular inches are allowed; thus, nominal horse-power $= \frac{\text{diameter}^2 \text{ in inches}}{16}$.

Glasgow Rule.—Square the diameter of piston in inches, and point off the unit figure. The result is the nominal horse-power. This is the same in form as the Manchester rule, as it is essentially a process of division by 10. The Leeds rule is more liberal than the other, as 16 circular inches are equal to about 13 square inches.

For compound engines, having both non-condensing and condensing cylinders, it is the custom in Leeds to throw in the small or non-condensing cylinder, taking no account of it, and to rule from the condensing cylinder only.

The elements of a sound and comprehensive rule for the power of steam-engines must comprise the mean speed of the piston, its area, and the mean effective pressure. The mean speed is based on the stroke and the number of revolutions in a given time; and as a given number of revolutions is usually required, the formula should contain these two data individually. The effective pressure, also, is the result of the positive and negative pressures, in the boiler on the one part, and the exhaust-pressure on the other part, with the additional element of expansive-working.

Actual horse-power, reckoned according to the principle with which Mr Watt originally started, of dealing with actual quantities, should constitute the basis of a revised code of rules for nominal power. There are two forms in which it may be reckoned: as the indicator horse-power, or the power communicated to the piston, undiminished by friction, measured by the indicator; or as the power delivered at the main or crank-shaft, measured by the brake, which is less than the indicator-power by as much as the friction of the mechanism of the engine employed in transmitting the power from the piston. For commercial purposes, the friction of the engine should be a consideration.

The indicator horse-power of a cylinder, reckoned in terms of the effective mean pressure in lbs. per square inch on the piston, the diameter in inches, the stroke in feet, and the revolutions per minute, is computed thus:—

$$\text{Ind.-h.-p.} = \frac{\text{pressure} \times \text{diam.}^2 \times \cdot 7854 \times \text{stroke} \times 2 \times \text{No. of turns}}{33{,}000}.$$

$$\text{,,} \quad = \frac{\text{pressure} \times \text{diam.}^2 \times \text{stroke} \times \text{No. of turns}}{21{,}000}.$$

$$\text{,,} \quad = \frac{\text{pressure} \times \text{area} \times \text{stroke} \times 2 \times \text{No. of turns}}{33{,}000}.$$

Horse-Power of Boilers.

CHAP. III.—HORSE-POWER OF BOILERS.

The nominal horse-power of boilers is reckoned variously —from the lineal, and from the superficial, dimensions. The old waggon boiler was reckoned at the rate of 1 foot in length per nominal horse-power. For ordinary cylindrical boilers without internal flues, $5\frac{1}{2}$ to 6—usually 6—square feet of horizontal area is allowed per nominal horse-power, the area being taken as the product of the diameter by the length in feet. For boilers having one or two internal fire-tubes, or "Cornish boilers," the diameter of the flue-tube is added to that of the shell to find the proper multiplier. Galloway allows only $5\frac{1}{2}$ to 4 square feet of horizontal area in his boilers, as they have upright water-tubes in the flues, available as heating surface.

Again, reckoning by superficies, 15 square feet of heating surface, and 1 square foot of fire-grate, are commonly allowed per nominal horse-power; the heating surface comprising the actual area of the shell exposed to heat, but only the upper half of the internal flues. For multitubular boilers, of the locomotive type, 16 to 20 square feet of the total heating or exposed surface, and $\frac{1}{2}$, $\frac{2}{3}$, or $\frac{3}{4}$ square foot of fire-grate, are allowed per nominal horse-power; that is, more heating surface, because it is not considered so effective, and less grate used, because the draft is stronger than in Cornish boilers.

SECTION IV.—CLASSIFICATION OF STEAM-ENGINES, WITH EXAMPLES.

The modern steam-engine, comprising under this general designation, the engine proper, and the boiler and furnace, has been moulded into many varieties of form, according to the systems on which it has been constructed, and the various uses to which it has been applied. Irrespective of the uses to which engines are applied, they are distinguished into the two great classes of *condensing engines*,

and *non-condensing engines;* the former exhausting the used steam into an artificial atmosphere of low pressure; the latter exhausting into the natural atmosphere of 14·7 lb. pressure per square inch. The former class is usually more efficient in the production of power from fuel than the latter; but the latter has fewer parts and is simpler in design.

The second classification is based on the uses to which steam-engines are applied, thus:—*First*, stationary-engines, placed in permanent situations, for driving factory-machinery, pumping water, &c. *Second*, portable-engines, placed on wheels, or transportable, to be shifted to the scene of operations, to do the work of stationary-engines. *Third*, locomotive-engines, for propelling vehicles on land, chiefly on railways. *Fourth*, marine-engines, for propelling vessels on water. With the first, second, and third, it is the province of this article to deal; the fourth is reserved for a separate article.

CHAP. I.—STATIONARY BEAM-ENGINES.

Stationary beam-engines are usually made with condensers, and may be typified by the large engines erected by Messrs William Fairbairn and Sons, Manchester, to drive the machinery for preparing, spinning, and weaving alpaca fabrics, at the Saltaire Mills, near Bradford, the property of Mr Titus Salt. The engines are arranged in two pairs, to obtain the requisite uniformity of action, and are placed in large engine-houses on either side of the front entrance to the buildings; and they are supplied with steam from boilers placed in a boiler-house beneath the surface of the ground, and a short distance in front of the mills, according to the general plan and sectional elevations of the engine and boiler houses, Plate XVIII. The following is Mr Fairbairn's account of the Saltaire engines and boilers:—

The Engines.—"Plate XIX. contains a side elevation of one of these engines, giving a general view of the arrangement of the parts. The power generated in the cylinders C, and transmitted through the working beam B B, to the large spur-flywheel W, 24 feet in diameter, is taken direct from its circumference by the pinions P, P, which give it off at the required velocity to the shafting of the mill.

"The working beam is supported on two massive columns *c*, 16 feet high, 14½ inches in least diameter, and 1¼ inch thick of metal; these columns are bolted down beneath the whole mass of masonry supporting the engine. The heavy entablature *e* bolted to each column, and to the columns of the adjoining engine, is firmly fixed in the walls of the engine-house on each side, and the spring-beams A, A, over this and at right angles with it, are similarly attached to the cross-beams, *b*, *b*. In this way an exceedingly strong and rigid support is secured for the main centre of the engine, which, resting in its pedestal *a*, has to sustain the principal strain of working. The spaces between the spring-beams and walls, excepting where the main beam vibrates, are filled with ornamental perforated iron-plates forming the beam-room, approached by the staircase *f*, for the purpose of oiling the centres, repairs, &c. The working-beam receives its motion from the piston-rod *g*, through the parallel motion *h h*, and transmits it by the connecting-rod F and crank G to the fly-wheel W.

"The steam is brought from the boilers through a prolongation of the tunnel in which the smoke passes to the chimney, and enters the engine-house by the pipe D. Having thence been admitted to the cylinder through the valve-chests K K, it repasses, after it has completed its work, to the condenser H, through the eduction-pipe E, in the usual way. The condenser is supplied with cold water from the river Aire, by the pipe *k k*, which communicates with the cold water cistern J; the injector through which the water enters is in these engines 6 inches in diameter, but the supply of water may be diminished if necessary by the injection gear hereafter described. Beside the condenser is the air-pump, for pumping out the water and the air which enters with the water into the condenser, and is worked by the rod *l l* from a part of the parallel motion. A pump to supply the cold-water cistern is worked by the rod *n*, and another pump is worked by the rod *p p*, by which part of the hot water from the condenser is pumped back again for the supply of the boilers, in proportion as the water in them is decreased by the evaporation into steam. The supply of steam to the engine is regulated by the governor N acting on the throttle-valve *q*, and thus the speed of the engine is kept uniform. A shaft *s s*, receiving motion from a bevel-wheel on the crank-shaft, works the equilibrium valves in the valve-chests K K, as will be described. T T is a flooring or stage by which access is gained to the cylinder covers for oiling and cleaning. The cylinder is 50 inches in internal diameter, and has 7 feet stroke; it stands on the circular cylinder bottom C′, which is firmly bolted to the masonry by the long holding-down bolts *r r*.

"Plate XIX. contains also a plan of one engine-house, showing the relative arrangement of one pair of engines. The length of this house is 50 feet, and its breadth 24 feet. It will be seen that the two engines are combined so as to act in concert upon the same crank-shaft and fly-wheel, the cranks being placed at right angles to each other, that, when one engine is passing its top and bottom centres, and exerting least power, the other is in mid-stroke, and exerting its whole power upon the full leverage of the crank. In this way the action of the engines is equalised, and the motion rendered smoother than is possible with an independent engine, whilst, in case of accident to either of the pair, its fellow may be employed alone until the damage is made good.

"Plate XX. exhibits a half elevation and half section of the valve-chests, condensers, air-pumps, &c., showing the valves and the manner of working them. As before, C C are the cylinders, C′ C′ the cylinder-bottoms, K K the upper, and K′ K′ the lower valve-chests, fixed right over the cylinder ports, and communicating by the side-pipes *t t′*. D D steam-pipe, H H condensers, L L air-pumps; M hot-well, into which the air-pump lifts the water accumulating in the condenser; this water passes away by the overflow-pipe *m*; *p*, *p*, *p*, feed-pipes for supplying the boilers, with an air-vessel *p′* for equalising the pressure and preventing injury to the pipes from sudden shocks; *u* injection-cock and injecter, the quantity of water admitted being regulated by the injection-cock, worked by the hand-wheel *f*, through the medium of the small shafts and bell-cranks *n*, *n*.

"The valves in these engines are of a peculiar construction, being modifications of the double beat or equilibrium valve, invented by Mr Hornblower, and generally employed in the mining engines in Cornwall, where the high price of coal has led to that rigid economy for which its engineers have long been justly famous. We believe Mr Fairbairn was the first to introduce and advocate the present system of high steam worked expansively for factory engines, which he accomplished (not without considerable opposition on the part of those for whose benefit it was designed) by perseverance, and with the assistance of an active trade competition, driving the manufacturers to greater economy. It has now become general, much to the advantage of manufacturers, where the same amount of work is accomplished with half the quantity of fuel. Most of the appliances for using steam expansively in rotative engines are open to the objections—first, of wire-drawing the steam; second, of cutting it off too slowly; and third, of leaving too much space between the cut-off valve and the cylinder, whereby much steam is wasted without producing any

Stationary Beam-Engines.

effect. To remedy these defects, Mr Fairbairn employs the shafts and expansion apparatus shown in the plates, which are applicable to all rotative engines working expansively, whether with high or low pressure-steam.

"The steam entering the upper steam-chest K, through the stop-valve *a*, has free access also to the lower steam-chest K′ through the side-pipe *t*, whilst the exhaust steam has also clear access to the condenser through the other side-pipe *t′*. The steam is admitted to the cylinder from the valve-boxes by means of the valves *x* and *x′*, and after having completed its work, it passes through the exhaust-valves *y* and *y′* to the condenser, these valves being opened and shut alternately at the right instant by an apparatus yet to be described. Each of the valves consists of two single conical valves, carefully secured together and accurately fitting their seats, the lower valve being slightly smaller than the upper. The steam is admitted on the upper and lower side of each of these pairs of valves, and presses in opposite directions, so that the downward pressure on the upper valve is neutralized by the upward pressure on the lower, excepting that a slight preponderance is given to the former in consequence of the difference of area in the valves, in order to aid in keeping the valves firmly pressed upon their seats when released by the cams. Hence they lift with the greatest ease, and expose any required opening for the admission of the steam.

"The mode of working these valves is very simple; a shaft (*s s*, Plate XIX.) receives motion from the crank-shaft, and imparts it by the bevel-wheels *b b* to the horizontal-shaft *c c*; this in turn gives motion to the valve-spindles *d d*, which pass continuously through bearings in the valve-chests, and are supported on footsteps on the brackets *e e*. Upon each of these spindles are fixed two discs *g g*, carrying cams upon their upper surfaces so arranged as to lift and release each valve at the proper instant of time. This is effected by a direct and simple action; the height of the cam corresponds with the lift of the valve, its length with the duration of the lift, and its position on the cam ring, which revolves at the same rate as the crank-shaft regulates the instant of time in the course of each stroke at which the valve is opened. The action of the cams is transferred to the valves through the medium of friction pulleys *k k k k*, fixed upon small cross-heads, which are guided in their upward and downward motion by the brass standards on which they work. In the case of the steam-valve, these pulleys are capable of adjustment by sliding along the cross-head, so as to bring them over any section of cam that may be required, and thus the steam may be cut off at a $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, or any required portion of the stroke, the remainder being effected by expansion.

"The exhaust steam being a constant quantity requiring a full opening into the condenser, it is desirable to retain the exhaust-valve open during the whole length of the stroke. By the present arrangement, this is effected with a greater degree of certainty than by any other means hitherto proposed. The exhaust-valves rise suddenly upon the short incline planes of the cams, and having allowed time for the escape of the steam through a wide passage to the condenser, they fall with equal celerity by their own weight, and thus a more complete vacuum is formed under the piston than is perhaps possible to obtain by any other process.

"The stop-valve *a* is a simple conical valve, worked by a lever and hand-wheel *z*, fixed by a bracket to the side of the steam-chest, and is chiefly used for shutting off the steam from the engine.

"The indicator-diagrams (figs. 140 and 141) were taken from these engines on May 4, 1859. The engines were then working at 25 revolutions per minute, and one pair with part of the load off. The maximum vacuum varies from 13·0 to 13·2 lbs. per square inch below the atmosphere; the average vacuum is $12\frac{3}{4}$ lbs. per square inch. Diameter of cylinder, 50 inches; area, 1963·50 square inches; speed of piston, 350 feet per minute.

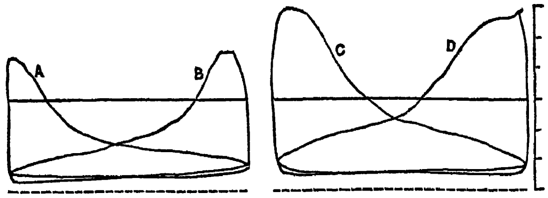

Fig. 140. Fig. 141.

"From these diagrams we get—

Per Square Inch.

"*Engine A.*—Mean pressure of steam..............=7·1684 lb.
Deduct for friction, air-pump, &c...=2·0000 „

Effective pressure.................... 5·1684 „
Actual horses power ... 107·63

"*Engine B.*—Mean pressure of steam..............=7·3646 lb.
Deduct for friction..................... 2·0000 „

5·3646 „
Horses power...........=111·46

"*Engine C.*—Mean pressure of steam..............=13.301 lb.
Deduct for friction ....= 2·000 „

11·301 „
Horses power...........=235·34

"*Engine D.*—Mean pressure of steam .... 12·946 lb.
Deduct for friction .... 2·000 „

10·946 „
Horses power .... 227·95

"With a higher pressure of steam, however, or a shorter expansion, these engines will work to a considerably higher power."

"*The Saltaire Boilers.*—Plate XVIII. contains a general plan of the boiler-house and boilers at Saltaire; and Plate XX. contains enlarged sectional views of one of the boilers. C′, C′, are the boilers, ten in number. They are 24 feet long and 7 feet in diameter, and are of the description known as multitubular. At B′ the upper half of one boiler has been removed so as to expose the flues in the interior, in which the heat is generated; and at A′ the whole boiler has been removed to expose the arrangement of the flues beneath, and the direction of the currents of heated gases as they pass from the furnace to the chimney. The fire generated in the fire-tubes *a′*, *a′*, passes into the mixing-chamber B′, where the air is thoroughly mixed with the flame and smoke, to ensure as perfect a combustion as possible, and thence the gaseous products pass through 109 small tubes, 3 inches in diameter, and descend at *b′*, *b′*, into the brick-work flues beneath the boilers; thence following the direction of the arrows, they return at *c′*, and enter at *d′* the great tunnel T′ T′, through which they are conveyed to a chimney 240 feet high, at some distance on one side of the mill.

"In the tunnel is placed the large steam-pipe *s′ s′ s′*, which communicates with all the boilers by means of the pipes *e′*, *e′*, *e′*; by this arrangement the hot gases round the pipe not only prevent the radiation of heat and condensation of the steam, but in fact in a slight degree superheat it, and render it more effective in working. The steam then passes to the engines by the pipes *t′*, *t′*, *t′*. To supply the waste of water in the boilers caused by evaporation, they are supplied from the engines by means of the feed-pumps, from which the water is conveyed by the feed-pipe *q′ q′* to the tunnel T′ T′, in which it is heated by the waste gases in an apparatus known as Green's fuel economiser. This apparatus consists of a series of upright tubes intro-

Stationary Beam Engines.

duced in the tunnel between the boilers and the chimney, through which the water is made to pass on its way to the boilers, and is there heated to above the boiling point. The practical difficulty in the employment of this apparatus was the formation of a coating of soot upon the pipes, which effectually prevented the absorption of heat by the pipes and the water. To obviate this, Mr Green employs a number of rings or scrapers encircling the pipes, and kept in motion by means of chains and pulleys, driven by a shaft from the engine; these scrapers traverse the whole length of the pipes, and thus prevent any accumulation of soot upon their surfaces. It has been found that, when the waste gases from a boiler escape at a temperature of only 400° to 500°, the feed water can be heated to an average of 225°, and the temperature of the gases on leaving the pipes is reduced to about 250°. To produce this effect, 10 square feet of heating surface in the pipes are required for each horse-power. In this way a considerable economy of fuel is said to be effected, amounting to 17 to 25 per cent. After passing through this apparatus, the heated feed-water re-enters the boiler-house by the pipe $r' r' r'$, and is thence distributed to the boilers. The safety-valves shown at f', f', f', consist, for each of these boilers, of two valves, each of 12 inches area, loaded with fixed weights to the maximum working pressure of the boiler, and of a third valve of five inches area, attached to a spring-balance, so that any required pressure may be secured by its adjustment. These valves are fixed upon a common valve-seating; m', m', m', are the man-holes by which access is gained when requisite to the interior of the boiler, for the purpose of examination, cleaning, &c. At D′ there is a self-acting elevator for raising the ashes and depositing them at once in railway waggons above. The coal is brought by railway and dropped at once from the waggons into the boiler-house at E′, E′.

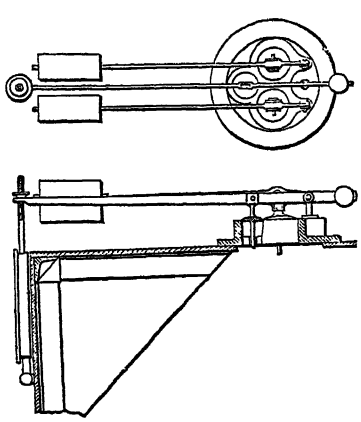

Fig. 142.
Safety-Valves.

"Referring to the sectional views of the boiler and boiler-house, a', a', are the fire-tubes and fire-grates, and n', n', the bridges; B′ the mixing-chamber, in which three vertical tubes p', p', p', will be noticed, which strengthen the flue in its weakest part, viz., where it is elliptical in form, and aid in absorbing the heat by increasing the heating surface; $b' b'$ the descending flue; $d' d$ the entrance to the common flue or tunnel T′; $e' e'$ the steam-pipe, with shut-off valve at y', entering the common steam-pipe s' in the tunnel; r' the feed-pipe, with valve for regulating the supply to each boiler, communicating with the interior by the pipe x'; v', v', v', stays or gussets for strengthening the ends of the boiler; f' safety-valves, with levers, weights, and spring-balance g'; h' the glass water-gauge; i' cock for drawing off the water when requisite; and k' additional man-hole for cleaning the boiler beneath the flues.

"The principal dimensions of the boiler are as follows:—Shell, 7 feet diameter, 24 feet long. The length is divided thus—Fire-tubes, 9 feet long; mixing-chamber, 8 feet; flue-tubes, 7 feet; total, 24 feet. The fire-tubes are 2½ feet in diameter; grates, 2½ feet by 6½ feet long; mixing-chamber, 3 feet 10 inches diameter; 109 flue-tubes, 3 inches diameter.

"The heating surface in each of these boilers may be stated as follows:—

Area of fire-tubes	135	square feet.
Area of mixing-chamber	102	„
Area of vertical tubes	28	„
Area of 3-inch tubes	550	„
Total	815	„
Area of fire-grate (16¼ × 2)	32½	„

"The chimney is 250 feet high above the level of the ground. It is built in the style of an Italian campanile, and consists of an outer ornamental stone casing, and an inner and perfectly distinct parallel brick flue, the space between the flue and the casing being free for the expansion and contraction of the flue. The flue is 6½ feet square, having 42¼ square feet of sectional area, to the summit. The external casing is 20 feet square outside at the base, and tapers to 10 feet square at the summit."

The following are additional particulars and illustrations of the Saltaire engines and boilers, with reference also to the foregoing detail illustrations:—The cylinders (fig. 143) are 50 inches diameter, with 7 feet stroke, of metal, 1½ inches thick, on a pedestal of the same thickness, bolted down to the foundation. The ports are 20 inches wide by 6 inches deep, with a sectional area $\frac{1}{16}$th the area of the piston. The equilibrium valves have the upper disc 12 inches diameter, area 113 square inches; the lower disc is 10½ inches diameter, with 86½ square inches area; difference of areas, 26½ square inches. Lift of steam-valves, 1⅝ inches; of exhaust-valves, 1⅞ inches; steam-branches, 12½ inches diameter; exhaust-pipe, 13 inches; stop-valve, 12½ inches diameter. Condenser, 40 inches diameter; air-pump, 33½ inches, by 3½ feet stroke; foot-valve, 30 inches by 6½ inches, 195 square inches, or $\frac{1}{4.5}$th of the sectional area of the air-pump; discharge-valve, 31 inches by 7 inches; injector, 7 inches diameter. The pistons and air-pump buckets (figs. 145 and 146) are packed with Goodfellow's notched V rings, in one piece. The beam is 21 feet 6 inches long between end centres, or over three times the length of the stroke; it is 3½ feet deep at the middle, or ⅙th of the length, and the web and the rim are 2½ inches thick; the main-centre (fig. 147) is 12 inches diameter in the beam, and 9 inches at the bearings; the connecting-rod (fig. 148) is about 20 feet long, of cast-iron, of a cruciform section in the body, measuring 22 inches across, and 1¾ inches thick at the edges. The spur-flywheel is 24 feet 5 inches in diameter, with 230 cogs in the rim, 14 inches broad, 4 inches pitch;

Feed-pump: 6 inches diameter, 21 inches stroke; water-way, 4 inches diameter.

Mr Fairbairn estimates each pair of engines at 200 nominal horse-power, or the gross nominal power of the two pairs at 400 horse-power. His rule for nominal power is to multiply the area of the piston, 1963·5 square inches, by 7 lb. pressure per square inch, and by a speed of piston of 240 feet per minute, and to divide by 33,000, which gives 100 nominal horse-power for one cylinder, or

$$\frac{1963{\cdot}5 \times 7 \times 240}{33,000} = 100 \text{ nom. horse-power,}$$

giving 400 horse-power for the four cylinders, or two pairs. According to the ordinary Manchester rule, the united nominal powers would be 341 horse-power.

The boilers are made of best Staffordshire iron-plates, $\frac{5}{16}$ inch thick for the shell, and $\frac{7}{16}$ inch for the ends; $\frac{3}{8}$ inch Lowmoor plates for the flues, except for the furnaces, or upper part of the fire-tubes. The pressure varies from 25 lb. to 30 lb. per square inch, according to the load; it is calculated that the pressure may safely amount to 40 lb. Eight boilers are in steam at one time to supply the mill and the engines when working with their full load; but nine boilers, and sometimes all the ten, are at work when inferior coal is used. In addition to the large engines of 400 nominal horse-power, there are two 25 horse-power blowing-engines, also worked by the boilers, to heat the mills. Each boiler is estimated at 50 nominal horse-power, allowing about $\frac{3}{8}$ square foot of fire-grate surface per horse-power, and is stated to be sufficient to supply steam for 150 indicator horse-power.

The consumption of fuel averages from 3 lb. to $3\frac{1}{4}$ lb of good coal per indicator horse-power per hour, and $4\frac{1}{2}$ to $4\frac{3}{4}$ lb. of slack per indicator horse-power.

The total weight of cast-iron in each pair of engines, exclusive of steam-pipes, is 157 tons, 7 cwt., 1 qr.; of wrought-iron, 11 tons, 8 cwt., 3 qrs.; of brass, 2 tons. 7 cwt., 1 qr.; total weight of metal in one pair of engines, exclusive of connections, 171 tons, 3 cwt., 1 qr.; in two pairs, 342 tons, 6 cwt., 2 qrs. The weight of one boiler complete is $10\frac{1}{2}$ tons; of ten boilers, 105 tons. The gross weight of metal in all the four engines and ten boilers, exclusive of connections, is 447 tons, 6 cwt., 2 qrs.

The peculiar design of non-condensing beam-engines (fig. 152) is the production of the Corliss Steam-Engine Company,

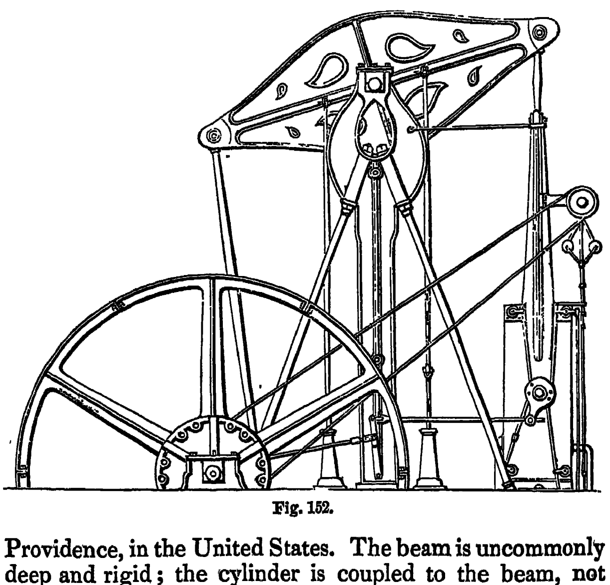

Fig. 152.

Providence, in the United States. The beam is uncommonly deep and rigid; the cylinder is coupled to the beam, not by the usual parallel motion, but by a connecting-rod, from the cross-head of the piston-rod, which is guided by an upright slide. The beam is supported by a cast-iron standard, stayed diagonally by wrought-iron rods. The engine is worked by Corliss's valve-gear. On this system, the steam-passages are reduced to the shortest length prac-

ticable, and a valve is applied to each passage, two for the admission of steam, and two separate passages for exhaust; four in all. The gearing is designed to work the steam with various degrees of expansion, and is operated on by the governor, so that the speed is regulated, not by wire-drawing, as is usual, but by varying the degree of expansion, admitting steam of full pressure into the cylinder before cutting off. The valves are segmental, and rotative-reciprocating in their action; they are worked from a "wrist-plate," shown in the figure, deriving its motion from the eccentric. They are easy to work, and are operated on by the governor, without any resistance to the latter, and thus a steady equable motion of the engine is insured. The governor operates through an ingenious contrivance for disengaging and re-engaging the valve-gear, by means of an inclined-plane motion. The indicator-diagrams produced by this motion are good, and the practical results of its working are excellent.

CHAP. II.—MODIFIED ARRANGEMENTS OF BEAM-ENGINES.

The non-condensing engines made by Messrs Mather, Dixon, and Co., erected to work the inclined plane on the Liverpool and Manchester Railway, at Liverpool Station, Plate XXI., shows how, by simple inversion of the engine, the power is transmitted from the cylinder through the beam, at once to the main-shaft under ground, which carries the large grooved pulley to work the rope. There is a pair of engines to work the main-shaft, connected at right angles. The centres of the beams L L rest at a level of 3 feet above the floor of the engine. A is the cylinder, in section in fig. 2; L *p* is a side-rod from the cylinder cross-head to the lever, and the connecting-rod L K descends to the crank-shaft X. S S the steam-pipes, D D the valves, and *x x* the valve-gear. The foundations are solid red-sandstone rock, in which excavations are made for the shafts and ropes.

Another arrangement of beam-engine, with low-hung beams, Plate XXII., was erected by Messrs Wm. Fairbairn, in a mill at Staley Bridge. The whole of the pair of engines stands on an independent metal sole-plate, and is similar in form to the well-known type of marine engines. The beam L L is, as it were, split in two, one of the halves being placed on each side of the engine, but united at the middle by a large gudgeon, or main-centre, and at the ends by cross-heads, side-rods, and connecting-rod, to the piston and the crank. A the cylinders; B the cross-heads; K the crank; L L the beams; W the spur-flywheel, driving the mill-shaft Y through the smaller spur-wheel *g*; *m* the parallel-motion; *x x* the motion for actuating the valve-gear; *d* a counterpoise to the valves; *w* the governor; H the cross-head to work the air-pump.

CHAP. III.—COMPOUND BEAM-ENGINES.

Mr Wm. M'Naught, of Manchester, introduced an important addition to the ordinary beam-condensing engine, in the application of an additional cylinder, non-condensing, to co-operate with the condensing cylinder, under the same beam, but on the other side of the main-centre. This system is illustrated by the diagram (fig. 153) of a pair of engines, erected at the Gutta Percha Company's Works, City Road, London. A, A, are the ordinary condensing cylinders at one end of the beam, 34 inches diameter, 6-feet stroke; B, B, are the additional, and smaller, non-condensing cylinders, 31 inches diameter, 3-feet stroke, placed under and connected with the other half of the beam, near the crank-end. "High-pressure" steam is admitted from the boiler to the small cylinders B, thence to the large cylinders A, thence to the condenser C, by means of suitably-arranged pipes and gearing; the steam is admitted to the former at a pressure of from 40 lb. to 50 lb. above the atmosphere, and is cut off by means of an ordinary lap-valve, at from ⅓d to ⅔ds, but usually at half-stroke; it is expanded

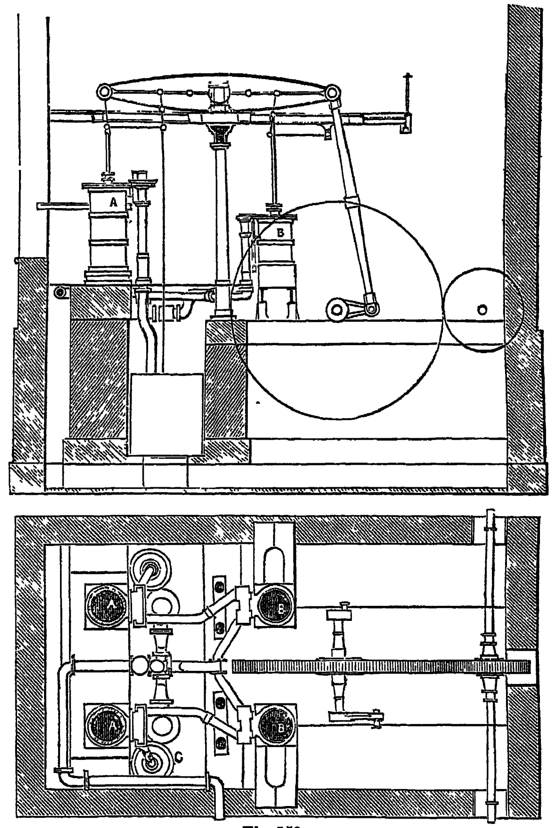

Fig. 153.

to the end of the stroke, and then is exhausted into the large cylinder, which commences its stroke at the termination of the stroke of the first cylinder, and the two cylinders perform respectively their steam-stroke and return-stroke at the same time, the steam continuously expanding from the smaller into the larger, and evacuating the former precisely as if it was exhausted into the atmosphere. At the end of the steam-stroke of the larger cylinder, the steam is exhausted in the usual way into the condenser; and at the end of the return-stroke of the smaller cylinder, the steam from the boiler is admitted into it for the next steam-stroke. The indicator-diagrams (fig. 154) show the conjoint working of the coupled cylinders of one of Mr M'Naught's engines, erected at a grain-mill at Drogheda, in which the high-pressure cylinder is 31½ inches diameter, with 37-inch stroke; and the low-pressure cylinder is 34 inches diameter, with 74-inch stroke, making 20 revolutions per minute. The nearness of the exhaust-line of the former to the expansion-line of the latter, proves the proper

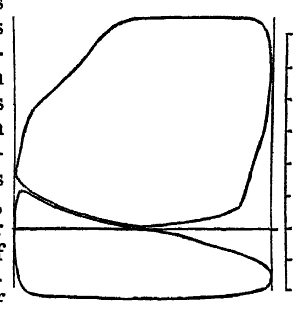

Fig. 154.

action of the system, and that there is no material loss of pressure by the passage of the steam from the one cylinder to the other. The steam is admitted at 33 lb. sensible pressure, and there is a vacuum of 11¼ lb. The indicator horse-power obtained in the small cylinder is 79¾ horse-power; and in the larger, 77 horse-power, nearly equal, making together 156¾ horse-power. The engine works day and night, and consumes 2·84 lb. of Welsh slack per indicator horse-power per hour. In other cases of M'Naught's engines, a fall

Compound Beam-Engines.

of 2 lb. to 3 lb. pressure may be observed in the passage of the steam from the small to the large cylinder, arising from the probable condensation and friction in the passages. The usual consumption of fuel by this class of engine in mills is about 3 lb. per indicator horse-power per hour, which includes the necessary steaming of the mill; in one case it was only 2$\frac{3}{4}$ lb., and if $\frac{3}{4}$ lb. be deducted for other purposes, the usual consumption of M'Naught's engines would be at the rate of 2$\frac{1}{4}$ to 2 lb. per indicator horse-power per hour. With very inferior fuel, the gross consumption has amounted to 5·28 lb. per horse-power. The system has been applied to upwards of 400 engines, and, besides the economy of fuel, it effects a perfectly steady motion, by the equal distribution of the moving force at the two ends of the beam, and reduces the violent strain, or "lift," usual in single-cylinder engines, working expansively at the main-centre and the crank-shaft bearings.

Beam-engines are occasionally compounded by placing two cylinders side by side, under the same end of the beam, exhausting from the top of the small cylinder to the bottom of the large one, and *vice versâ*. On this system the passages between the two cylinders are shorter than on M'Naught's; but there is an obvious disadvantage in the united action of the two cylinders on the beam and the bearings in the same direction.

Mr Charles Swift, Blackburn, constructs a single slide-valve, for exhausting from the high to the low-pressure cylinder, shown in detail in figs. 155, 156. The exhaust takes

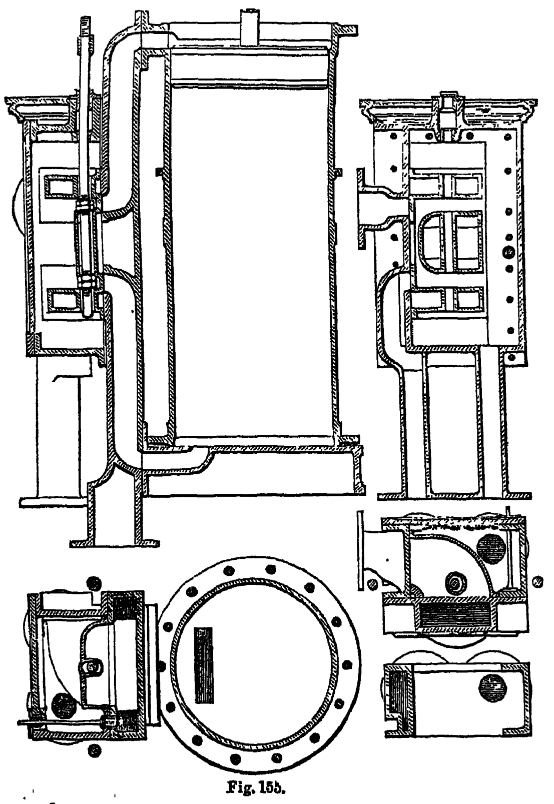

Fig. 155.

place close to the low-pressure cylinder, as shown in the fig. 156, which represents in plan a pair of cylinders, high-pressure and low-pressure, with separate beams and cranks on one shaft. Thus the full pressure of the steam exhausted from the high-pressure cylinder is obtained on the low-pressure piston.

Direct Action Horizontal Engines.

CHAP. IV.—DIRECT ACTION HORIZONTAL ENGINES.

Non-condensing engines are now almost invariably con-

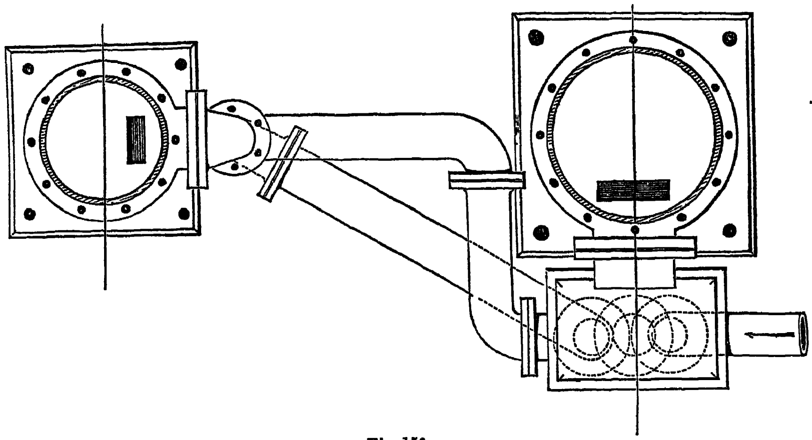

Fig. 156.

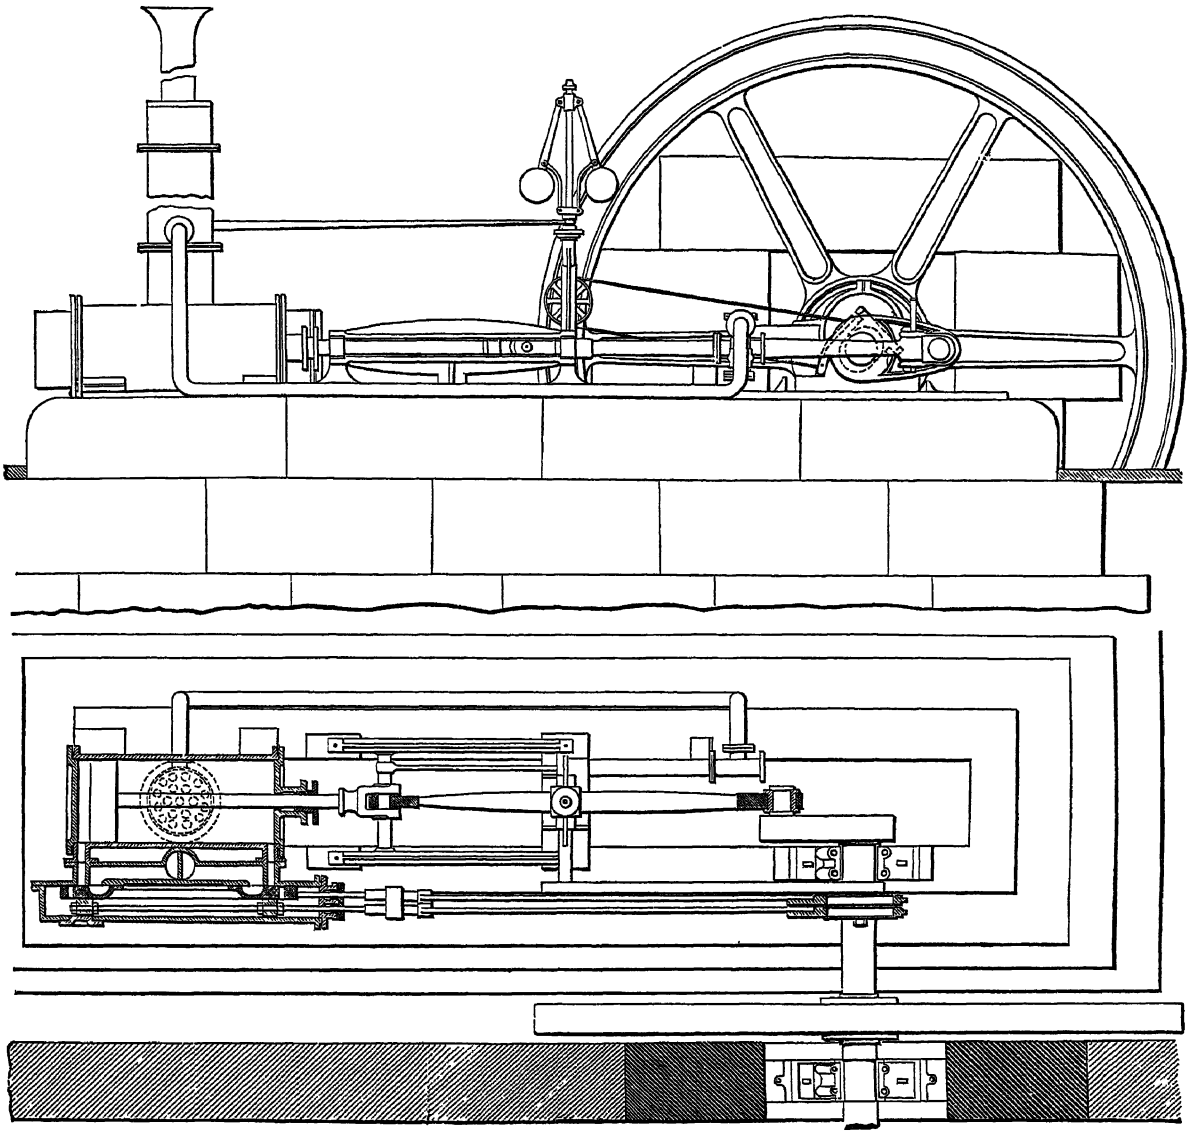
structed "direct-action," or without the intervention of a beam—the connecting-rod uniting the cross-head of the piston-rod to the crank-pin. They are made horizontal and vertical; but the former disposition is most common, and is adopted where space is not limited, and other arrangements permit, as the whole of the engine lies low, under easy inspection, and may be firmly placed on a solid cast-iron base, rested on a plain foundation. The non-condensing horizontal engine, made by Messrs Carrett, Marshall, and Co., Leeds, of 30 nominal horse-power, is shown in figs. 157 and 158. The cylinder is 21 inches in diameter, with 42-inch stroke, with short ports, and is fitted with double valves, to effect variable expansion, the expansion-valve being placed upon the back of the ordinary valve, and worked by a separate eccentric on the main-shaft, adjusted to cut off at various points of the stroke. There is also a feed-water heating apparatus placed over the cylinder, consisting of a fagot of small tubes placed in an upright cylindrical vessel; the steam is exhausted through the tubes, and the feed-water is forced into the vessel around the tubes, by which it is heated from the steam, on its way to the boiler. The advantage of so heating the water on its way from the pump is, that it may be lifted cold by the pump from considerable depths, with more certainty than when hot. The sole-plate of the engine is 20 feet long, in one piece.

Another variety of direct-action horizontal engine, non-condensing, of 10 nominal horse-power, by Messrs Clayton, Shuttleworth, and Co., Lincoln, is represented by figs. 160 and 161. The cylinder is 10 inches diameter, 14-inches stroke, and the engine makes 110 revolutions per minute. The distinguishing feature of this engine is the apparatus for heating the feed-water, which consists of a large pipe underground, 9 feet long, 5 inches diameter, into which the steam is exhausted from the cylinder at one end, and from which it escapes at the other end. The cold water is pumped by the engine into a 2-inch tube, which traverses the heating-pipe from end to end, where it becomes heated on its way to the boiler. The engine is placed on a sole-piece, 8$\frac{1}{2}$ feet long.

Condensing engines of moderate power are frequently made horizontal direct-acting. They are distinguished in appearance from the non-condensing engine by the addition of the air-pump and condenser on the same base-plate. Two examples are illustrated in Plate XXIII. The first is an engine of 20 nominal horse-power, by Messrs Barrett, Exall,

Direct Action Horizontal Engines.

and Andrewes, of Reading, with a cylinder 16 inches diameter, and 20-inch stroke, working with 50 lb. steam; number of revolutions, 80 per minute. The steam-ports are made as short as is practicable; there are two valves, for

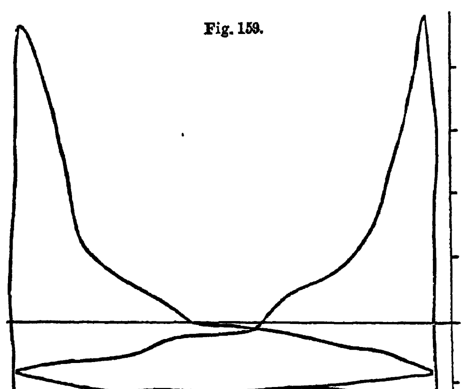


Figs. 157 and 158.

variable expansion, worked by two eccentrics, one to each; the expansion is varied by altering the position of the expansion-eccentric on the shaft, by means of a screw and hand-wheel moving the eccentric on a diagonal key fixed on the shaft. The piston-rod is extended through the bottom of the cylinder to force the air-pump rod, the air-pump being situated within the condenser, at the extreme left of the engine. The injection-water is discharged from the condenser through an overflow-pipe, and the injection-water rises to the condenser in virtue of the vacuum. The base-plate of the engine is $15\frac{1}{2}$ feet long.

An engine of this class was subjected to a ten hours' continuous trial by Messrs Barrett and Co., at their works. It had a 21-inch cylinder, 30-inch stroke, jacketed on the sides and ends; it cut off steam at $3\frac{1}{8}$ inches, or 9·4 per cent., or about $\frac{1}{11}$th of the stroke, besides a clearance of 1 inch of the stroke, with 50 lb. steam in the boiler. The boiler evaporated 9 lb. of water per lb. of coal, fed from the hot-well at a temperature of 82° Fahr., the cold water being supplied at 38° Fahr. The average speed of the engine was 60·03 revolutions, or 300 feet of piston per minute, and the power measured at the main-shaft, by the friction-dynamometer, was 40 horse-power. The indicator-diagrams (fig. 159) were taken from the two ends of the

Fig. 159.

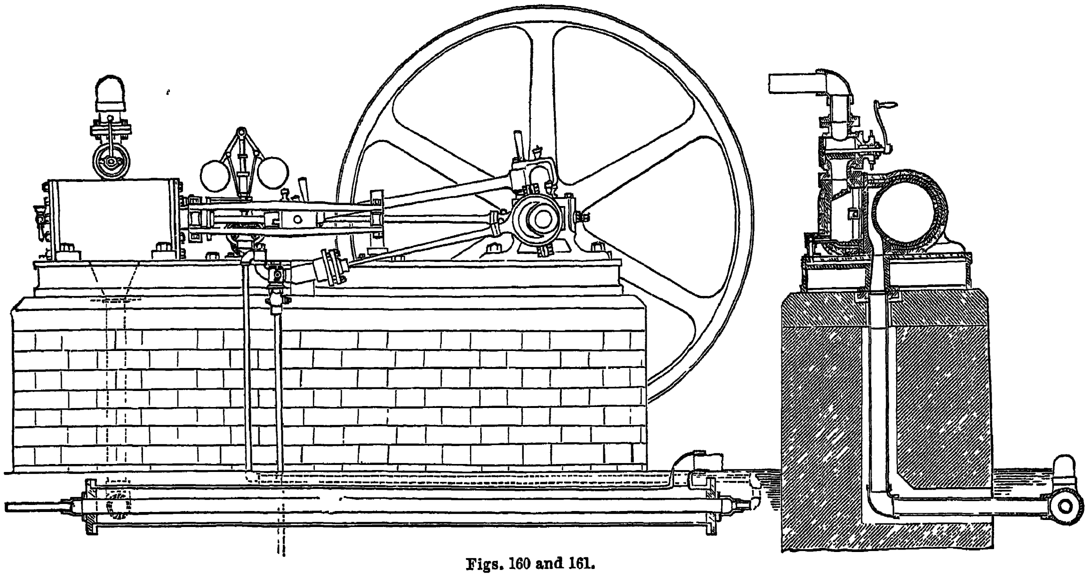


cylinder during the trial, and show an indicator-power

Direct Action Vertical Engines.

of 47 horse-power, from which it appears that the resistance of the engine consumed 7 horse-power, or 15 per cent. of the whole indicator-power. The fuel consumed was 3·06 lb. per dynamometric horse-power, or 2·6 lb. per indicator horse-power. The figure shows an average vacuum of nearly 12 lb. below the atmospheric line, whilst the vacuum in the condenser was 27 inches of mercury, or $12\frac{1}{4}$ lb. per square inch.

The compound-engine, by Messrs Carrett, Marshall, and Co., Leeds, Plate XXIII., comprises a variety of new and useful features. The high and low cylinders, $9\frac{1}{2}$ and 16 inches diameter respectively, with 20-inch stroke, are placed



Figs. 160 and 161.

side by side on one base-plate, and work to cranks, diametrically opposed on the same shaft. Thus the pistons do not, as is usual in compounded twin-cylinders, work together on the same cross-head, making their forward and backward strokes together; but they alternate, and by this means the steam is exhausted by the medium of a single slide, straight across from the high-pressure to the same end of the low-pressure cylinder, through the shortest possible passage. Thus, also, the reciprocating mechanism balances itself, and a perfectly steady motion is obtained. By the cross sections it is shown, that the valve-faces of the cylinder are at right angles to each other, connected by a single slide, and are at 45° with the horizontal plane of the cylinders. The air-pump, which is double-acting, and the condenser, are placed apart behind the low-pressure cylinder; the pump is within the condenser, and is worked by a prolongation of the low-pressure piston-rod. In this way, it is apparent, the weight of the heavier piston is carried in stuffing-boxes, and on slide-blocks, at both ends of the cylinder. The feed-water is heated in a simple, ingenious, and effective way, by injecting water from the hot well through a perforated pipe into the interior of the exhaust-pipe, from the low-pressure cylinder, where it acquires the temperature of the steam, and whence it is pumped into the boiler. The base-plate of the engine is about 10 feet long, and does not include the condenser.

Mr B. Goodfellow, of Hyde, constructs compound horizontal engines, working on cranks at right angles on the main-shaft, in which the high-pressure piston is worked at a higher speed than the low-pressure, by the expedient of giving it a longer stroke; and the air-pump and condenser are placed on the base-plate between the low-pressure cylinder and its crank, being worked by the continued piston-rod of the cylinder. The condenser and air-pump for horizontal engines are frequently placed beneath the base-plate, and worked by bell-cranks; but the arrangements illustrated are now generally preferred.

CHAP. V.—DIRECT ACTION VERTICAL ENGINES.

Where space is confined, and compactness an object, upright engines are serviceable. They are made variously; but the chief distinctions are—first, with the cylinder above and the crank below, near the ground; second, with cylinder below and the crank overhead. Of the first class, the engine (figs. 162 and 163) of 16 nominal horse-power, by

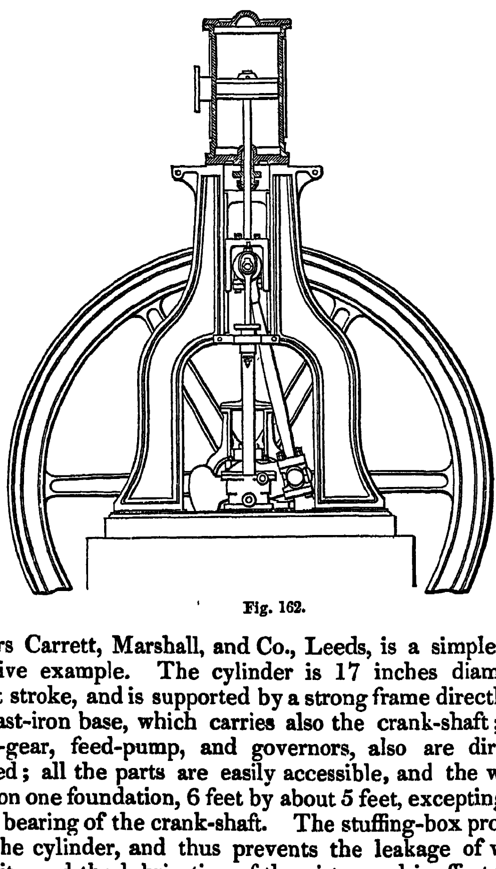


Fig. 162.

Messrs Carrett, Marshall, and Co., Leeds, is a simple and effective example. The cylinder is 17 inches diameter, 2 feet stroke, and is supported by a strong frame directly on the cast-iron base, which carries also the crank-shaft; the valve-gear, feed-pump, and governors, also are directly worked; all the parts are easily accessible, and the whole rests on one foundation, 6 feet by about 5 feet, excepting the outer bearing of the crank-shaft. The stuffing-box projects into the cylinder, and thus prevents the leakage of water from it; and the lubrication of the piston-rod is effected by a receptacle in the gland for lubricating packing, distinct from the ordinary packing. In addition to the ordinary

Direct Action Vertical Engines.

valve there is a sepa... expansion, or cut-off valve, on the back of it, worked by a separate eccentric, by means of which the steam may be advantageously cut off at any

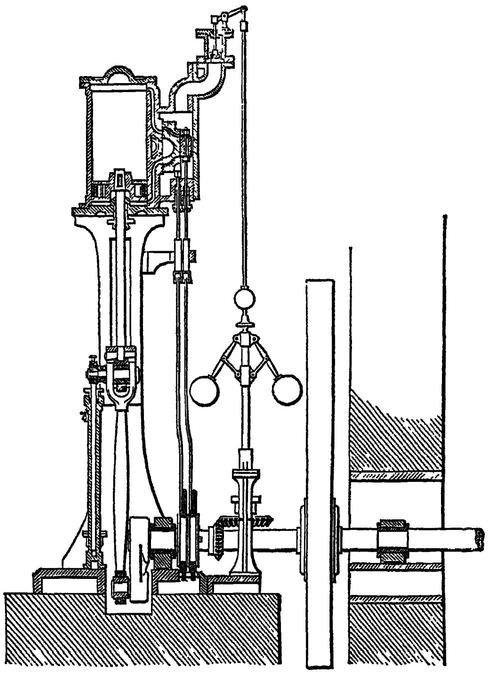

Fig. 163.

point, from $\frac{1}{10}$th to $\frac{8}{10}$ths of the stroke:—the lead remaining constant, and the exhaust unvarying. With heated feed-water, engines of this class work with from 3 to 4 lb. of good coal per indicator horse-power. In some cases this kind of engine is made with a condenser.

The vertical engine, by Messrs Williamson Brothers, of Kendal (figs. 164 and 165), exemplifies the reverse arrange-

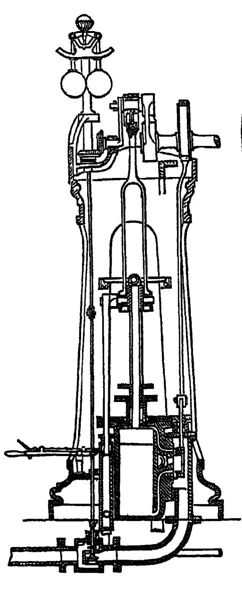

Fig. 164.

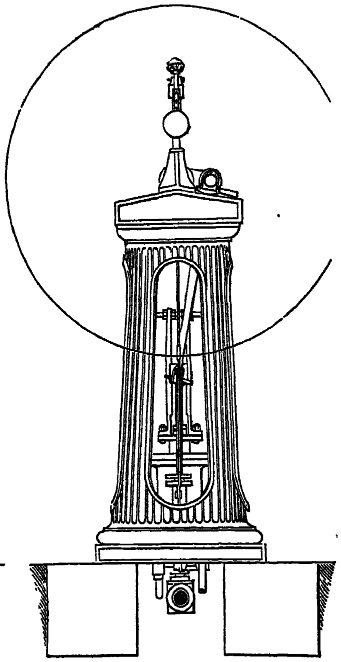

Fig. 165.

ment, where the crank is overhead and the cylinder below. Here a stiffer and more solid erection is needed for resisting the swing and action of the crank, and it is made in the form of a hollow pillar, equally stiff in every direction, and combining strength with lightness. The strain is confined to one casting, and there are few separate parts. The engine is fitted with an equilibrium-valve, controlled by the governor, designed without arms or rings, to prevent sticking in any part; the governor can be disconnected instantly by a lever, which shuts off the steam at the same time. The same form of engine is applied to underlying crank-shafts, when the engine is required to stand independent, and to drive only by a belt from the fly-wheel, or from a pulley on the main shaft.

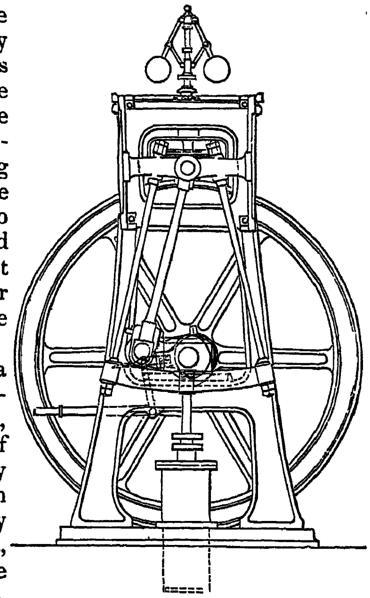

Fig. 166.

In situations where a medium level of crank-shaft is to be observed, the "steeple" form of engine is occasionally used, exemplified in fig. 166, as applied by Messrs Dunn and Co., Manchester, to the driving of sugar-mills. Here the cylinder is below, the cross-head and guide-bars at the top, and the crank-shaft is half-way up, worked by a connecting-rod depending from the cross-head. To effect this arrangement, the piston-rod must be united to a triangular frame, wide enough to clear the vibrations of the connecting-rod.

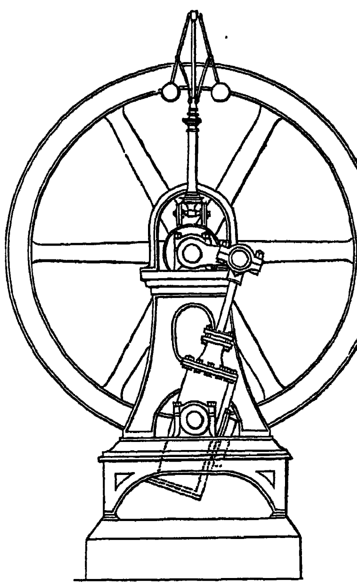

Fig. 167.

Oscillating engines, also, are occasionally applied vertically, so as to diminish the weight of the engine; and for small power they are useful and convenient. The Example (fig. 167), made by Mr Michie, of Nine Elms, London, has a $4\frac{1}{2}$-inch cylinder, 12-inch stroke, and makes 100 revolutions per minute. The slide-valve is not worked by an eccentric, but derives its motion from a fixed stud in the framing, to which is jointed a link and double lever, passing to the spindle of the slide in the side of the cylinder; thus the oscillation of the cylinder gives the action to the valve. Engines in this style are made up to 12 horse-power, and they work well, with few repairs.

Pumping-Engines.

CHAP. VI.—PUMPING-ENGINES.

Pumping water from mines, or for the service of towns, or for other purposes, has, until of late, been almost universally performed by direct lifts, after the style introduced

by Newcomen and Cawley, and adopted by Smeaton and by Watt (figs. 7 and 14). As the duty was simple—the lifting of a dead-weight—so was the engine, the steam cylinder at one end, the pump at the other, and the beam between to connect them, with no superfluous rotative or crank-motion. Lately, double-acting rotative pumping-engines, with crank and fly-wheel, have been introduced. They are more convenient and more compact than the direct-lift engines, but they are not so efficient. The "duty," as it is technically called, is inferior, owing to the greater internal friction of the rotative engine, and to the less nearly perfect adaptation of the action of the engine to the nature of the material to be dealt with and the work to be done. The term "duty" was first employed by Mr Watt to signify the net effect resulting from the consumption of a given quantity of coal; and was expressed by the product of the weight in pounds of water raised, by the height through which it was lifted in feet, divided by the weight in bushels of the fuel consumed in performing a given quantity of work. The duty of the best of Smeaton's engines was, in 1772, 9,450,000 foot-pounds per cwt. of coal. On the expiration of Watt's patent, about the year 1800, the highest duty of his engine amounted to 20,000,000, or more than double the former duty, which may represent the economic value of the improvement effected by Watt under his various patents. The reported duty of Cornish pumping-engines, by the consumption of 94 lbs. of coal, rose from an average of 19,500,000, and a maximum of 26,500,000 in 1813, to an average of 60,000,000 and a maximum of 96,000,000 in 1843. The average duty in 1856 was only 47,000,000, probably on account of inferior qualities of coals used.

It is necessary to bear in mind the distinction between the duty of a bushel of coals, 94 lb., and the duty of a cwt. of coals, 112 lb., both of which are employed as measures of fuel and of duty. In terms of 112 lb. of coal, the average duty of Cornish engines, in 1843, would be 71,500,000; and, in 1856, 56,000,000; and the maximum duty, in 1843, would be 114,500,000.

The functions of pumping-engines, for the supply of water to towns, &c., are chiefly distinguished from those of Cornish engines in the relatively shallow lifts, or depths from which the water is pumped, together with the height to which it is elevated, or the "head" of pressure against which the engine works. Thus Austin's engine, Fowey Consols, in Cornwall, in 1856, lifted the water through a height of 183 fathoms, or 1100 feet. In the London water-bearing district, the depth from the surface of the ground to the level of water does not exceed 100 to 120 feet. No water-works engines are employed to lift water from a greater depth than 15 or 16 feet below the pump; but at the East London Water-Works, the combined lift and head of pressure is about 140 feet. The extreme variety of duty of course involves a variety of proportions, chiefly in the ratio of the diameter of the cylinder to that of the "plunger-pole" of the pump. The Fowey Consols engine has an 80-inch cylinder, with 10 feet 4 inches stroke; the pump has 9 feet 3 inches stroke, drawing six lifts—that is to say, pumping by six successive stages: three of the plunger-poles are 15 inches, one 13½ inches, and two 12 inches diameter—the diameter of the plunger-poles being about ⅕th that of the cylinder. On the contrary, the pole of the "Victoria" pumping-engine at the East London Water-Works is 50 inches diameter, with 100-inch cylinder, being one-half the diameter. The obvious ruling element is the "head" against which the engine is to work; the greater the head, the smaller is the pole in proportion to the cylinder, other circumstances being alike.

The duty of a pumping-engine may be variously defined. Preliminarily, there is the gross work done by the steam in the cylinder, or the "total load," measured by the indicator, comprising the whole work done of whatever kind, useful and useless—water lifted, friction of pump, and friction of the engine itself. The "steam-duty" is the duty performed within the pump, measured by an indicator, comprising the whole work done in lifting the water into the pumps and expelling it into the mains—the steam-duty being equal to the gross work of the steam, minus the friction of the engine. The pumping, or effective duty, is the duty realised in the mains; this is measured by the head of pressure outside the pump, measured by the guage, and is equal to the steam-duty, minus the resistance of the pump. The effective duty is that which is usually understood to be signified by the "duty" of an engine.

At the East London Water-Works there are four engines, particulars of the working of which have been kindly contributed by the engineer, Mr C. Greaves. The leading dimension is respectively as follows for the four engines:—

Engine.	Diameter of Cylinder.
Ajax	72 inches.
Cornish	80 "
Wicksteed	90 "
Victoria	100 "

These engines are worked with 35 lb. steam in the boiler, and the initial pressure in the cylinder is 20 lb. to 25 lb. per square inch on the piston. The cylinders are steam-jacketed, and the steam is usually cut off at about ¼th of the stroke, and expanded during the remainder. The following are particulars of regular working results in 1857. The relative effective steam pressures per square inch on the piston, or the "total load," and the work done in the pump, reduced to the equivalent pressure on the steam-piston, being elements respectively of the total load, or gross work of the steam, and of the steam-duty, are as follow:—

Cylinder.	Total Load in lbs. per Square Inch.	Pumping Work done in lbs. per Square Inch.	Difference, or Friction of Engine in lbs. per Square Inch.
72-inch	15·00	14·00	1·00 or 6·64 per cent.
80 "	14·38	12·73	1·65 " 11·47 "
90 "	15·58	14·10	1·48 " 9·51 "
100 "	16·58	15·01	1·57 " 9·47 "
Mean......	15·38	13·96	1·42 or 9·23 per cent.

Showing a mean friction of engine equal to 1·42 lb. per square inch of piston, being 9¼ per cent. of the gross work of the steam; and showing that the steam-duty is 90¾ per cent. of the gross work of steam. The performance of three of these engines is as follows:—

Cylinder.	Usual Length of Stroke. ft. in.	No. of Strokes per Minute.	Duty per 112 lbs. of Fuel.	Effective H.P.
80-inch	9 9	6·48	86,576,976	104
		8·08	78,675,829	135·4
90 "	10 7	5·38	86,749,117	120·5
		5·97	93,595,265	133·9
100 "	11 0	4·75	78,667,331	165·5
		5·06	79,848,876	180
Mean	...	5·95	84,018,899	140

Showing that, with a mean of 6 strokes per minute, 140 effective horse-power was realised, with a duty of 84,000,000, the maximum duty being about 93,600,000. The horse-power developed at different points was as follows, that in the cylinder being estimated in terms of the friction-ratios previously deduced:—

Pumping-Engines.

Cylinder.	H.P. in Cylinder (estimated).	H.P. in Pump.	Effective H.P.
80	128·4	113·7	104·0
	...	...	135·4
90	150·3	136	120·5
	167·1	151·2	133 9
100	199·8	180 9	165·5
	219·2	198·5	180 0
Mean	173·0	156·1	140 0
Ratio to cylinder H.P.	...	90¼ per cent.	81 per cent.

Showing that the effective horse-power,—the "pumping duty," is 81 per cent., or about ⅘ths of the indicator horse-power exerted in the cylinder—the "total load;" and that the remaining 19 per cent., or ⅕th, is absorbed almost in equal proportions by the friction of the engine, including that of the pole on one part; and the friction and resistance of the pump on the other part, being each nearly 10 per cent. of the "total load."

The East London pumping-engines are supplied with steam from Cornish boilers, with single internal flue, of the following dimensions:—

Cylinder.	No. of Boilers.	Diameter of Shell.	Diameter of Flue.	Length.	Total Area of Fire Grate.
		ft. in.	ft. in.	ft. in.	sq. ft.
80	3	6 5½	3 10½	27 9	62· 5
90	3	6 6	4 0	34 0	74·25
100	4	5 9	3 6	30 0	76· 8
	5	...	...	...	116· 0

It is found from long-continued observation, that these boilers evaporate 10 lb. of water per lb. of gas coke, or Welsh coal, and the duty of the engines has already been stated according to this ratio. The following are the proportional consumptions of fuel:—

Cylinder.	Fuel per Hour.	Per Foot of Grate per hour.	Per H.P. Gross Load per Hour.	Per H.P. in Pump per Hour.	per H.P. Effective per Hour.
	lb.	lb.	lb.	lb.	lb.
80	266	4·25	2·07	2·34	2·55
	382	6·10	...	...	2·81
90	308	4·14	2·05	2·26	2·56
	317	4·26	1·81	2·09	2·37
100	467	6·07	2·34	2·58	2·82
	499	4·30	2·28	2·51	2·78
Means	373	4·19	2·11	2·36	2·65

The following are the proportional consumptions of water from the boilers:—

Cylinder.	Water per lb. of Fuel.	Water Per Hour.	Per Boiler per Hour.	Per Foot of Grate per Hour.	Per Stroke.
	lb.	Cubic ft.	Cubic ft.	Cubic ft.	lb.
80	10	42·7	14·2	·68	6·8
	10	61·1	20·4	·98	8 0
90	10	49·6	16·5	·67	9·6
	10	50·9	17·0	·67	8·9
100	10	75·0	18·7	·98	16·4
	10	80·1	16·0	·69	16·4
Means	...	60·0	17·1	·78	11·0

Showing that an average of 4⅕ lb. of fuel is consumed per square foot of grate per hour, and $2\frac{1}{10}$ lb. per cylinder horse-power per hour, or 2⅔ lb. per effective horse-power per hour; that an average of 60 cubic feet of water per hour is evaporated for each engine, and 17 cubic feet by each boiler, or about ⅘ cubic feet per square foot of grate per hour; and 11 lb., or above a gallon per stroke is consumed.

As the average cylinder or indicator horse-power is 173 horse-power, performed with an average of 3·6 boilers, the gross actual horse-power of one boiler averages only 47 horse-power. About ⅓ cubic foot of water is consumed per actual horse-power.

The air-space through the grates averages from ¼th to ⅙th of the area of the grate. The force of the draft at the base of the chimney varies from $\frac{7}{10}$ to $\frac{3}{10}$ inch of water. In the side-flues the draft was $\frac{1}{10}$th inch for the boilers of the 80 and 90 inch cylinders, and $\frac{2}{10}$ to $\frac{3}{10}$ inch for the 100-inch boilers. In the side-flues the temperature varied from 280° to 415° Fahr., according to the opening of the damper and the strength of the draft; and in the chimney, at a level 10 feet from the top, the temperature varied from 260° to 318°—the average for 24 hours being 274°. The temperature of 35 lb. steam, of 50 lb. total pressure, is 281°, which approaches the lower limit of temperature in the side-flues.

The condensation of steam in the jacket of the 90-inch cylinder, cutting off at ¼th, amounts to $\frac{1}{26}$th, or about 4 per cent. of the steam consumed in the cylinder, and would average about 2 cubic feet per hour for this engine. The steam-jackets are thickly clothed with sand or ashes, to prevent loss of heat by radiation, which, when the clothing is omitted, causes a loss of more than 10 per cent. of the efficiency.

The expenditure of fuel necessary to keep up the steam in one boiler—that is, to keep up the heat of one boiler and the surrounding building—was less than 1 cwt. of coke per day of 24 hours. To keep up the steam in the jacket additionally, the consumption was 2 cwt. per day.

The duty of double-acting rotative pumping-engines, having a crank and fly-wheel, averages from 40,000,000 to 50,000,000; and, in general, their efficiency is not above two-thirds of that of single-acting engines. A pair of rotative engines, with two fly-wheels, for pumping, were found to absorb about 30 per cent. of their power in driving themselves, leaving 70 per cent. for the interior of the pump, or the "steam-duty."

Single-acting pumping-engines are of two general classes:—beam-engines, represented by Plate XXIV., and direct-action, or bull-engines, represented by Plate XXV. In the former, the cylinder is at one end of the beam, the pump at the other; in the latter, the beam is dispensed with and the pump placed under the cylinder, and directly connected to it by the piston-rod. In the beam-engine, the steam from the boiler is admitted to the upper side of the piston and worked expansively, forcing it down, and lifting the weighted pole of the pump at the other end of the beam. The impetus communicated to the moving mass by the initial charge of steam, together with the expansive action of the steam, carries it through the remainder of the stroke,—the velocity of the piston being gradually retarded till the end of its course, while the resistance remains the same. The uplifting of the pole causes a vacuum in the pump into which the water flows. At the end of the steam-stroke the exhaust-valve closes, and the equilibrium-valve opens, admitting the steam above the piston to the under side, and the pressure is equalized above and below the piston; then the weighted pole descends and forces the water out of the pump; the piston ascends also to the top of the cylinder, and, just before reaching the top, the equilibrium-valve closes, and compresses the portion of steam left above the piston, forming a cushion, to bring the piston to a state of rest. The outlet-valve from the lower side of the piston to the condenser is then opened, and fresh steam from the boiler admitted above the piston, when the piston performs the next descending stroke. The speed of the engine is regulated by a "cataract," a mechanical appliance connected with the gearing, which is set in action at every stroke of the engine, and is adjusted to expend itself, and, at a suitable interval, to release the detents by which the

movements of the valve-gearing are controlled. The detents being disengaged, the steam-valve opens, by means of the action of the treadle-weights, and the steam is admitted for the next steam-stroke. All the valves fall open by means of the treadle-weights, and are closed by means of tappets.

The "Victoria" engine, made for the East London Water-Works, by Messrs Harvey and Co., to the specification of Mr Greaves, the Engineer of the company, is represented in Plate XXIV. It is a single-acting beam-engine. The cylinder A is 100 inches in diameter, and is capable of making a stroke of 12 feet. The beam B is 36 feet long and 7 feet 6 inches deep at the middle. The pole C is 50 inches diameter, same stroke as the piston; D is the pole-case, 68 inches diameter, with the water supply W, and the discharging main E, upwards of 4 feet in diameter; *p* is the piston; *i* the inlet valve; *o* the outlet valve; *t* the tappet rod, moved by the beam, having tappets to shut the valves, by means of levers and rods; *c* the condenser; *a* the air-pump; *h* the hot well; *f* the feed-pump; *w* inlet into water-pump; *x* exit from pump into mains; *v* air-vessel on the mains, to equalise the head of pressure; *d* detents, or cross-bars on the beam, to limit the stroke of the engine. For particulars of the boilers, the reader is referred to previous statements.

The direct-acting pumping-engine, made by Messrs Harvey and Co., for the Grand Junction Water-Works at Campden Hill Station (Plate XXIV.), has a 70-inch cylinder, with 10 feet stroke; pole 32½ inch diameter, with 3 feet water-pipes. The letters of reference are the same as for the beam-engine. The pump and valve-gear are worked by means of the lever L, actuated by connection with the pole. The engine is supplied with steam from six boilers *b*, *b*, shown in section longitudinally, and endwise in a separate view on the same plate. The boilers are 5 feet 9 inches diameter, with 3 feet 6 inches flues; and are expanded to 6 feet 1 inch, with 3 feet 10 inch fire-places at the furnaces; *s* is the steam-chest, to collect the steam from the boilers. The fire-grates are 6 feet long.

There are many varieties of pumping-engine on a small scale. Horizontal direct-action engines are in use. Upright

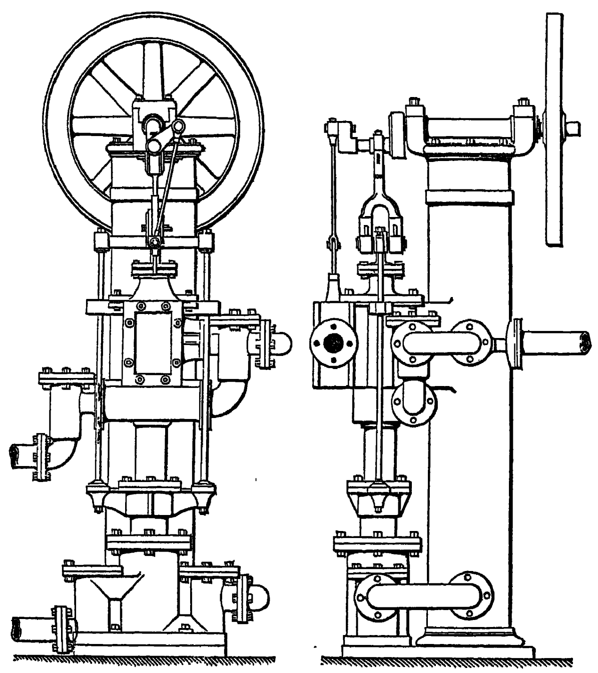

Fig. 168.

direct action-engines, by Messrs Carrett and Co. of Leeds, are also much in use, similar in general appearance to their ordinary upright engine. A new and good system, by Messrs T. Cowburn and Co., of Manchester (fig. 168), deserves notice. The steam-cylinder and the pump are fixed against a cast-iron pillar, which carries the crank-shaft on the top, and a fly-wheel, from which power may be taken off if wanted. The plunger is novel; it is hollow, so as to admit a second plunger, or ram, to work within it. Thus a continuous delivery of water is effected.

CHAP. VII.—PORTABLE ENGINES.

The term *portable engines*, formerly signifying self-contained engines, is now used to signify engines placed on wheels, capable of being moved from place to place, either by their own power of self-propulsion, or by horse-traction. They are in general use for agricultural purposes, and are carried on four broad wheels; they are made light enough to be handy and manageable by the staff of an agricultural establishment. Their boilers are of the locomotive type, with inside fire-box and flue-tubes, and the cylinder, or cylinders if two in number, are fixed on the top of the boiler at one end, and the shaft at the other. The 8 horse-power portable-engines, made by Messrs Clayton, Shuttleworth, and Co., of Lincoln, are shown in elevation and section in Plate XXVII., in two varieties, from which it is apparent that, practically, the boiler constitutes the foundation or basis of the whole structure. Small boilers are proportionally stronger than large ones; in the latter, independent frame-work, is needed. Messrs Barrett, Exall, and Andrewes, of Reading, formerly made their portable-engines on a bed-plate fixed to the boiler, which, with several advantages, had the disadvantage of increasing materially the weight of the engine, and was subsequently abandoned. In Clayton and Co.'s engine there is one cylinder A, 9 inches diameter, with 12-inches stroke; and B, the band-pulley on the crank-shaft is 5 feet in diameter. The boiler C has a fire-box 1 foot 6 inches long, 2 feet 7 inches wide inside, and 2 feet 1 inch in height above the grate. There are 30 flue-tubes 2⅜ inches outside diameter, 6 feet 4 inches long within the boiler. The following are the amounts of surface:—

Heating surface in the fire-box	18·5	square feet.
Do. do. tubes	124·5	„
Total inside surfaces	143·0	„
Area of grate	3·87	„

The cylinder is placed directly over the fire-box, from which it is supplied with steam, and the exhaust-pipe from the cylinder is carried through the boiler into the chimney. The chimney is made with a joint to fold back over the boiler, and rest in a crutch, when not required. In the whole design of this engine there is freedom of access to and inspection of all parts. Agricultural engines are, in general features, much alike.

Messrs Clayton and Co. make engines with the cylinders within the hot smoke-box, and jacketed, from which, no doubt, the cylinders derive benefit, leading to economy of fuel.

CHAP. VIII.—LOCOMOTIVE ENGINES.

The general features and characteristics of modern locomotive practice are represented in Plates XXVI., XXVII., and XXVIII., showing English and American engines. The passenger-locomotive, Plate XXVI., by Messrs Robert Stephenson and Co., is a type of the prevailing kind of engines used in this country for passenger-traffic; and it is specially adapted for drawing express trains at high velocity. It has two cylinders coupled to cranks at right angles on the driving-axle. They are 15⅝ inches diameter, and have 20 inches stroke. The driving-wheels are 6 feet 2 inches diameter; so that, at a speed of 50 miles per hour, the

Locomotive Engines.

piston would move at a mean speed of 760 feet per minute; and at 60 miles per hour, it would have a speed of 910 feet per minute, or three times as much as ordinary stationary engines. There are 170 flue-tubes 2 inches diameter, and 11 feet 4 inches long, and the heating surface is as follows:—

Inside heating-surface of tubes	915	square feet.
Do. do. fire-box	80	"
Total	995	"
Area of fire-grate	13·63	"

The goods-engine, with six coupled wheels, Plates XXVI. and XXVII., made by Messrs Beyer, Peacock, and Co., Manchester, represent in like manner the ordinary form of goods engine used in this country. The sections and plans show in detail the construction of the engine. The cylinders are 16 inches diameter, with 24 inches stroke; the wheels are 5 feet diameter. The fire-box is 4 feet 3 inches long, by 3 feet 6 inches wide; there are 191 flue-tubes, 2 inches diameter outside, and 11 feet 7 inches long. The following are the surfaces:—

Heating surface of fire-box	86·3	square feet.
Do. do. tubes	1052·4	"
Total	1138·7	"
Area of grate	14·9	"

The following literal references in Plate XXVII. will explain the details of the goods engine. A, the cylinder; B, the driving, or crank axle; C, the driving-wheels; D, the fire-box; E, the fire-box shell; F, the barrel of the boiler; G, the flue-tubes; H, the steam-pipe from the boiler, proceeding from the regulator *h*, in the dome I, to the smoke-box K, and thence by branches L to the cylinders; M, the blast-pipe; N, the chimney; O, the valve-gear, handled by the reversing lever P; Q, the regulator-handle; R, the safety-valves; S, the feed-pumps.

The following formulas, based on experimental data, have been given for the resistances of engines and trains on railways, at various speeds. Resistance is divided into two parts:—a fixed or constant quantity, and a variable quantity, increasing as the square of the speed. The conditions under which the formulas are applicable, are—

1. A good sound road.
2. A straight and level road.
3. An average side wind.
4. Engine, tender, and train, in good working order.

Let v = the speed of the train in miles per hour, and R the total resistance per ton of weight moved. Then, first, to find the total resistance per ton gross, of the engine, tender, and train, there is a constant resistance of 8 lb. per ton, and

$$R = 8 + \frac{v^2}{171}.$$

Second. To find the resistance per ton, R′, of the train alone, there is a constant of 6 lb. per ton, and

$$R' = 6 + \frac{v^2}{240}.$$

Third. For the resistance per ton (R″) of the engine and tender alone, including machinery-friction, let W = the weight of the engine and tender in tons, w = the weight of the train in tons, then

$$R'' = \left(6 + \frac{v^2}{240}\right) + \left(\left(2 + \frac{v^2}{600}\right) \times \left(\frac{W + w}{W}\right)\right),$$

in which the first member is the resistance of the engine and tender as carriages simply, and the second member is the whole machinery-friction, the amount of which varies with the weight of the train.

Note 1. On inclines, the resistance is increased or diminished by gravity, according to the ratio of the incline, and according as the train ascends or descends.

2. The results obtained by the above formulas must be increased one-half more, in order to find the resistance under the ordinary conditions of railways.

Classification of Steam-Boilers.

The following are examples of the tractive resistance per ton, gross, of engine, tender, and train, on a level, at various speeds:—

Speeds. Miles per hour.	Resistance under superior Conditions. lb. per ton.	Resistance under ordinary Conditions. lb. per ton.
10	8·6	13·0
20	10·3	15·5
30	13·2	20·0
40	17·3	26·0
50	22·6	34·0
60	29·0	43·5
70	36·6	55 0

The prevailing types of American locomotives are shown in Plate XXVIII. for passengers and for goods traffic in the United States. It is remarkable with what a degree of unanimity American engineers have matured the designs of their engines.

For an account of the history of locomotives, their peculiarities, their performances, and other information, see RAILWAYS.

The annexed cut (fig. 169) shows a simple design of balanced slide-valve, by Mr Gregory of Lisbon, for locomotives. The back of the valve is formed cylindrically with a groove, and a packing ring is let into the groove or circular channel, with an elastic tube of india-rubber between. By the partial compression of this tube the ring is pressed against the back of the valve-box, and steam-tightness is produced, preventing the steam from pressing on the protected portion of the back of the valve. This is an object of considerable importance.

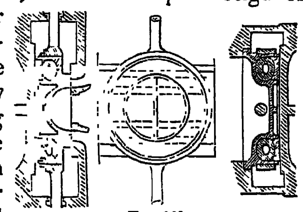

Fig. 169.

SECTION V.—CLASSIFICATION OF STEAM-BOILERS, WITH EXAMPLES.

In the course of the preceding section on steam-engines, a few examples of boilers have been illustrated and described, and performances recorded. It is the object of this section to complete the survey of steam-boilers. Boilers may be classed, generally, as horizontal and as upright boilers, in which the direction of the heating surface is respectively horizontal and vertical. Or they may be classed as open flue-boilers, and as multi-tubular boilers. But it is not necessary to follow any particular classification; a consecutive notice of each kind will suffice.

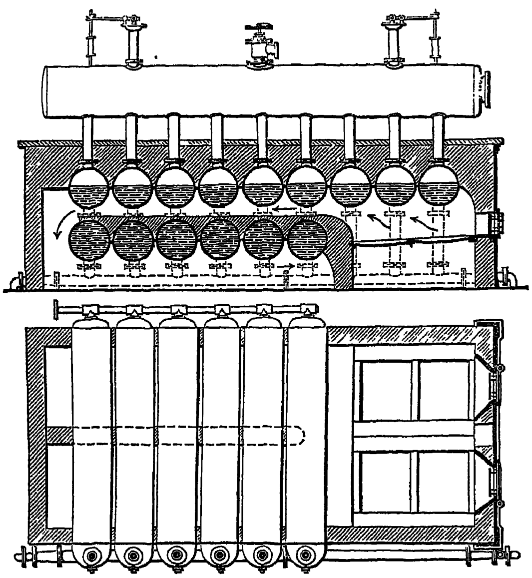
The Waggon Boiler.—This form of boiler has already been illustrated and described in PART I. It is suitable for low pressure only, and was for a long time the most generally used of all boilers.

The Cylindrical Egg-end boiler, fig. 65, has been in extensive use, but is now used chiefly at collieries, where simplicity is a particular object, and fuel of small value. This boiler is 4 feet 6 inches diameter, and 30 feet long. The grate is 6 feet 6 inches long, and 3 feet wide, and the flue proceeds direct to the other end. The form of this boiler is favourable for strength and safety, but it requires great length of boiler to provide sufficient heating surface. The steam is taken from the receiver at the centre, with a stop-valve above. There are two safety-valves towards the front, and a man-hole behind; and the feed-water is introduced at the far end.

The *Retort Boiler*, the production of Messrs Dunn and Co., Manchester, is composed of a series of independent cylinders placed side by side (figs. 170), about 19 inches in diameter, and upwards of 9 feet long, with cast-iron ends. They all communicate upwards with a steam-receiver above

Classification of Steam-Boilers.

the furnace. This class of boiler is undoubtedly safer than



Figs. 170.

the ordinary large boiler, and is equally efficient in evaporative performances. It is compact and portable.

The *Cornish Boiler* has already been illustrated and described in the previous section.

The *Cylindrical Double-Flue Boiler*, Plate XX., is in general use in the north of England. It has two fires, one in each flue *a*, *a*, which are fed with fuel alternately, so that the smoke from one furnace mixes with, and is consumed by, the hot gases and air from the other furnace. The products of combustion descend and pass through the flues *c*, *c*, twice along the whole length of the boiler, and thence by the tunnel T to the chimney. The steam is taken from a dome *d*, in order to insure its dryness, and is conveyed by the steam-pipe *s s* to the engine. The other arrangements are similar to those in the Saltaire boilers. *m*, man-hole; *k*, additional man-hole; *f*, safety-valves; *g*, spring-balance; *h*, glass water-gauge; *i*, blow-off cock; *r*, *r*, feed-pipe; *v*, *v*, *v*, gussets, or stays.

In this drawing the flues *a*, *a*, *a*, are represented with the strong ribs of angle iron *b*, *b*, *b*, *b*, as recommended by Mr Fairbairn, for obviating the dangers of collapse. The flue, as shown, is in accordance with the laws deduced in the experimental researches recently conducted by him, according to which the strength is three times that of the same flue constructed in the ordinary method without intermediate supports; and the light thrown upon the subject by these experiments is likely to cause a considerable

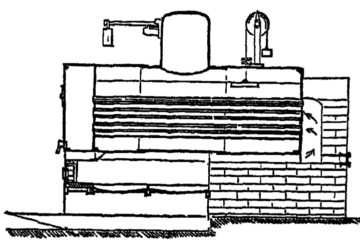


Fig. 171.

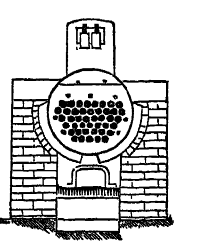

Fig. 172.

revolution in the construction of flues. (See *Experimental Researches on the Collapse of Boiler-Flues*, by Mr Fairbairn, 1858.)

Multitubular Horizontal Boilers.—Of these, the Saltaire boilers, introduced by Mr Fairbairn, Plates XVIII. and XX., and already described, are examples of one kind—the double flue in conjunction with the multitubular arrangement. An effective and compact plan of boiler, introduced and constructed by Messrs Smith and Coventry, Manchester, is shown in figs. 171 and 172, in which the boiler consists of a cylindrical shell, and furnace beneath, with return multitubular flues through the boiler, ending in a smoke-box at the front. The safety-valve of this boiler, detailed in fig. 173, is

Classification of Steam-Boilers.

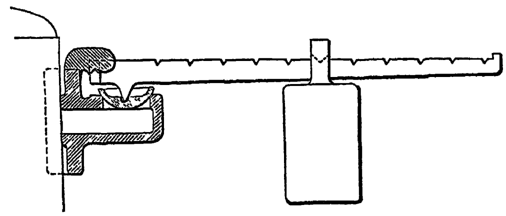

Fig. 173.

worthy of note. It is placed on knife-edges, and the valve, being spherical, is free to suit itself to the seat.

Agricultural boilers, and locomotive boilers, multitubular, have already been described.

The Butterly boiler, already described (figs. 79, 80), is frequently used.

Varieties of Boilers.—Galloway's boiler (fig. 174) is made

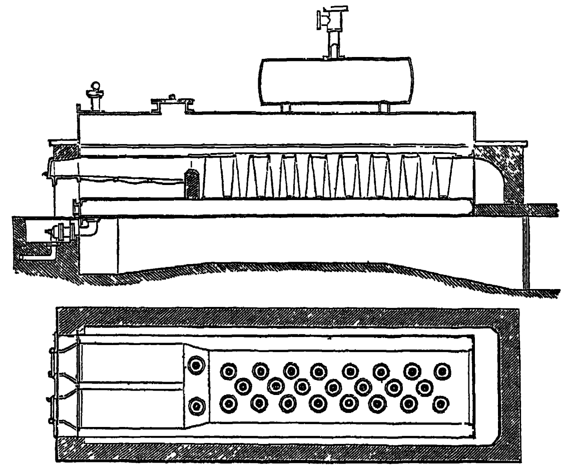

Fig. 174.

with a large oval flue within the boiler, having a number of vertical conical water-passages uniting the top and the bottom; so that a free circulation of water is maintained, and a considerable addition to the heating surface is effected. It is a species of "water-tube" boiler, and there is no doubt it produces good results. There is a double furnace, so as to allow of alternate firing, and the presence of the water-tubes in the thoroughfare of the draft promotes the mixture and combustion of the gases. A steam-reservoir is placed upon the boiler.

In Cowburn's cellular boiler (fig. 175), the internal flue

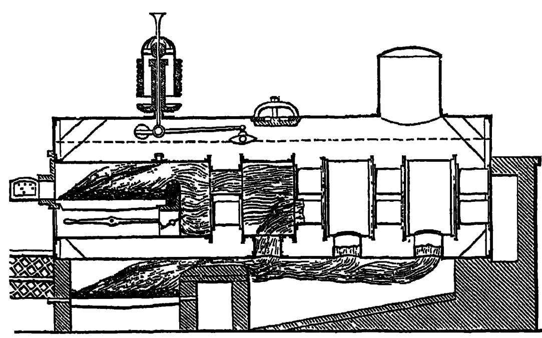

Fig. 175.

consists of a number of compartments or cells, connected by short wrought-iron pipes to each other, and to the lower

side of the boiler. There are two distinct furnaces, one within the flue, and one below the boiler, and the flame and smoke from the two furnaces commingle within the cells, and become effectually consumed. The flue, by being subdivided, as shown, yields to expansion elastically endwise; and as, in addition to this advantage, the boiler is more uniformly heated by the distribution of the fires inside and outside, the over-straining of joints is prevented, and the chances of leakage and rupture are diminished. The safety-valve of this boiler, detailed in figs. 176 and 177, is worthy of note. It is direct-acting, without levers; is freely suspended, so preventing adhesion or sticking to its seat, and readily adjusts itself to the seat, the bearing surfaces being spherical. The fusible plug, or valve (figs. 178, 179), to give warning in case of low water, is another good feature. It consists of an inverted brass cup, fixed on the top of the hottest part of the flue, with a cap screwed on, and numerously perforated, screwed, and filled with block-tin. When the water in the boiler falls, accidentally, below the level of the cap, the plugs are melted out by the heat, and the steam rushing into the furnace, gives the needful warning of danger.

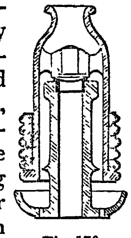

Fig. 176.

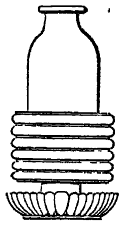

Fig. 177.

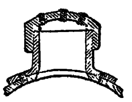

Fig. 178.

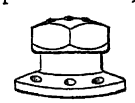

Fig. 179.

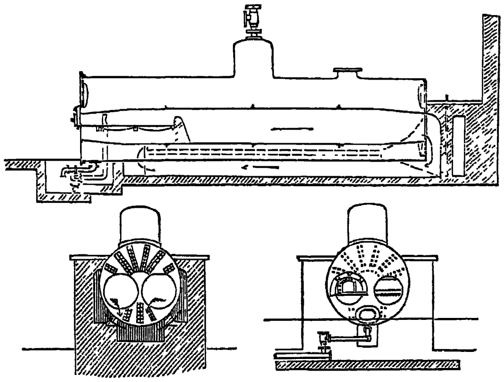
Mr Goodfellow of Hyde, in order to prevent the unequal expansion and straining of flue-boilers, contracts the flue at each end conically (figs. 180), so as to admit of elastic action. It is difficult to perceive how, with such a gentle taper, there can be sufficient scope for the elastic movement.

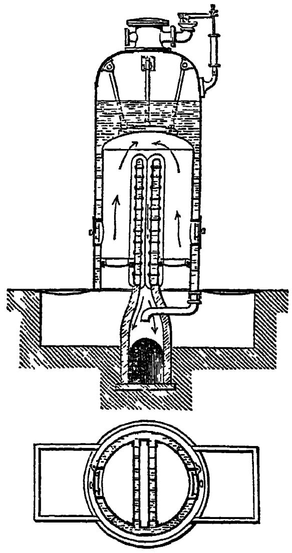


Figs. 180.

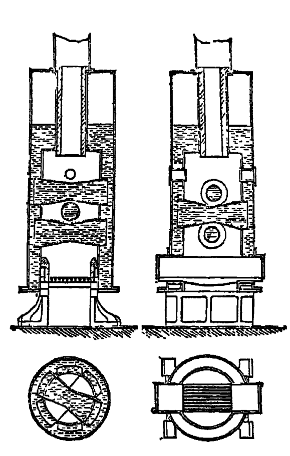
The steeper taper employed in the Cornish boilers, exemplified in Plate XXV., is more likely to be of service, as in fact it has been proved to be sufficient to prevent injurious overstraining of those boilers.

Upright Boilers.—The ordinary form of upright boiler is cylindrical, with the axis vertical. An internal fire-box is placed near the bottom, and a faggot of small tubes proceeds from the crown of the fire-box to the roof of the boiler, and thence to the chimney. The direct upward draft thus occasioned, though it quickens combustion, and excites a high temperature, is wasteful, inasmuch as the heat is too rapidly conveyed, and much of it is carried away into the chimney. Expedients for detaining or deflecting the current are found to operate with advantage. Messrs Dunn and Co. have produced an effective boiler (figs. 181), on the principle of down-draught; the boiler is cylindrical, with a plain domed fire-box within, divided transversely by two water-partitions; there are two grates, one on each side, and the gases ascending from them meet at the crown, are deflected, and descend through the vertical flue. The shell of the boiler is 4 feet 6 inches diameter, and 10 feet high; the fire-box is 3 feet 10 inches diameter, with a total height of 7 feet. The segmental grates have a versed sine of 15⅝ inches, and have a combined area equal to 7 square feet.

The upright boiler of Messrs Armstrong and Bowman, the former of whom is the well-known authority on boilers, contains a number of transverse double-cone steam-generators (figs. 182), within which water circulates, which baffle and divert the ascending hot currents; the ends of these generators project into the surrounding water space of the boiler, and so throw off the steam which is discharged from them, out of contact with the vertical sides of the fire-box. This boiler is found to work effectively.



Figs. 181.



Figs. 182.

An objection to ordinary conical safety-valves, directly weighted, fig. 183, or by a lever (fig. 184), is, that they do not rise with a sufficient degree of freedom to let escape the surplus steam, and the pressure in the boiler consequently rises considerably above that to which the valve is weighted. Mr R. Bodmer has removed this objection, in the design (fig. 185), by admitting water or steam, at the whole pressure in the boiler, under the valve, through an independent tube, free from the interference of the rushing steam. Thus the valve is lifted well off its seat, and a free exit provided for the steam. The valve is in the form of a hollow cylinder, fitting exactly, but easily, over a piston or plug, on which it slides vertically.

SECTION VI.—THE WORK OF STEAM IN THE STEAM-ENGINE.

CHAP. I.—PRINCIPLES OF THERMO-DYNAMICS.

The following general outline of the principles of thermo-dynamics—a science of recent origin, and underlying the whole theory of heat-engines—is abstracted from Professor Rankine's work on the *Steam-Engine and other Prime Movers*, which contains the first systematic exposition of the science.

Principles of Thermo-Dynamics.

Thermo-dynamics defined.—It is a matter of ordinary observation, that heat, by expanding bodies, is a source of mechanical energy; and, conversely, that mechanical energy, being expended either in compressing bodies or in friction, is a source of heat. The reduction of the laws, according to which such phenomena take place, to a physical theory, or connected system of principles, constitutes what is called the science of thermo-dynamics.

First Law of Thermo-dynamics.—Heat and mechanical energy are mutually convertible; and heat requires for its production, and produces by its disappearance, mechanical energy in the proportion of 772 foot-pounds for each British unit of heat (Joule's equivalent); the said unit being the amount of heat required to raise the temperature of one pound of liquid water by one degree of Fahr., near the temperature of the maximum density. This law may be considered as a particular case of the application of two more general laws, namely,—1. All forms of energy are convertible. 2. The total energy of any substance or system cannot be altered by the mutual actions of its parts.

Dynamical Expression of Quantities of Heat.—All quantities of heat, such as the specific heat of any substance, or the latent heat corresponding to any physical effect, or any other of the quantities of heat treated of, may be expressed dynamically, that is, in units of work, by multiplying their values in ordinary units of heat by Joule's equivalent. The following are examples of this mode of expressing quantities of heat, which is by far the most convenient in treating of thermo-dynamical questions:—

	Foot-Pounds.
Latent heat of evaporation of 1 pound of water, from and at 212°	745,812
Total heat of combustion of 1 pound of carbon	11,194,000

Total Actual Heat.—Let a substance, by the expenditure of energy in friction, be brought from a condition of total privation of heat to any particular condition as to heat. Then, if from the total energy so expended, there is subtracted, *first*, the mechanical work performed by the action of the substance on external bodies, through changes of its volume and figure, during such heating; *secondly*, the mechanical work due to mutual actions between the particles of the substance itself during such heating; the remainder will represent the energy which is employed in making the substance hot, and which might be made to reappear as ordinary mechanical energy, if it were possible to reduce the substance to a state of total privation of heat. This remainder is the quantity called the *total actual heat* of the substance, being the total energy, or capacity for performing work, which the substance possesses in virtue of being hot.

Second Law of Thermo-dynamics.—If the total actual heat of a homogeneous and uniformly hot substance be conceived to be divided into any number of equal parts, the effects of those parts in causing work to be performed are equal.

This law may be considered as a particular case of a general law, applicable to every kind of actual energy; that is, capacity for performing work, constituted by a certain condition of each particle of a substance, how small soever, independently of the presence of other particles (such as the energy of motion).

Absolute Temperature—Specific Heat, Real and Apparent.—*Temperature* is a function depending on the tendency of bodies to communicate the condition of heat to each other. Two bodies are at equal temperatures, when the tendencies of each to make the other hotter are equal. All substances absolutely devoid of heat are at the same temperature. Let this be called the *absolute zero of heat;* and let the scale of temperature be so graduated, that for a given homogeneous substance each degree shall correspond to an equal increment of actual heat. This mode of graduation necessarily leads to the same scale of temperature for all substances. The amount of actual heat expressed in units of work, which corresponds in a given substance to one degree of absolute temperature, is the *real dynamical specific heat* of that substance, and is a constant quantity for all temperatures. The total quantity of mechanical energy required to raise the temperature of unity of weight of a substance by one degree, generally includes, besides the real specific heat, work performed in overcoming molecular forces and external pressures. This is the *apparent dynamical specific heat*, and may be constant or variable. Joule's equivalent is the apparent dynamical specific heat of liquid water at and near its maximum density; and it is probably equal sensibly to the real specific heat of that substance. The real specific heat of each substance is constant at all densities, so long as the substance retains the same condition, solid, liquid, or gaseous; but a change of real specific heat, sometimes considerable, often accompanies the change between any two of these conditions. From the mutual proportionality of actual heat and absolute temperature there follows:—

The Second Law of Thermo-dynamics, expressed with reference to absolute temperature. If the absolute temperature of any uniformly hot substance be divided into any number of equal parts, the effects of those parts in causing work to be performed are equal.

The first and second laws virtually comprise the whole theory of thermo-dynamics.

Of Heat Potentially, and Thermo-dynamic Functions.—The second law of thermo-dynamics may also be expressed in the following form:—The work performed by the disappearance of heat during any indefinitely small variation in the state of a substance, is expressed by the product of the absolute temperature into the variation of a certain function, which function is the rate of variation of the effective work performed with temperature; that is to say, in Professor Rankine's notation, let U = the effective work performed, τ = the absolute temperature, J = Joule's equivalent, h = the quantity of heat in common thermal units, H = the same quantity of heat in foot-pounds, k = the real dynamic specific heat of the substance; and make $\frac{dU}{d\tau} = F$; then the work performed by the disappearance of heat is $\tau\, dF$. This function F has been called the *heat potential* of the given substance for the kind of work under consideration. Now, let the substance both perform work and undergo a variation of absolute temperature $d\tau$; then the whole heat which it must receive from an external source of heat to produce those two effects simultaneouly, is

$$J\, dh = dH = k\, d\tau + \tau\, dF = \tau\, d\phi;$$

in which

$$\phi = k \times \text{hyp. log}\ \tau + \frac{dU}{d\tau}.$$

ϕ is called the *thermo-dynamic function* of the substance for the kind of work in question, and sometimes the *heat-factor*. The above equation is the *general equation of thermo-dynamics.*

Principal Applications of the Laws of the Expansive Action of Heat.—The relation between the temperature, pressure, and volume, of 1 pound of any particular substance being known by experiment, the principles of thermodynamics serve to compute the quantity of heat which will be absorbed or rejected by 1 pound of that substance under given circumstances; and, conversely, in some cases, when the quantities of heat absorbed or rejected under given circumstances are known by experiment, the same principles serve to determine relations between the temperature, pressure, and density of the substances. The chief subjects to which the principles of the expansive action of heat are applicable are the following:—Real and

Principles of Thermo-Dynamics.

apparent specific heat, the heating and cooling of gases and vapours by compression and expansion; the velocity of sound in gases; the free expansion of gases; the flow of gases through orifices and pipes; the latent and total heat of evaporation of fluids; the latent heat of fusion; the efficiency of thermo-dynamic engines.

Analysis of the Efficiency of Heat-Engines.—The total heat of combustion of the fuel is expended in any given engine in producing the following effects, whose sum is equal to the heat so expended:—

1. The waste heat of the furnace.
2. The necessarily rejected heat of the engine, being the excess of the whole heat communicated to the working fluid by each pound of fuel burned, above the portion of that heat which permanently disappears, being replaced by mechanical energy.
3. The heat wasted by the engine, whether by conduction or by nonfulfilment of the conditions of maximum efficiency.
4. The useless work of the engine employed in overcoming friction and other prejudicial resistances.
5. The useful work.

Efficiency of the Fluid in an Elementary Heat-Engine.—An elementary engine is one in which the reception of heat by the fluid takes place wholly at one absolute temperature T_1, and its rejection wholly at another (lower) absolute temperature T_2. Consequently, in such an engine the change between those two limiting temperatures must be made entirely by compression and expansion of the fluid. Let H_1 = the heat received by the fluid from the furnace at each stroke, H_2 = the heat rejected at each stroke, and abstracted (as by a jet of cold water in the condenser of a steam-engine); then the efficiency of the engine is—

$$\frac{H_1 - H_2}{H_1} = \frac{T_1 - T_2}{T_1} = \frac{t_1 - t_2}{t_1 + 461^\circ{\cdot}2},$$

in which t_1 and t_2 are the higher and lower temperatures by Fahrenheit's scale. This equation expresses the law of the *efficiency of elementary thermo-dynamic engines*, viz.:—

The heat transformed into mechanical energy,—
Is to the whole heat received by the fluid,—
As the range of temperature,—
Is to the absolute temperature at which heat is received.

Heat-Engine of Maximum Efficiency.—Between given limits of temperature, the efficiency of a thermo-dynamic engine is the greatest possible when the whole reception of heat takes place at the higher limit, and the whole rejection of heat at the lower; that is to say, when the engine is an elementary engine, and the efficiency of the fluid in such an engine is independent of the nature of the fluid employed.

Heat Economiser, or Regenerator.—To fulfil strictly the above condition of maximum efficiency between given limits of temperature, the elevation of the temperature of the fluid must be performed wholly by compression, and the depression of its temperature wholly by expansion: operations which are, in many cases, impracticable from the great bulk of cylinders which their performance would require. This difficulty is almost entirely avoided by the following process, for producing alternate elevation and depression of temperature with a small expenditure of heat, invented about the year 1816, by Dr Robert Stirling, and subsequently improved and modified by Mr James Stirling, Captain Ericsson, Mr C. W. Siemens, and others. The fluid whose temperature is to be lowered is passed through the interstices of an apparatus, called an economiser or regenerator, formed by a number of thin plates of metal or other solid conducting substance, or by a network of wires, exposing a great surface within a small space. The material of the economiser becomes heated by the cooling of the fluid. When the temperature of the fluid is again to be raised, it is passed through the interstices of the economiser in the contrary direction, and the heat which it had previously given out is in part restored to it. It is impossible to perform this process absolutely without waste. In some experiments by Mr Siemens on air, the waste of heat at each stroke was about $\frac{1}{20}$th part of the heat ultimately abstracted from and restored to the air, and in the air-engines of the ship Ericsson about $\frac{1}{10}$th.

Air-Engines.—The ease with which air is obtained in any quantity, and its safety from explosion at high temperatures, have induced many inventors to devise engines in which it is the working fluid. Very few, however, of these engines have been brought into practical operation, owing chiefly to the difficulty of obtaining a sufficiently rapid convection of heat to and from the mass of air employed, and to the necessity for using a more bulky cylinder than is required for a steam-engine of the same power, and with the same maximum pressure.

Such, very summarily, are the principles and the scope of the modern science of thermo-dynamics, as propounded by Professor Rankine, and investigated by him at considerable length in his work on *Prime Movers*. His treatise embraces also, in detail, the applications of the power of steam in the steam-engine, and the results of his investigations will be referred to in the sequel as occasion may arise.

CHAP. II.—PRELIMINARY.

Preliminary.

In calculations of the duty of steam in a cylinder, the back-pressure on the piston, whether arising from the atmosphere or from a condenser, is an essential element. The piston of an engine, in fact, works between two pressures, and continues in motion, or has a tendency to do so, as long as the pressure in the boiler is greater than that in the condenser, or in the exhaust passage; and when steam is very greatly expanded in a condensing-engine, a low pressure in the condenser is no less necessary than a high pressure in the boiler. If all losses and difficulties incidental to, and perhaps in some degree inseparable from, the use of steam of very high pressure, be neglected, then it must be maintained that the highest pressure in the boiler, coupled with the lowest pressure in the condenser, would give the highest duty for a given quantity of heat, provided the steam is expanded in the cylinder from the greater pressure down to, or nearly down to, the lower pressure.

The term "vacuum," it may be remarked, is liable to a double interpretation, signifying either the absolute pressure in the condenser, or the difference between this and the atmospheric pressure. Now, in questions affecting the quantity of work of steam, and its efficiency in the steam-engine, there are the total pressures respectively in the two separate vessels which require to be considered; that is to say, the initial pressure in the cylinder, and the total pressure in the condenser, into which the exhausted steam is propelled by the superior pressure on the other face of the piston. If the pressure of the atmosphere were 10 lb. or 30 lb., in place of 14·7 lb. per square inch, as it is, it would not at all affect the action of a condensing engine, farther than slightly diminishing or increasing the force required to work the air-pump, and causing a greater or less weight to be placed upon the safety-valve, in order to obtain the same total pressure in the boiler. When the mercury in an ordinary barometer is observed to stand at a height of 30 inches, and the mercury in another tube communicating with the condenser of a steam-engine, at a height of 5 inches, instead of describing the conditions of the case as representing a vacuum of 25 inches of mercury, it would afford a clearer conception of the matter to consider that the total pressure in the condenser is equal to 5 inches of

Work of Steam without Expansion.

mercury, while the total pressure in the boiler is equal to 30 inches of mercury plus the load on the safety-valve. In short, the operations of a condensing engine are practically independent of the incidental variations of atmospheric pressure.

Again, the operations of a non-condensing engine, exhausting into the atmosphere, are referable to the atmospheric pressure, as it affords the datum or base line to which the expansive and exhaust pressures should be approximated, and below which they cannot be extended. It is usual, therefore, in dealing with non-condensing engines, to designate the pressure of steam by the difference or excess of its pressure above that of the atmosphere,—14·7 lb. absolute pressure per square inch being adopted for the zero of the non-condensing scale. The round number, 15 lb., is occasionally adopted.

CHAP. III.—THE WORK OF STEAM WITHOUT EXPANSION.

The development of heat into pressure and motion by the media of the water in the boiler and the piston of the engine may, sinking details, be thus concisely illustrated. Let *a b c d* (fig. 186) be a tall cylindrical upright vessel, open at the top, and having one square foot of area of base or cross section; and *e* a piston or disc, without weight, exactly fitting the vessel, and capable of moving up and down without friction. Let there be 1 pound weight of water at the bottom of the vessel, with the piston resting upon it. If a fire be lighted beneath the vessel, and heat communicated to the water, the temperature of the water will be raised to 212° Fahr. before any steam is generated, being subject to the atmospheric pressure on the piston, of 14·7 lb. per square inch. When the temperature reaches 212° Fahr., the heat of the fire being continued, it will not rise higher, but, instead of an ascending temperature, steam will be formed and disengaged under the piston; the piston will be raised, with its atmospheric load of 14·7 lb. per square inch, or 2116·8 lb. on the 1 square foot area of the piston, through successive stages, 1 foot high, to the positions e', e'', e''', until it reaches an elevation of 26·36 feet above the bottom of the cylinder, when the whole of the pound of water will be evaporated, having a constant elasticity throughout the process, of 14·7 lb. per square inch, and a temperature of 212°. In this instance, the boiler and the engine are represented by one vessel, in which the piston and the water are brought into direct contact, and the intervention of pipes or passages for the steam is dispensed with. The work done or duty performed is the raising of a weight of 2116·8 lb, through a height of 26·36 feet, equal to 55,799 foot-pounds, by 1 pound of saturated steam at atmospheric pressure.

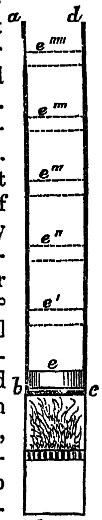

Fig. 186.

Work of Steam without Expansion and without Condensation.—This duty or work done is performed by the steam pushing its way into space, and repelling or pushing aside whatever resisting medium is opposed to its development,—the resistance in the case under consideration being the pressure of the atmosphere. Suppose the experiment to be repeated, with the addition of a weight on the piston equal to the pressure of the atmosphere, making, say, in round numbers, a total incumbent pressure of 30 lb. per square inch, or 4320 lb. absolute weight on the square foot, the area of the piston. On the application of heat, the temperature of the water will be gradually raised to 250·4° Fahr., when the temperature will become stationary, and evaporation will commence, and will proceed until the whole of the water is evaporated. At this stage, the piston, with its load, will have been raised to a height of 13·46 feet; and the work done will be the raising of a weight of 4320 lb. though a height of 13·46 feet, equal to 58,147 foot-pounds, by 1 pound of saturated steam at a total pressure of 30 lb. per square inch, of which about a half is only atmospheric resistance, or exactly 14.7 lb. × 144 × 13·46 feet = 28,492 foot-pounds, having a balance of 29,655 foot-pounds of tangible work done, which will be all the available useful duty of the pound of steam, supposing it then to be discharged. Generally, whatever be the load imposed on the piston, a deduction must be made from the total duty of an amount necessary for repelling the atmosphere, to find the available useful duty.

Such are precisely the conditions of a non-condensing steam-engine worked without expansion, the steam being admitted behind the piston throughout the whole of the stroke, and then discharged into the atmosphere. The cylinder of a steam-engine, it is true, is placed at a convenient distance from the boiler, and not immediately over the water, as in the experimental apparatus; the difference is, however, only circumstantial, the steam is generated at one end of the boiler, and it goes out simultaneously at the other.

To find how much of the whole quantity of heat consumed in generating the steam, is, by this non-condensing non-expansive process, converted into useful effect, let it be assumed that the water is supplied to the boiler at a boiling temperature, 212° Fahr.; then, according to the formula for the total heat of steam, of 30 lb. pressure per square inch, and 250·4° Fahr.

$$H = 1113{\cdot}4 - 212{\cdot}9 + {\cdot}305t = 900{\cdot}5 + {\cdot}305t;$$

and the total heat given to the boiler for 1 pound of water evaporated, is 976·9 degrees, or units of heat. On the contrary, the tangible work done, or useful effect, has been found to amount to 29,655 foot-pounds, or to 29,655 ÷ 772 = 38·4 units of heat. The loss of heat, that is to say, the unappropriated heat, is therefore 976·9 − 38·4 = 938·5 units thrown away, and the proportion of heat utilised is only about $\frac{1}{25}$th of the total heat expended.

The amount of heat expended in repelling the atmosphere, expressed in force, was found to be 28,492 foot-pounds; or, expressed in units, it is 28,492 ÷ 772 = 36·9 units. If this be added to the heat utilised, the sum 36·9 + 38·4 = 75·3 units, expresses the total exertion of the steam in forcing its way into existence behind the piston. Of course, the generation of the steam demands the same exertion, whether it takes place behind a piston, or under a safety-valve loaded to the given pressure, through which the surplus steam escapes; and the whole amount of heat supplied to the boiler in the formation of 1 pound of steam of 30 lb. total pressure per square inch, must, therefore, be distributed as follow:—

	Units of Heat.
1. In overcoming the molecular attraction, and separating the particles, 696,020 foot-pounds ÷ 772 = ...	901·6
2. In repelling the incumbent pressure; in other words, to raise a load of 4320 pounds through a height of 13·46 feet = 58,147 foot-pounds ÷ 772 = ...	75·3
The total heat expended........	976·9

Of all this heat, there is, as already estimated, only about a half of the second and smaller portion utilised by a common non-condensing non-expansive steam-engine. Even this twenty-fifth part of the total is too favourable an estimate, as applied to engines in ordinary condition, because there is usually a portion of the steam condensed in the cylinder, or, it may be, burdened with priming, and a back-pressure is caused which still further diminishes the efficiency. The annexed indicator-diagram, fig. 187, was taken from a small non-condensing steam-engine, from which it

Work of Steam without Expansion.

appears that, of the whole sensible pressure, 20 lb. above the atmosphere, exerted on the piston, 5 lb. was destroyed by back-pressure, leaving only an effective pressure of 15 lb. on the piston, or only three-fourths of the whole sensible pressure.

Fig. 187.

If, under the same conditions, steam of 45 lb. total pressure be raised from water supplied at 212°, and worked at that pressure in the cylinder, it is found, by a similar calculation, that for each pound of steam consumed, 77 units of heat are absorbed in repelling the incumbent pressure; of this only 25 units are expended on the atmospheric resistance, and the remainder, 52 units, may be utilised on the piston, being one-third more than with 30 lb. steam, and constituting one-nineteenth of the whole of the heat, 984·2°, supplied to the water in generating steam.

Again, with steam of 60 lb. total pressure, by the same calculation, 78·5 units of heat are absorbed in repelling incumbent pressure, of which only 19 units are expended on the atmospheric resistance, leaving 59·5 units for useful work, or a little over one-half more than with 30 lb. steam.

There is a common notion, that in proportion as steam of higher pressure exceeds the atmospheric pressure, the efficiency for useful work increases in the same ratio. This is true only of the capacity of a cylinder of given dimensions for delivering useful work. But it is very far from the truth if applied to the efficiency of a given weight of steam; for, in the examples above, it has been found approximately that—

For 1 pound weight of steam of	30,	45,	60	lb. total pressure.
The effective useful pressures are	15,	30,	45	„
In the ratio of	1,	2,	3	„
But the useful quantities of work are only	38·4,	52·0,	59·5	units of heat.
Only in the ratio of about	1,	1·3,	1·5	„

Showing, that with three times the excess of pressure above the atmosphere, there is only one and a half times the useful work, with equal weights of steam. And, in order to get double the useful work from the same weight of steam, worked, of course, in the manner which has formed the subject of this chapter, it would be necessary to introduce high-pressed steam of 180 lb. absolute pressure per square inch, compared with steam of 30 lb. per inch.

Work of Steam without Expansion, but with Condensation.—That is to say, the steam is supposed to be condensed within the cylinder (fig. 186), after the piston has been raised through the height due to its volume, against the resistance of the atmosphere; and the development of useful duty from the steam, heretofore terminated on having raised the piston with its incumbent load, comprising the unprofitable atmospheric resistance, may be further promoted. Let the material weight placed on the piston be removed, and the piston be attached to a rising weight over a pulley nearly equal to the amount of atmospheric pressure on the piston, or 2116·8 lb.; then, if an absolute vacuum be established within the cylinder, the piston will descend to the bottom, and the suspended weight will rise through a height equal to the descent. This weight may, for present purposes, be supposed to equal the atmospheric pressure, and the additional work done will be equal to 2116·8 lb., multiplied by the descent of the piston, or the ascent of the weight, in feet; being, in fact, equal to the work before unprofitably expended in opposing the atmosphere. The work thus redeemed was found to be, for 1 pound weight of 30 lb. steam under the piston, 28,492 foot-pounds, or 36·9 units; for 45 lb. steam, 25 units of heat; for 6 lb. steam, 19 units.

These reclaimed quantities of work being added to the useful work previously done in raising the piston, the total useful work done would be—

For 30 lb. steam	75·3	units.
For 45 lb. steam	77·	„
For 60 lb. steam	78·5	„

Work of Gaseous Steam with Expansion.

being, in any case, just about one-thirteenth of the heat supplied to the boiler.

The above conclusions are directly applicable to the steam-engine; and it appears, that when steam is worked in a common steam-engine, in direct continued connection with the boiler, non-expansively, that is to say, without applying its inherent expansive energy, there is only a small fraction, about a thirteenth, of all the heat given to the boiler, converted into useful work on the piston, with the advantage of a perfect vacuum behind the piston; and the proportion of useful work is still less than that if the steam be exhausted into the atmosphere. These deductions are based on otherwise favourable conditions.

CHAP. IV.—THE WORK OF GASEOUS STEAM WITH EXPANSION.

The action of gaseous or superheated steam, maintained at a constant temperature within the cylinder, is based on comparatively simple conditions. The total pressure of gaseous steam, when the temperature is constant, falls in proportion as the volume by expansion is increased, the pressure being inversely as the volume; and, consequently, the product of the diminishing pressure by the increasing volume, at all points of the stroke, is constant; and, for 1 pound weight of steam, it is equal to 85·4 times the absolute temperature; or, $PV = 85{\cdot}4\ T$. This constant relation of the pressure and volume of expanding steam may be represented diagrammatically on a base line A B (fig. 188), representing volume, which is supposed to be developed in a straight line, in a cylinder, of which A B is the length of stroke. Neglecting clearance for the present, let steam be admitted into the cylinder at a total pressure of 10 lb., represented by the ordinate A C, and for a space of 1 foot in length represented by A D, then the rectangular area A C E D represents the product of the pressure and volume of the steam admitted into the cylinder.

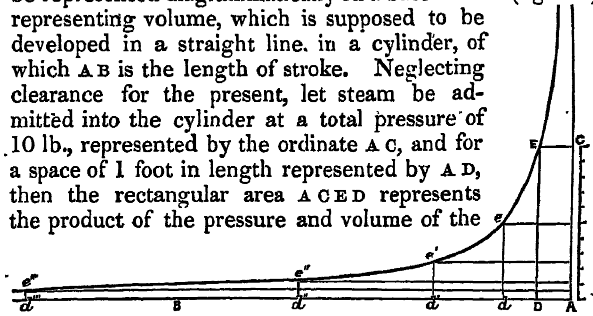

Fig. 188.

Let the steam be expanded at a constant temperature into double the volume A d, and to half the pressure $d\,c$; the area of the elongated rectangle A $d\,e\,c$, will be equal to that of the initial rectangle A E. Expanding, further, to three volumes A d', and to the third part of the initial pressure $d'e'$, the still more extended rectangle A e' is equal to each of the others. The expansion may be further extended to four and five volumes, and to a fourth and a fifth of the pressure, constituting the rectangles A e'' and A e'''; and while the products of the pressure and volume are always the same, represented by the successively elongated rectangles, the elevations $d\,e$, $d'\,e'$, &c., will correctly represent the successively reduced pressures for the several increments of expansion. It is obvious, that any number of intermediate pressures may be interpolated by the simple process of dividing the product of the initial pressure and volume by the distance traversed by the piston, and that they may be joined by a curve E e''', traced through their summits, representing the continuous expansion curve of the steam, which would be traced by the pencil of an indicator applied to the cylinder. This curve of expansion is, according to the principle of its construction—the equality of the rectangles—a portion of a hyperbola; and it may be indefinitely extended at either end, to embrace on the one part intense pressures and small volumes, and, on the other part, very low pressures and large volumes. In the extension upward of the curve into

Work of Gaseous Steam with Expansion.

the higher pressures, it would only be correct as an exponent of the mutual relation of pressure and volume, on the understanding that a proportionally high uniform temperature should be adopted, to ensure the gaseous condition of the steam. A curve constructed on this principle, though indefinitely extended in either direction, does not meet or touch the base line A B, or the vertical A C.

As the rectangular area A E, in the foregoing figure, expresses the work done by the steam in entering and occupying the cylinder, the hyperbolic area D E $d''' e'''$ likewise expresses the work done by the steam by expansion against the piston. This area, and consequently the quantity of work done, may be computed from the known relations of hyperbolic superficies with their base lines, according to which, if the base lines A D, A d, A d', &c. (fig. 188), extend in a geometrical ratio, the successive areas D e, D e', &c., increase in an arithmetical ratio. If, for example, the lines or volumes A D, A d, &c., are as 1, 2, 4, 8, 16, &c., the areas D e, D e', &c., are as 1, 2, 3, 4, &c. On the principles of logarithms, which represent, in arithmetical ratio, numbers naturally in geometrical ratio, special tables of hyperbolic logarithms are compiled, to facilitate the calculation of areas of power due to various degrees of expansion,—such logarithms being, in fact, direct expressions of the proportion borne by the expansive duty pertaining to different degrees of expansion, to the work done by the initial volume of steam. If, for example, the initial volume be expressed by 1, and the total volumes by expansion to different degrees be represented by

2, 4, 8, 16, &c.,

the hyperbolic logarithms of these numbers are,

·693, 1·386, 2·079, 2·772,

which are in arithmetical proportion thus—

1, 2, 3, 4,

and express the actual ratios of the entire expansive duties successively to the initial duty of the steam in entering and occupying the cylinder previous to expansion. The logarithms, it will be noted, are, in each case, the logarithm of the number expressing the ratio of expansion, or the number of times the initial volume is expanded.

It is needful, of course, to make a deduction for the unavoidable back-pressure in the condenser, to find the effective duty of the steam. Suppose a cylinder 5 feet long, with 1 square inch area of piston; steam being admitted, as before, at 10 lb. pressure; let the back-pressure be taken as a uniform resistance of 2 lb. throughout the stroke, and applied to the diagram of duty, constructed as before, as in fig. 189, where the 2 lb. zone of resistance is shaded. It is plain, in the first place, that if the steam, after following the piston through the first foot of the stroke A D, be exhausted into the condenser, with a residual pressure of 2 lb., the effective pressure is $10-2=8$ lb., and the work done is equal to 8 foot-pounds. But let the steam be expanded through the remaining four-fifths of the stroke; then—

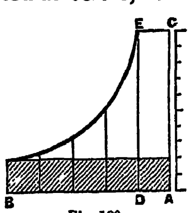

Fig. 189.

At the end of the...............	1st,	2d,	3d,	4th,	5th	foot of stroke	
The total pressures would be	10	5	3⅓	2½	2 lb.	per sq. inch.	
The back-pressures.............	2	2	2	2	2 lb.	do.	do.
The effective pressures.........	8	3	1⅓	0½	0 lb.	do.	do.

Then the total work done by expansion up to the end of each foot of stroke is represented by the hyperbolic logarithm of the ratio of expansion, when the work done during admission is represented by unity, thus—

At the end of the...........	1st,	2d,	3d,	4th,	5th	foot of stroke
The steam is expanded into		2	3	4	5	volumes.
Of which the hyp. logs. are	0	·69	1·10	1·39	1·61	
The initial duty being as...	1	1	1	1	1	unity.
And the total duty as.......	1	1·69	2·10	2·39	2·61	

showing that the total duty of the steam, by expanding it to five times the initial volume, is increased to fully 2½ times the initial duty without expansion, if no deduction be made for back-pressure. To make this necessary deduction at the rate of 2 lb. per square inch, and also to express the relative duty in foot-pounds, the whole initial duty is, as already said, 10 foot-pounds on a piston of 1 square inch area, moved through 1 foot, with a pressure of 10 lb.; the total work done in the first and second feet of the stroke is $10 \times 1·69 = 16·9$ foot-pounds; and so on. Then there is a drawback of 2 foot-pounds on each foot of the stroke. The relations of the work of the same weight of steam in the cylinder are therefore as follows:—

At the end of the.........	1st,	2d,	3d,	4th,	5th	foot of stroke
The total work done is...	10,	16·9,	21·0,	23·9,	26·1	foot-pounds.
The total resistance is....	2,	4,	6,	8,	10	do.
The total effective work is	8,	12·9,	15·0,	15·9,	16·1	do.
And the gain by expansion is.................	0	61	87	99	101	per cent.

Here it is to be observed, that by expanding the steam five times, the effective work is doubled, that is, it is increased from 8 foot-pounds to 16·1 foot-pounds; and that when the expansion is extended to the utmost useful limit—to the point at which the pressure of the expanded steam becomes equal to the back-pressure—the total resistance of the back-pressure in foot-pounds amounts to as much as the total work, which is done by the steam previous to expansion,—namely, 10 foot-pounds. It follows, therefore, that the total effective work of the steam expanded down to the pressure in the condenser is just equal to the total work developed by expansion alone,—that is, 16·1 foot-pounds is equal to $26·1-10$ foot-pounds. The initial performance of the steam may be said, conventionally, to go for nothing, being balanced by the resistance, and the whole of the useful work may be said to be accomplished by the residual expansive force alone. This conclusion applies generally wherever the steam is expanded down to the pressure in the condenser. It may further be concluded, that the utmost ratio of expansion, or limit to which expansion can be carried efficaciously,—regard being had simply to the operations of the steam, as indicated in the cylinder,—is measured by the number of times which the total pressure of the vapour in the condenser is contained in the total initial steam in the cylinder.

For further illustration, let the total initial pressure A C of the steam in the cylinder (fig. 189), during the first foot of stroke be 75 lb. per square inch, and suppose it to be expanded five times as before, and then exhausted into the atmosphere, with a back-pressure of 15 lb. per square inch throughout the stroke, indicated by the shaded zone. Then, as before, if the steam be maintained at a uniform temperature, the pressure at the end of the stroke will be $75 \div 5 = 15$ lb. per square inch, or down to atmospheric pressure, beyond which it would be useless to expand it. On a piston of 1 square inch area, the ratios of work done will be as before—

At the end of the......	1st,	2d,	3d,	4th,	5th	foot of stroke
The total work done is as................	1	1·69	2·10	2·39	2·61	
The total work done is actually..........	75	51·7	157·5	179·2	195·7	foot-pounds.
The total resistance is	15	30	45	60	75	do.
The total effective work is............	60	48·7	112·5	119·2	120·7	do.
And the gain by expansion is.........	0	61	87	99	101	per cent.

The proportions of work, in this case, where steam of five atmospheres is expanded five times, and exhausted into the atmosphere at a pressure of one atmosphere, are the same as when steam of 10 lb. pressure per inch is also expanded five times, and exhausted at a pressure of one-fifth, or 2 lb. per inch; and they indicate an equal efficiency of the steam in the way it is applied.

Work of Gaseous Steam with Expansion.

It is observable from the foregoing illustration, that when the opposing pressure is not less than one-fifth of the initial pressure in the cylinder, or, say in the boiler, there is no material extra duty gained by expanding to more than four volumes; in further expanding to five volumes, the proportion of further gain is only 0·2 upon 15·9, or $1\frac{1}{4}$ per cent.

The clearance which must be allowed between the piston and the end of the cylinder, for safety of working, and also the space or passage from the valve to the cylinder, must necessarily be filled with steam of the initial pressure, at the commencement of every stroke, which, doing no work, must be reckoned as entirely non-effective in non-expansive engines, and, in that respect, as wasted. Where the steam, however, is expanded within the cylinder, the clearance-steam contributes its quota of effect by expansion; and, therefore, in estimating the work done by steam, a distinction must be drawn between the quantity of steam effectively engaged in the cylinder before the suppression or cut-off, and the quantity after suppression—that is to say, before expansion and during expansion. For simplicity of calculation, the volume of the clearance may be expressed in units of the stroke, and added to the period of suppression, in order to express proportionally the initial volume of the steam submitted to expansion.

In the construction of a formula for the relative efficiency of gaseous steam worked expansively, viewed simply as a problem of absolute duty, irrespective of drawbacks on account of the resistance in the condenser and otherwise, the length of the stroke, the clearance, the period of admission, and the absolute initial pressure, are essential elements; and whereas the ratio of expansion is commonly expressed by the number of times the period of admission is contained in the length of stroke, or otherwise by the fraction of the stroke at which the steam is cut off, the actual ratio for the calculation of efficiency must be formed upon the addition of the amount of the clearance.

Let the duty of steam, without expansion, when the clearance is neglected, be expressed by unity, or 1; then the additional duty by expansively working it, is expressed by the hyperbolic logarithm of the ratio of expansion, and the entire duty is expressed by 1 + hyp. log. ratio of expansion. When the clearance is added, the initial duty is proportionally less than unity, as the clearance adds to the volume consumed; and the duty is expressible by the period of admission divided by itself plus the clearance. The ratio of expansion also is less, inasmuch as the clearance augments the initial volume proportionally more than it does the expanded volume, and is, in fact, equal to the initial volume plus the clearance, divided by the final volume plus the clearance. Let L = the length of stroke, l = the period of admission, and c = the clearance. Then the relative expression of the entire duty, neglecting clearance, is $1 + \text{hyp. log.} \frac{L}{l}$.

If the clearance be added, the expression becomes

$$\frac{l}{l+c} + \text{hyp. log.} \frac{L+c}{l+c};$$

in which the first fraction expresses something less than 1, or unity (which is the assumed datum or measure of the entire non-expansive duty of steam without clearance), being the depreciation caused by the presence of clearance; and the second fraction is the modified ratio of expansion.

Now, the period of admission plus the clearance, or $(l+c)$, is the measure of the volume of steam actually admitted to the cylinder for the performance of work, to which the foregoing general expression of entire duty is related; and if it be multiplied by the area of the piston (a), the product will be the volume of the steam admitted, or $a\,(l+c)$. The entire duty of which the steam actually expended would be capable, without expansion and without clearance, would be equal to this volume multiplied by the pressure (p) per unit of surface, or to $a\,p\,(l+c)$; and it is to this standard measure of duty that the general expression of entire duty must be applied by multiplying the one by the other, in order to show how the work of steam is affected by the clearance. If W = the actual entire duty, then

$$W = a p\,(l+c) \left\{ \frac{l}{l+c} + \text{hyp. log.} \left(\frac{L+c}{l+c} \right) \right\}.$$

For non-expansive engines, the actual entire duty is expressed by the equation—

$$W = a p\,(l+c) \frac{l}{l+c} = a p l,$$

in which l becomes equal to L, and signifying that the actual duty is, of course, equal to the product of the volume described by the piston, or the area multiplied by the stroke, and the pressure per unit of surface.

To indicate the importance of the clearance as an element in the efficiency of steam, take a locomotive-cylinder 15 inches in diameter and 20 inches stroke, with a clearance of $\frac{1}{4}$ inch off each end of the cylinder, and steam-passages 10 inches wide by $1\frac{1}{4}$ inch broad, and brought up in the usual manner to a single valve-face in the middle of the cylinder. Taking each passage at 12 inches in length, its cubic contents are $10 \times 1\frac{1}{4} \times 12 = 150$ cubic inches, which, divided by the area of piston, gives $\frac{3}{4}$ inch as the equivalent length of cylinder; and $\frac{3}{4} + \frac{1}{4} = 1$ inch, or one-twentieth of the stroke, is the total clearance or steam-room at each end of the cylinder. Now, if the steam were cut off at one-fifth, or 4 inches, and expanded to the end of the stroke, it would not properly be expanded so much as five times; for there are 5 inches of steam to be expanded into 20 inches, and the real expansion would be only four times. In cylinders, of course, where higher ratios of expansion are practised, the influence of clearance is still greater; and if, with a clearance of one-twentieth of the stroke, the steam be cut off at a twentieth, the volume admitted would be two-twentieths, and the steam would only be expanded into ten volumes, and not twenty. The advantages in this respect of short and direct passages from the valve-chest to the cylinder are obvious:—insuring a higher initial pressure, a higher ratio of expansion, and a less proportion of inactive steam in the cylinder than with long passages.

Professor Rankine proposes the following formula for the work U of 1 pound of gaseous steam, or "steam-gas," in which p_1 and v_1 are the initial pressure and volume, r is the ratio of expansion, and p_3 is the back-pressure:—

$$U = p_1\, v_1 \left(4{\cdot}29 - 3{\cdot}29 \frac{1}{r^{\cdot 304}} \right) - p_3\, r\, v_1.$$

He estimates that the gain of efficiency by superheating steam, of 34 lb. total pressure, in an ordinary engine, cutting off at one-fifth, by the heat of the furnace, is about 15 per cent., and that if the heat for this purpose be derived from the flues, which would otherwise be wasted, the saving is about 23 per cent. The latter result agrees very nearly with the general results of recent practice.

The preceding discussion comprehends the ordinary hypothesis on which the work of steam by expansive working is usually estimated. It assumes too much, however:—that steam, as used in practice, is entirely gaseous; and it does not consist with the true ratio of expansion in a steam-cylinder. The exemplifications of its application, in estimating the particular gains by expansive-working, are, nevertheless, important, as they measure, with a sufficient degree of exactitude, the value of expansive-working generally, in various degrees, as a means of increasing the efficiency of steam, and they point to the special significance of back-pressure in neutralising in an important degree the

Work of Gaseous Steam with Expansion.

Work of Dry Saturated Steam with Expansion.

expected benefit of prolonged expansion. In the following chapter is treated the work of dry saturated steam,—the condition in which steam exists in actual good practice.

The "regenerative steam-engine" of Mr C. W. Siemens is worked with gaseous steam, maintained at a nearly constant temperature, by placing the cylinder over a furnace; but the steam on its way to and from the space below the plunger of the cylinder traverses a "regenerator," the effect of which is, that nearly the whole of the heat employed to raise the temperature of the steam above the boiling point corresponding to its pressure is obtained at each stroke from the regenerator in which that heat has previously been stored by steam leaving the hot end of the cylinder. Mr Siemens states, that in some of his experiments with this engine, the consumption of fuel was only 1·5 lb. per indicator horse-power per hour.

CHAP. V.—THE WORK OF DRY SATURATED STEAM WITH EXPANSION.

The pressure of saturated, or ordinary steam, expanding in a jacketless or unheated cylinder, it has already been stated, falls more rapidly than that of steam of equal temperature, during the first stages of expansion; but ultimately less rapidly, if the expansion be sufficiently prolonged. This has been proved by the writer, from his observations on locomotive-engines, and by others on stationary-engines, to arise from the evaporation of water from the heated sides of the cylinder, when the expanding steam has fallen to a relatively low pressure and temperature—on the same principle as the spontaneous ebullition of hot fluids in vacuo—the water having been formed by the precipitation of steam during the admission to the cylinder, and in the first stages of expansion, upon the relatively cold surface of the cylinder.

There is another, but secondary source of the production of water in the cylinder,—the condensation of ordinary steam during the process of expansion behind the piston, owing to the conversion of part of the heat into work, and the precipitation of the water thus forsaken. This is a species of condensation which arises independently of the relative temperature of the cylinder, and would exist even if the material of the cylinder were a perfect non-conductor. Its existence was originally demonstrated, contemporaneously and independently, by Professor Rankine and Professor Clausius, in 1849.

This condition of things supplies an explanation of the whole mystery of expansive-working of steam. It fully accounts for the failure of attempts to economise fuel by expansive-working, without any provision for preventing the condensation of the steam within the cylinder, arising from the extreme alternations of temperature of the steam itself, during a double stroke of the piston, and the sympathetic condition of the cylinder, heated and cooled by the steam. In ordinary practice, the higher the initial pressure in the cylinder, and the greater the extent of expansive-working to which the steam is subjected, the more difficult it is to prevent the pressure in the condenser from rising, because, as before stated, if the cylinder be exposed, and the integrity of the steam be affected by the alternations of temperature within, there is a considerable amount of supplementary evaporation of water within the cylinder towards the end of the steam-stroke, as well as during the return stroke, when the cylinder is open to the condenser, which partially overpowers the latter, and excites additional back-pressure; and yet, if the back-pressure be not subdued, the gain by expansive-working is neutralised. The loss of expansive efficiency from this cause is important also in non-condensing engines.

The means of preventing the existence of water in the cylinders, thus caused, is provided by supplying heat to the cylinder from an independent source—an external jacket of hot steam, for example—in virtue of which the cylinder is not only maintained at a temperature as high as that of the steam within it, but may also communicate a portion of its heat to the expanding steam. And the question arises, is it sufficient that the steam should be simply preserved from being diminished in quantity by condensation during expansion: being supplied from the jacket while expanding, with just sufficient heat to prevent condensation? Or, is it preferable that the steam should be superheated into the gaseous condition, either within the cylinder from the jacket, or by other means, before it is admitted, so as to act as a perfect gas, considerably removed from the state of saturation? It can be shown that the best result is obtainable when there is just a sufficient supply of heat communicated to the steam in the cylinder, to prevent the precipitation of any portion of it as water. If the steam be discharged from the cylinder in a superheated state, it carries with it a greater quantity of rejected heat than if discharged at the saturation-point.

The liquefaction of steam in the cylinder, by the legitimate process of the conversion of heat into work, is not in itself a loss; it is, in fact, an expenditure of steam representing its equivalent of duty, and if the water of condensation thus precipitated could be instantly removed from the cylinder as soon as formed, so as to leave the cylinder dry at the end of the stroke, a still better result would be obtained per unit of heat expended, than when heat is absorbed from the jacket to prevent its condensation. But the objection to this liquefaction of steam in the cylinder is a practical one, as water in the cylinder, by whatever cause it may be formed, cools the cylinder by evaporation from its surfaces:—an evaporation doing but little good for the time, that is to say, during the remainder of the steam-stroke, and otherwise positive harm.

It is believed that, practically, the use of the steam-jacket does not extend materially beyond the maintenance of the steam in a state of dry saturation while expanding; the steam in the cylinder receiving just enough of heat from the steam in the jacket to prevent any appreciable part of it from condensing without superheating it. Professor Rankine, in adopting this view of the case, bases the assumption on the fact, "that dry steam is a bad conductor of heat, as compared with liquid water, or with cloudy steam; and that after cloudy steam has received enough of heat to make it dry, or nearly dry, it will receive additional heat very slowly. The assumption," he adds, "is justified by the fact, that its results are confirmed by experiment." Professor Rankine investigated, and published in 1859, exact and also approximate formulas for the work of dry saturated steam, under such conditions, and for the expenditure of heat in producing and using that steam. Adopting his notation, let T=absolute temperature in degrees of Fahrenheit = temperature measured from the ordinary zero + 461·2°; p=pressure in pounds on the square foot; v = volume of 1 pound of steam in cubic feet; t_1, p_1, v_1, refer to the admission of steam into the cylinder; t_2, p_2, v_2, to the end of the expansion; let $r = v_2 \div v_1$ the ratio of expansion; p_3, the pressure of exhaustion, or back-pressure; t_4, the absolute temperature of the feed-water; J=Joule's equivalent, or specific heat of 1 pound of liquid water, = 772 foot-pounds per degree of Fahrenheit; W=work of 1 pound of steam in foot-pounds; H= expenditure of heat per pound of steam in foot-pounds; a=1,109,550 foot-pounds; b=540·4 foot-pounds per degree of Fahrenheit; efficiency of steam, $W \div H$.

Let the curve B C K (fig. 190) be the expansion-curve of a body of dry saturated steam. Let $OA = p_1$, and $AB = v_1$, represent the pressure and volume of admission; also let $OD = p_2$, and $DC = v_2$, represent the pressure and volume at the end of the expansion; and let $OF = p_3$ the pressure of exhaustion; then $v_2 \div v_1 = r$ is the ratio of expansion,

Work of Dry Saturated Steam with Expansion.

and $\frac{v_1}{v_2}=\frac{1}{r}$ is the period of admission or effective cut-off. The following are the exact formulas :—

$$W = a \text{ hyp. log. } \frac{t_1}{t_2} - b\,(t_1 - t_2) + v_2\,(p_2 - p_3).$$

$$H = a\,(1 + \text{hyp. log. } \frac{t_1}{t_2}) - bt_1 + J\,(t_2 - t_4).$$

The approximate formulas are founded on the facts, that for total initial pressures of steam from 30 to 120 lb. per

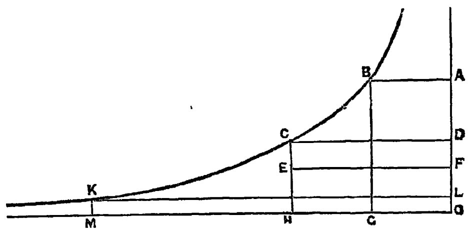

Fig. 190.

square inch, and for ratios of expansion up to sixteen times, the pressure of saturated steam varies nearly as the seventeenth power of the sixteenth root of its density, or of its volume inversely; and that the expenditure of heat in an engine in which dry saturated steam is used, expressed in units of work, is nearly equal to $15\frac{1}{2}$ times the product of the initial pressure and volume of steam expended. If p and v represent relative pressures and volumes, then, as aboved stated,

$$p \text{ varies as } \frac{1}{v^{\frac{17}{16}}}.$$

The ratio of the mean total pressure to the initial pressure of the steam, for different values of the ratio of expansion, r, is given by the expression—

$$\frac{17}{r} - \frac{16}{r^{\frac{17}{16}}}.$$

Then,

the final pressure, $p_2 = \frac{p_1}{r^{\frac{17}{16}}}$;

the mean total pressure $= p_1 \left(\frac{17}{r} - \frac{16}{r^{\frac{17}{16}}}\right)$

the mean effective pressure $= p_1 \left(\frac{17}{r} - \frac{16}{r^{\frac{17}{16}}}\right) - p_3$

the work of 1 pound of steam, exerted on the piston (area, ABCFA, fig. 190), =

$$W = v_2\,\{p_1 \left(\frac{17}{r} - \frac{16}{r^{\frac{17}{16}}}\right) - p_3\}.$$

The work per cubic foot of the space swept through by the piston, is

$$W \div v_2 = p \left(\frac{17}{r} - \frac{16}{r^{\frac{17}{16}}}\right) - p_3.$$

It is evident that if the pressure of exhaustion be given, and any two of the three quantities, namely, the initial pressure, the mean effective pressure, the ratio of expansion,—the fourth quantity can be calculated directly, except it be the ratio of expansion, which can be found by trial and error.

The approximate formula for the expenditure of heat per pound of steam, when the feed-water is supplied at a temperature of from 100° to 120° Fahr., is as follows :—

Expenditure of heat per pound of steam—

$$H = 15\tfrac{1}{2}\, p_1\, v_1.$$

The heat expended per cubic foot is—

$$H \div v_2 = \frac{15\frac{1}{2}\, p_1}{r}.$$

The efficiency of the steam, W÷H, is by reduction,

$$\frac{17 - \frac{16}{r^{\frac{1}{16}}}}{15\frac{1}{2}} - \frac{r p_3}{15\frac{1}{2}\, p_1}.$$

Work of Dry Saturated Steam with Expansion.

By efficiency is meant the proportion which the actual useful effect bears to the whole expenditure of heat communicated to the steam.

In the foregoing formulas, the initial volume for the effective cut-off is measured to the point at which the curve of expansion, if produced upwards, intersects the horizontal line of admission. It is thus that the action of wire-drawing is accounted for, and an example of the operation is shown in fig. 134, where, by an extension of the expansion-line upwards, the shaded area D is enclosed, and the point of effective cut-off is placed 2 inches in advance, at 5 inches of the stroke, instead of 7 inches, to which the valves are set.

There is a small loss of effect by the release of the steam from the cylinder before the end of the stroke, shown also by shaded spaces in fig. 134. The compression or cushioning of the exhaust steam, though it reduces the area of the diagram, and the work done, does not, unless excessive, reduce the efficiency of the steam.

The clearance, as before mentioned, adds to the space to be filled with steam for each stroke, and reduces the ratio of expansion. This effect is more or less counterbalanced by the wire-drawing, the influence of which is to increase the ratio of expansion.

When the feed-water is delivered at other temperatures than 104° Fahr., or thereabouts, for which temperature the approximate formula for the expenditure of heat was obtained, an allowance must be made for the greater or less expenditure of heat, in proportion to the total heat of the steam generated. For example, if the water be heated to 204° Fahr., 100° higher than assumed in the formula; and if the steam be generated at 100 lb. total pressure, having 1181·4° total heat, the addition of 100° to the temperature of the feed-water reduces the expenditure of heat by $\frac{100}{1181{\cdot}4}$ or $\frac{1}{11{\cdot}8}$; and the co-efficient of the formula $H = 15\frac{1}{2}\, p_1\, v_1$ is reduced by $15\frac{1}{2} \div 11{\cdot}8 = 1{\cdot}3$, to 14·2; and the expression becomes $H = 14{\cdot}2\, p_1\, v_1$.

The following example of the application of the formulas to actual engines, and of the comparison of their results with those of experiment, is given by Professor Rankine :—

Example.—Double-cylinder engines of 744 indicator horse-power, calculated by the exact formulas :—

Data.

	Bottom of Cylinders.	Top of Cylinders.
Pressure of admission, $p_1 \div 144$	33·7	34·3
Back-pressure, $p_3 \div 144$	4·0	4·0
Ratio of expansion, r	$4\frac{1}{3}$	$6\frac{1}{4}$

Ordinary temperature of feed-water, 104° Fahr.

Calculated Results.

	Bottom.	Top.
Final volume of 1 pound of steam, $v_2 = rv_1$	50·375	74·4
Final pressure, $p_2 \div 144$	7·367	4·867
Work of 1 pound of steam,	109562	117338
Mean effective pressure in pounds on the inch	15·1	10·95
Mean of both results	13·03	
Mean effective pressure, as observed	13·1	
Difference	−0·07	

	Bottom, foot-pounds.	Top, foot-pounds.
Available heat expended per pound of steam	906989	925678
Pressure in lbs. per square inch, equivalent to heat	125	86·4
Mean	105·7	
Efficiency	0·121	0·127
Mean, 13·03÷105·7	0·123	

Work of Dry Saturated Steam with Expansion.

The same example calculated by the approximate formula:—

Data.

	lbs. per inch.
Mean pressure of admission, $p_1 \div 144$	34
Mean back-pressure, $p_3 \div 144$	4

$$\text{Mean cut of } \frac{1}{r} = \frac{0\cdot24+0\cdot16}{2} = 0\cdot2$$

Results.

Mean gross pressure, $34 \times \cdot505$	17·17
Mean effective pressure, $17\cdot17-4$	13·17
Observed	13·10
Difference	+0·07
Pressure equivalent to expenditure of heat	105·4
Efficiency	0·125

Both the exact and the approximate formulas appear to possess a great degree of accuracy in their practical application.

Mr Brownlee, in July 1859, published the following formulas for the work and heat of dry saturated steam, founded, like Rankine's approximate formula, on the fact of the uniform variation of the density, with a constant power of the pressure; in fact, the ·941 power. (See STEAM.) Conversely, the pressure varies as the $\frac{1}{\cdot941}$ power of the volume inversely, or as the $\frac{17}{16}$ power, or as the 1·0627 power inversely, which are equivalent expressions of the power; and

$$p_2 = p_1\left(\frac{v_1}{v_2}\right)^{\frac{1}{\cdot941}} = p_1\left(\frac{v_1}{v_2}\right)^{1\cdot0627}$$

If the steam be discharged after expansion at the same terminal pressure p_2, as the pressure at which the steam is condensed or exhausted, the total available work done, in foot-pounds, including clearance, and other drawbacks, is

$$W = \frac{1\cdot0627}{\cdot0627} P_1 \, v_1 \left\{1 - \left(\frac{v_1}{v_2}\right)^{\cdot0627}\right\}$$

$$= 16\cdot949 \, P_1 \, v_1 \left\{1 - \left(\frac{v_1}{v_2}\right)^{\cdot0627}\right\}$$

Let H_1 = the total heat of the initial steam, and H_2 = the total heat at the end of the expansion; then the heat required to be supplied from the jacket to prevent condensation, while the steam expands from p_1 to p_2

$$= \frac{W}{J} - (H_1 - H_2),$$

in which $J = 772$, Joule's equivalent.

If, again, the steam is permitted to flow into the condenser, or any space in which the pressure is less than that, p_2, at which expansion is terminated, and the pressure in the cylinder is thereby reduced to p_3, at which pressure the remaining vapour is finally expelled, there is obtained the additional work $v_2\,(p_2 - p_3)$; and the whole available work of the steam is

$$W = 16\cdot949 \, p_1 \, v_1 \left\{1 - \left(\frac{v_1}{v_2}\right)^{\cdot0627}\right\} + v_2\,(p_2 - p_3).$$

The exhaustion from the cylinder to the lowest pressure p_3, has a slightly cooling effect on the cylinder, as the exhausted vapour falls in temperature, and partially condenses while expanding and expelling that portion which flows off. Neglecting, in the meantime, this small expenditure of heat, Mr Brownlee takes for illustration the case of 1 pound of steam at 100 lb. total pressure per square inch, or 14,400 lb. per square foot, expanded to ten volumes, and maintained in a state of dry saturation by the addition of heat from the jacket. The terminal pressure will be

Work of Dry Saturated Steam with Expansion.

$$p_2 = 100 \times \left(\frac{1}{10}\right)^{1\cdot0627} = 8\cdot656 \text{ lb. per square inch,}$$

with a temperature of 185·5°; $p_1 = 14{,}400$ lb. per square foot; $v_1 = 4\cdot3351$ cubic feet; $\frac{v_1}{v_2} = \frac{1}{10}$, and $1 - \left(\frac{1}{10}\right)^{1\cdot0627}$ = ·1344. If the back-pressure be equal to the pressure of final expansion p_2, the whole available work will be $W = 16\cdot949 \times 14400 \times 4\cdot3351 \times \cdot13441 = 42200$ ft.-pounds.

Then, assuming the water to be supplied at 100°, the total heat H_1, of 100 lbs. steam, reckoned from this temperature, will be 1113·4° (see STEAM), whilst at 185·5° and 8·656 lb. pressure, the total heat H_2 will be, $1013\cdot4 + (\cdot305 \times 185\cdot5) = 1070\cdot2°$; and $H_1 - H_2 = 1113\cdot4 - 1070\cdot2 = 43\cdot2°$. Also, $\frac{W}{J} = \frac{142200}{772} = 184\cdot2$ units. Therefore, the heat absorbed from the jacket, necessary to prevent condensation, is $184\cdot2 - 43\cdot2 = 141$ units of heat. Hence, with water supplied at 100°, the total heat necessarily expended per pound of steam $= 1113\cdot4 + 141 = 1254\cdot4$ units, and the work done for each unit of heat expended, is

$$\frac{142200}{1254\cdot4} = 113\cdot4 \text{ foot-pounds.}$$

But, further, let the steam, after expanding to 8·656 lb. pressure per inch, be exhausted to 2 lb. back-pressure in the cylinder during the return-stroke. To find the additional work, $v_2\,(p_2 - p_3)$, thus done, $v_2 = v_1 \times 10 = 43351 \times 10 = 43\cdot351$ cubic feet; and $p_2 - p_3 = 6\cdot656$ lb. per square inch; then the additional work is

$$43\cdot351 \times 6\cdot656 \times 144 = 41540 \text{ foot-pounds;}$$

and the total available work is $142200 + 41540 = 183740$ foot-pounds for 1 pound of steam; or, for each unit of heat expended, it is

$$\frac{183740}{1254\cdot4} = 146\cdot4 \text{ foot-pounds.}$$

It appears that, in this case, nearly $11\frac{1}{4}$ per cent. of the whole heat consumed within the cylinder would be supplied to the steam while expanding, to maintain it in a state of dry saturation; and the efficiency of the engine is measured by the fraction $\frac{146\cdot4}{772} = \frac{1}{5\cdot3}$, or 18 per cent., showing that 82 per cent. of the heat expended is rejected.

Formulas have been constructed for the work of high-pressure steam, worked expansively by means of the link-motion, based on the indicator-power of locomotives, detailed in the work on *Railway Machinery*. The cylinder from which the data were obtained, was 18 inches diameter, 24 inches stroke, and had 1·8 inches total clearance, or $\frac{1}{13}$th of the stroke at each end, with steam-ports 13 by 2 inches, or about $\frac{1}{10}$th of the piston-area. The cylinders were placed in the smoke-box, and the steam maintained in good condition. The maximum pressure in the cylinder varied from 70 to 90 lb. per square inch above the atmosphere. The volume of steam admitted was estimated in terms of the indicator-pressure at the point of suppression, and is now recalculated from the most recent investigations of relative volume. The formulas give the nett performances, allowing for drawbacks of every kind, as clearance, back-pressure, wire-drawing; and it is remarked that the incidental advantage by the increased wire-drawing of steam at greater speed during admission, is practically equivalent to the loss by increase of back-pressure. Thus, the formulas are applicable with accuracy for all the different observed speeds of piston, from 200 to 800 feet per minute. Let r = the percentage of the stroke at which the steam is cut off, then the consumption of steam in lbs. per horse-power per hour

$$= 24r + 15\,;$$

and dividing the result by the evaporative ratio of the fuel,

Work of Saturated Steam under Normal Conditions, with Expansion.

the quotient is the consumption of fuel in lbs. per indicator horse-power per hour.

Again, as one actual horse-power is equal to 1,980,000 foot-pounds per hour, the work of 1 lb. of steam

$$=\frac{1,980,000}{(\cdot 24r+15)}.$$

The effective mean pressure in lbs. per square inch in the cylinder, for a given maximum pressure P, and percentage of admission, r, is

$$\text{Eff. mean pressure} = P \times \cdot 135\sqrt{r} - \cdot 28.$$

The above three formulas are applicable without material error for periods of admission from 10 to 80 per cent., and for pressures of 60 lb. to 150 lb. per square inch. For high pressures, the results they give are slightly under the actual results,—a negative error. The effective mean pressure, by the last equation, is slightly too small for the lower speeds, and slightly too great for the higher, but is exact for a speed of piston of 560 feet per minute.

CHAP. VI.—THE WORK OF SATURATED STEAM UNDER NORMAL CONDITIONS, WITH EXPANSION.

In the two preceding sections the work of steam in a cylinder has been considered, first, as gaseous steam, where the steam has been super-heated above its temperature of saturation, and maintained at a uniform temperature; second, as dry saturated steam, where it receives, during expansion, just as much heat as is sufficient to prevent the condensation of any portion of it. It remains to consider the action of steam, when it neither parts with nor receives heat during any part of the stroke. This condition supposes a normal state of things, and implies that the material of the cylinder is a perfect non-conductor, and that the water of condensation during expansion is discharged with the steam at the end of each stroke. Such a condition of things does not, and perhaps cannot, exist in practice, but the consideration of it as an elementary question will be useful.

It has been stated that, whatever the fluid employed, the proportion of heat utilised, in working over the same range, or between the same pair of temperatures, is the same, whatever the fluid employed, when all the heat derived from the heater or boiler is communicated to the fluid at the maximum temperature, and when the entire fall of temperature is effected by the useful expansion of the fluid. On these principles it is necessary, first, that the substance should be raised from the temperature of the condenser to that of the boiler, without directly abstracting heat from the source of heat,—for example, the feed-water should be heated independently to the temperature in the boiler; second, that the fluid should be expanded down to the temperature of the condenser. Under these circumstances, the ratio $\frac{T_1 - T_2}{T_1}$ expresses the efficiency of the heat expended, or the proportion of heat utilised, and the remainder, $T_1 - T_2$, being the measure of the heat utilised, and T_2 the measure of the heat rejected, the relative proportion of the latter can never, under any conceivable circumstances, be less than $\frac{T_2}{T_1}$. For example, let the absolute temperature of the condenser, $T_2 = 600°$, and that of the boiler $T_1 = 800°$, then the heat utilised cannot be more than $800 - 600 = 200°$, or the fraction $\frac{2}{8}$, and the heat rejected cannot be less than 600°, or the fraction $\frac{6}{8}$. The ultimate maximum of work, in foot-pounds per unit of heat expended, would, with any vapour or gas, equal $772 \times \frac{T_1 - T_2}{T_1}$; and suppose, again, $T_1 = 718°$, and $T_2 = 563°$; the heat utilised would be $718 - 563 = 155°$, and there would be $\frac{155}{718}$ parts of the heat converted into work, and $\frac{563}{718}$ parts rejected, or transferred to the condenser. The work done for each unit of heat expended would be $772 \times \frac{155}{718} = 166 \cdot 6$ foot-pounds. This is for a perfect heat-engine.

Now, reverting to the steam-engine, whilst the maximum of duty is obtained by the expansion of the steam within the cylinder down to the pressure in the condenser, prior to its being discharged, it is obviously impossible to comply with the first condition of a perfect engine, namely, the heating of the feed-water to the temperature in the boiler, without abstracting heat from the furnace, or from the boiler itself; the only other source of heat is in the condenser, which is only at the temperature due to the pressure—that is, for, say 1 lb. absolute pressure, the sensible temperature is 102° Fahr., and the feed-water supplied from the condenser cannot exceed this temperature. The heat expended, under such circumstances, must therefore be increased by a quantity arising from the inferiority of the sensible temperature of the feed-water at 102°, to that of the steam in the boiler, expressed by $T_1 - T_2$ degrees; so that, if the water at 102° be converted into saturated steam at 102°, and the temperature and pressure of the resulting steam be raised to those of the saturated steam in the boiler, though $T_1° - T°_2$, or 155°, the quantity of heat thus absorbed is measured by $\cdot 305\,(T_1 - T_2)$, or, say, to allow for the varying specific heat of water, $\cdot 3\,(T_1 - T_2)$. The denominator of the ratio of efficiency must therefore be increased by this quantity; and putting h = the greatest proportion of the heat expended, it is possible to convert into work, by expanding the steam down to a temperature of 102°, with the condenser at this temperature, and an absolute pressure of 1 lb. per square-inch. Then we have Mr Brownlee's formula,—

$$h = \frac{T_1 - T_2}{T_1 + \cdot 3(T_1 - T_2)}$$

Let, for example, as before, $T_1 = 718°$, for a total pressure of 33·7 lb. per square inch; then T_2 being 102° sensible, or 563° absolute, $(T_1° - T_2°) = 155°$, and

$$h = \frac{155}{718 + (\cdot 3 \times 155)} = \frac{155}{764 \cdot 5} = \cdot 2027,$$

or about one-fifth, being the ratio of efficency; and the work done for each unit of heat expended is $772 \times \cdot 2027 = 156 \cdot 5$ foot-pounds.

The comparison, in the particular cases under consideration, between the efficiency of the most perfect engine conceivable, and that of an ordinary condensing engine, working under the conditions specified, may thus be stated:—

	Extreme absolute temperatures.	Extreme total pressures.	Work done per unit of heat expended.
Perfect engine,...	718° to 563°	33·7 lb. to 1 lb.	166·6 foot-pounds.
Ordinary do.,...	718° to 563°	33·7 lb. to 1 lb.	156.5 „

It would appear, then, that the ordinary engine would yield 10·1 foot-pounds, or only 6 per cent. less duty than the perfect engine, when working over the same range, or between the same pairs of temperatures.

It has been said that, in a perfect engine working between the same temperatures, the total work performed for a given expenditure of heat is the same, whatever the substance or vehicle of the heat may be. But in ordinary working,—confining the comparison to condensing engines for the present,—the liquid is supplied directly from the condenser at a lower than the initial temperature; and the work done with different liquids is not the same for equal quantities of heat expended, although working similarly between the same pair of temperatures, and regularly expanding from the highest to the lowest. A steam-engine, for instance, with the boiler at 212°, and the condenser at

Coal, its Composition and Decomposition.

104°, the steam expanded in the cylinder from the former to the latter temperature, and the feed-water supplied at 104°, would convert into work ·1526 of the heat expended, represented by unity. With a sulphuric ether engine, under the same conditions, the maximum utility would be expressed by ·1406. In an air-engine, let the air be supplied to the heater at the constant temperature 104°, and therein raised at constant pressure from 104° to 212°; thence admitted to and expanded upon a piston till the temperature falls to 104°, and then discharge at this temperature, then it cannot utilise more than ·09 of the heat expended.

In order to compare, by an example, the action of steam in an ordinary engine, where it neither gains nor loses heat while expanding with its action in a jacketed cylinder,—being supplied with just as much heat while expanding as to prevent condensation of any kind in the cylinder—the example already detailed, in illustration of Mr Brownlee's formula for the action of steam in a jacketed cylinder may be assumed. It was found in that case, that 121·6 foot-pounds of work was done for each unit of heat expended, with initial steam of 100 lb. total pressure per square-inch expanded to 10 volumes, with a final pressure in the cylinder of 8·656 lb., and the same pressure in the condenser. The initial and final absolute temperatures due to the pressures were 788·8° and 646·5°; then $T_1 - T_2 = 142·3$, and

$$\frac{T_1 - T_2}{T_1 + ·3\,(T_1 - T_2)} = \frac{142·3}{831·5} = ·1711; \text{ and } 772 + ·1711 = 131$$

foot-pounds of work per unit of heat expended, when heat was neither given to nor taken from the steam in the cylinder, to be compared with 121·6 foot-pounds in the jacketed cylinder. Again, for 1 pound of steam, the expenditure of heat in the act of expansion was found to be 1028 units, exclusive of the heat derived from the jacket; and 1028 × 131 = 134,700 foot-pounds would be the total action of 1 pound of steam in the unjacketed cylinder, to be compared with 142,200 foot-pounds, which comprises the additional work arising from the absorption of heat from the jacket. Hence it appears that, in the unjacketed non-condensing cylinder, there was less work per pound of steam, but more work per unit of heat expended, than in the jacketed cylinder. Of course this comparison, though just, is hypothetical, as it supposes that no part of the heat of the steam is absorbed or wasted through the cylinder, which is not a state of things that can be said ever to occur in practice. The jacketed cylinder, then, is not essentially better than the unjacketed, but is so only because of practical imperfections arising from the conducting power of metals, in the latter case, and the consequent precipitation and unprofitable re-evaporation of steam.

SECTION VII.

CHAP. I.—COAL:—ITS COMPOSITION AND DECOMPOSITION. COKE.

The combustion of fuel consists in the chemical union of the combustible elements with atmospheric oxygen, and the practical management of the process consists, therefore, in so disposing of the fuel in layers on the grate, and so administering the air as to effect their intimate mixture in order to effect their final combustion. The process is simple or complex, according to the composition of the fuel. Coke consists, substantially, of but one combustible, carbon, and the whole process is comprised in the union of the carbon with oxygen in the proper saturating proportion. But coal is not a homogeneous substance; the combustible matter of it is found, by analysis, to consist mainly of carbon and hydrogen:—carbon, dull and unevaporable;—hydrogen, the most elastic gas known:—at the extreme of the scale of existence. The question of the prevention of smoke is intimately associated with that of the combustion of coal. They are, indeed, essentially one question; for, if coal be completely burnt, there cannot be any smoke; and, otherwise, if there be smoke, the coal is certainly not completely burnt. Now, as coke and anthracite coal give no smoke during combustion, although composed of the very matter of smoke—carbon,—it follows that the property of smoke-making is in some way associated with the hydrogen of the coal, which is at the same time the most perfect type of gaseity known in chemistry. The constituent hydrogen is associated in chemical union with a portion of the carbon, forming with it a complex group of compounds, known collectively as hydro-carbons, which present themselves in various forms, when separated or distilled, by the application of heat. At the lowest temperature, the products obtained are chiefly oils, resins, and like distinctive compounds, vaporizable at temperatures under red heat. A somewhat higher temperature brings off fluids of volatile character, as naphtha. A higher still, the third stage of temperature, produces the rich illuminating gas, olefiant gas, or bi-carburetted hydrogen. The fourth stage discharges the common gas, carburetted hydrogen, which continues to be given off after the coal has reached low red heat. But as the temperature rises, pure hydrogen also is given off; until, finally, in the fifth and last stage, hydrogen gas alone is discharged. What remains is the fixed or solid carbon of coal—the coke; with earthy matter—the ash of the coal.

These hydro-carbons, especially those which are given off at the lowest temperatures, which are richest in carbon, constitute the flame-and-smoke making part of the coal; and the greater their entire weight, as compared with that of the fixed carbon, the more highly is this character developed. When subjected to degrees of heat much above the temperatures required to vaporize them, they become decomposed, and pass successively into more and more permanent forms, by precipitating portions of their carbon. At the temperature of low redness, none of them are to be found, and the olefiant gas is the densest type that remains, mixed largely with carburetted hydrogen and free hydrogen. It is in these transformations that the great body of smoke is produced, when the precipitated carbon passes off uncombined; even olefiant gas, at a bright red heat, deposits half its carbon, changing to carburetted hydrogen, and this gas may deposit the last remaining equivalent of carbon, at the highest furnace-heats becoming pure hydrogen.

Throughout all the primary and secondary conditions of the hydro-carbon compounds, raised by distillation from coal, the hydrogen maintains the first claim to the oxygen present above the fuel; until it is satisfied, the precipitated carbon remains unburnt.

There are very great individual differences in the chemical composition and properties of coals, and their varieties are very numerous. The proportion of fixed carbon in coal ranges from 30 to 93 per cent.; of hydro-carbons, from 5 to 58 per cent.; of water, or oxygen and hydrogen, in the proportions to form water, from a mere trace to 27 per cent.; and of ash, from 1½ to 26 per cent. The varieties of coal may be arranged into five classes:—

1. Anthracite, or blind coal, consisting almost entirely of free carbon. 2. Dry bituminous coal, having from 70 to 80 per cent. of carbon. 3. Bituminous caking coal, having 50 to 60 per cent. of carbon. 4. Long flaming or cannel coal, differing from the last in containing more oxygen; and in some varieties it does not cake. 5. Lignite, or brown coal, containing 27 to 50 per cent. of carbon.

The following summary presents the mean composition and characteristics of English, Welsh, and Scotch coals, derived from the *Report on Coals suited to the Royal Navy*, by Dr Playfair and Professor De La Bèche:—

Coal, its Composition and Decomposition.

Table of the Mean Chemical Composition of Coals.

Locality.	Constituent elements, by weight.						Coke left by Distillation.	Water evaporated per pound of Coal.
	Carbon.	Hydrogen.	Oxygen.	Nitrogen.	Sulphur.	Ashes.		
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	lbs.
Wales, 36 samples	83·78	4·79	4·15	0·98	1·43	4·91	72·60	9·05
Newcastle district, 18 samples	82·12	5·31	5·69	1·35	1·24	3·77	60·67	8·37
Lancashire, 28 samples	77·0	5·32	9·53	1·93	1·44	4·88	60·22	7·94
Scotch, 8 samples	78·53	5·61	9·69	1·0	1·11	4·03	54·22	7·70
Derbyshire, 7 samples	79·68	4·94	10·28	1·41	1·01	2·65	59·22	7·58
Gross means	80·22	5·20	7·87	1·33	1·25	4·05	61·40	8·13

It appears from this summary that the composition of British coals averages about 80 per cent. of carbon, 5 per cent. of hydrogen, 8 per cent. of oxygen, $1\frac{1}{3}$ per cent of nitrogen, $1\frac{1}{4}$ per cent. of sulphur, and 4 per cent. of ashes. Also, that the coke, or fixed carbon, as distinguished from the volatilized carbon, averages a little over 60 per cent. of the weight of the coal; the volatilized carbon averaging 20 per cent. Of the volatile portions of coal, then, generated in the preliminary stage of decomposition and distillation, prior to combustion, those which arise in chemical combination are, say,

Carbon	20	per cent.
Hydrogen	5	„
Oxygen	8	„

One part of the hydrogen is united to the 8 parts of oxygen, in the chemically combining proportions forming steam, and of the remaining 4 parts of hydrogen, $3\frac{1}{3}$ parts unite in chemical proportion with the 20 parts of carbon, forming carburetted hydrogen, and $\frac{2}{3}$ of one part passes off as pure hydrogen. The elements of the decomposed fuel, prior to combustion, may thus be summarised:—

100 *lbs. of Coal.*

	lb.		lb.	
Fixed carbon	60	forming	60	fixed carbon.
Volatilized ditto	20		$23\frac{1}{3}$	carburetted hydrog.
Hydrogen	5		9	steam.
Oxygen	8		$\frac{2}{3}$	hydrogen.
Nitrogen, ash, &c.	7		7	nitrogen, &c.
	100		100	

Coke exists in various degrees of purity. The purest coke contains about $97\frac{1}{2}$ per cent. of carbon, according to the following analysis of the best Newcastle coke:—

Carbon	97·6	per cent.
Sulphur	0·85	„
Ashes	1·55	„
	100·00	

Coke is classified into three kinds: good, middling, bad; of which the good contains an average of 94 per cent. of carbon; the middling 88 per cent.; and the bad 82 per cent. Coke usually contains more sulphur than coal, and that is the most injurious element in its effects on the metallic substances exposed to the products of combustion.

Peat, or turf, is in considerable use in Ireland. Perfectly dry peat, of the best quality, contains, in 100 parts—

Carbon	58	per cent.
Hydrogen	6	„
Oxygen	31	„
Ash	5	„
	100	

In its ordinary state of dryness, it contains 25 to 30 per cent. of water.

CHAP. II.—THE CHEMISTRY OF THE COMBUSTION OF COAL.

One pound of hydrogen unites with and requires 8 lb. of oxygen for its combustion; measuring by volume, 1 cubic foot of hydrogen requires just half a cubic foot of oxygen for combustion; the product being steam, aqueous vapour, or water. Oxygen is sixteen times as weighty as hydrogen, and so hydrogen combines with eight times its weight, and but half its volume, of oxygen. In round numbers, 1 pound of hydrogen is 200 cubic feet in bulk, at 62° Fahr., and the combining volume of oxygen is 100 cubic feet.

One pound of carbon unites with $2\frac{2}{3}$ lb., or 32 cubic feet, of oxygen for its complete combustion, forming carbonic acid.

Atmospheric air is composed of oxygen and nitrogen, in the proportion of 1 lb. of the former to $3\frac{1}{2}$ lb. of the latter; or, by volume, 1 cubic foot of oxygen to 4 cubic feet of nitrogen. Nitrogen is a neutral gas in combustion, and is present as a diluent simply; and for every cubic foot of oxygen required in combustion 5 cubic feet of air must be supplied.

It follows, that for the combustion of 1 lb. of hydrogen 500 cubic feet of air are required; and for the complete combustion of 1 lb. of carbon, 160 cubic feet of air are required.

These are the combining proportions of hydrogen and carbon with oxygen, and air, in combustion. In practice, the presence of an excess of oxygen above that which is chemically appropriated, is essential to the completeness of the combustion of the volatilised portions; but the amount of excess necessary becomes less as the general temperature in the furnace becomes greater. It is not needful, for present objects, to entertain the question of excess of air specifically, nor the relative demands of the varieties of hydro-carbons generated from coal. It suffices to show, generally, the proportions of air required for full chemical union with the volatile and the solid portions of the fuel; and thus illustrate the relative importance of the claims of the gases upon the general oxygen fund. It was shown that the average proportion of volatilised hydrocarbons was $23\frac{1}{3}$ per cent. by weight of the whole body of coal, of which the hydrogen constituted $3\frac{1}{3}$ per cent. and the carbon 20 per cent.; and there remained 60 per cent. as solid carbon. For illustration, take 100 lb. of coal; then the relative quantities of air chemically consumed in completely burning the combustible elements are as follows:—

Volatile	Hydrogen,	4 lbs. consumes		2000 cubic feet of air.		
	Carbon,	20 do.	do.	3200	do.	do.
				5200		
Fixed	Carbon,	60 do.	do.	9600	do.	do.
		85 do.	do.	14,800	do.	do.

It may be assumed, in round numbers, that, for the complete combustion of 100 lb. of coal, that is, of its combustible elements, 15,000 cubic feet of air is chemically consumed, or 150 cubic feet for 1 lb. of coal. And, of this supply of air, the volatile and fixed elements consume respectively, for the volatile, about one-third, and for the fixed, two-thirds.

If allowance be made for the excess of air practically

Heat of Combustion of Coal and Coke.

required for the complete combustion of the gases, say double the chemical equivalent, the total supply of air required for the combustion of 100 lb. of coal would be as follows:—

Volatile elements,	10,400, or say, 10,000	cubic feet of air.
Fixed element,	9,600, or say, 10,000	do, do.
Total for 100 lb. of coal,	20,000	cubic feet of air.

Thus, finally, it is estimated, that for the complete combustion of 100 lb. of coal of average composition, 15,000 cubic feet of air are chemically consumed; and that 20,000 cubic feet of air are required in practice, or 200 cubic feet of air for 1 lb. of coal, of which one-half is devoted to the fixed portion of the fuel, and one-half to the volatile portion.

The importance of the share in the business of the furnace, taken by the volatilised parts of the fuel, evinced by the large proportion of air allotted to it, is enhanced by the reflection, that the development of heat by combustion is generally in the ratio of the quantity of oxygen chemically combined in the process; and that thus the heat developed by the complete combustion of the volatile elements is one-third of the entire quantity of heat generated. There is, then, scope for the economization of fuel, as well as for the prevention of smoke; but, as there is no doubt that much of the air consumed in burning the volatile elements is drawn through the grate, in company with that which is devoted to the solid portion, there remains so much the less fresh air to be thrown in above or beyond the fuel. There are, doubtless, empiricists who do not believe in the increase of economy by smoke-prevention. Unquestionably, however, when the prevention of dense smoke is not accompanied by a material saving of fuel, there must be a want of adjustment of the appliances, and necessarily imperfect combustion, or waste of means. Carbon, as already stated, may combine with oxygen in one of two proportions, forming carbonic oxide and carbonic acid, of which both are colourless; but, in the production of the former of these, much less heat is developed than in that of the latter.

Besides the combustibles, hydrogen and carbon, the other elements of coal—oxygen, in union with its equivalent of hydrogen, with nitrogen and sulphur—are driven off in the gaseous form. Ammonia is the product of the union of hydrogen and nitrogen, and may possibly be driven off direct from the coal. However the chemical details of combustion may be developed, it is certain that hydrogen from coal practically monopolises a considerable portion of atmospheric oxygen; for the supply of which, therefore, to the hydrogen, provision must be made without prejudice to the requirements of the fixed carbon, in order to effect complete combustion.

CHAP. III.—THE HEAT OF COMBUSTION OF COAL AND COKE.

The total heat of combustion of the elements of coal, simple and compound, has been the subject of elaborate experiment by several physicists, amongst whom are MM. Favre and Silbermann, who employed in their observations the mercurial calorimeter, an instrument from which great accuracy may be expected. The following table of the results arrived at by the above-named experimentalists shows the total heat of combustion with oxygen, of one pound of each of the substances named, in British thermal units, and also in pounds of water evaporated from 212° Fahr., with the weight of oxygen required to combine with one pound of each of the combustibles.

The result arrived at by MM. Favre and Silbermann, as the total heat of combustion of carbon, is higher than that of Dulong, 12,906 units, and that of Despritz, 14,040 units; but it is preferred, as the highest result in experiments of this kind is the most likely to be correct.

Table of the Total Heat of Combustion of the Constituents of Coal and other Fuels.

Combustible (1 pound).	Weight of Oxygen consumed per pound of combustible.	Total heat in British units.	Evaporative power in weight of water, from 212° Fahr.
	lbs.	units.	lbs.
Hydrogen gas	8	62,032	64·2
Carbon, imperfectly burned, so as to make carbonic oxide	$1\frac{1}{3}$	4,400	4·55
Carbon, completely burned, so as to make carbonic acid	$2\frac{2}{3}$	14,500	15·0
Olefiant gas	$3\frac{3}{7}$	21,344	22·1
Various liquid hydro-carbons	...	21,000 to 19,000	22 to 20
Coal (average)	$2\frac{9}{20}$	14,081	14·57
Coke (average)	$2\frac{1}{3}$	12,760	13·2

It is to be observed, that the imperfect combustion of carbon, making carbonic oxide, produces less than one-third of the heat yielded by the complete combustion of it; also, that the heating power of hydrogen gas is $4\frac{1}{4}$ times that of carbon. It may be deduced, further, that the total heat of combustion of any compound of hydrogen and carbon is the sum of the quantities of heat which the hydrogen and carbon contained in it would produce separately by their combustion. It has also been inferred from other experiments, that the presence of oxygen and hydrogen in fuel, in the proportion to form water or steam, does not affect the total heat of combustion; and that it is only the excess of hydrogen that can be made serviceable as a source of available heat. It would appear, however, that one essential element in the question of the total heat of combustion of coal has not yet been determined, namely the quantity of heat absorbed from the general stock, or rendered latent, in gasifying the hydro-carbons, which is to be charged against the hydrogen, as the evaporative efficiency of the hydrogen must be measured by the quantity of heat developed in its union with oxygen, minus the heat absorbed in the preliminary gasification of it. As Professor Rankine concisely puts it, "the heat obtained is the excess of the heat produced by the combinations, above the heat which disappears in consequence of the decompositions. Sometimes, also, the heat produced is subject to a further deduction, on account of heat which disappears in melting or evaporating some of the substances which combine, either before or during the act of combination." One thing is clear, that in order to make the best of it, the hydrogen, once volatilised, should be oxidized, as well as the carbon associated with it, in order to realize the large measure of heat generated by their combustion. There is a favourite theory, having at least the merit of simplicity, that the heating power of coal is just equal to that of the coke derived from it, which is manifestly absurd. It would be nearer the truth to say, that the heating power of coal is measured by that of its constituent carbon. The evidence of the evaporative powers of coals, abstracted in the table, page 629, appears to support this mode of estimation, in so far as the evaporative efficiency varies generally with the percentage of constituent carbon. The percentages of constituent hydrogen vary within narrow limits, and do not afford data for any marked comparison; but it may be suggested, that generally, the evaporative efficiency is less, as the constituent hydrogen is greater in quantity. Neither the variations of the hydrogen nor those of the carbon, however, suffice to account for the comparatively wide differences of efficiency; but, on referring to the next column, of the constituent oxygen, it is remarkable, that the efficiency of the fuel decreases regularly as the percentage of oxygen in the fuel increases.

Physical Conditions of the Combustion of Coal.

Welsh coal, with about 84 per cent. of carbon, and 4 per cent. of oxygen, evaporates 9·05 lb. of water per lb. of fuel; whilst Derbyshire coal, with about 80 per cent. of carbon and 10 per cent. of oxygen, evaporates only 7·58 lb. of water per pound of fuel. The difference of carbon does not sufficiently account for the difference of evaporative efficiency; nor does the difference of hydrogen, which is practically the same in both cases. The prime cause, apparently, is the oxygen, which is in great excess in the inferior coal; and an explanation readily occurs. All this oxygen must, in the first place, be volatilised, and it must absorb a portion of heat, which is thus diverted from the business of evaporation; and, though, no doubt, it may subsequently restore the heat thus temporarily abstracted in combining with the hydrogen as a gas, yet, as compared with the atmospheric oxygen, which, in the absence of solid oxygen, supplies its place, the solid oxygen is at a disadvantage, in so far as atmospheric oxygen is yielded at once in the half converted, desirable condition of a gas.

It appears, then, that the evaporative efficiency of coal varies directly with the quantity of constituent carbon, and inversely with the quantity of constituent oxygen; but that it varies, not so much because there is more or less carbon, as, chiefly, because there is less or more oxygen. The percentages of constituent hydrogen, nitrogen, sulphur, and ash, are practically constant, with individual exceptions, of course, and their united influence should be so also. Practically, then, treating the question as one of evaporative efficiency, the solution of it lies between the carbon and the oxygen.

The theoretical estimate of the calorific value of coal of average quality, namely, the evaporation of 14·57 lb. of water, from and at 212°, is confirmed by the results of an apparatus constructed by Mr Wright of Westminster; so contrived, that a portion of coal is burned under water, and the products of combustion actually passed through the water, so that the whole of the heat generated is absorbed. By means of this apparatus, the following calorific values, or total heats of combustion, were obtained, the particulars of which were published in the *Reports on the Use of the Steam Coals of the Hartley District of Northumberland*, by Messrs Armstrong, Longridge, and Richardson:—

Welsh coal	14·30 lb. from 212°
Hartley coal	14·63 „
Mean (by experiment)	14·46 lb.
By theoretical estimate	14·57 lb.

The total heat of combustion of coke is deducible directly from that of carbon, which constitutes the combustible matter of coke. The percentage of carbon in coke determines the percentage of its heating power. Thus:—

Coke.	Constituent Carbon.	Total heat of Combustion of one pound.	Total Evaporative power in pounds of water from 212°
Good	94 per cent.	13,620 units	14·0
Middling	88 „	12,760 „	13·2
Bad	82 „	11,890 „	12·3

CHAP. IV.—PHYSICAL CONDITIONS OF THE COMPLETE COMBUSTION OF COAL.

It has been seen that coal undergoing combustion is exhibited in two forms, solid and gaseous, of which the solid (coke) rests on the grate, and the gaseous (hydro-carbons and hydrogen) rise from the solid portion. To get the air into immediate contact and mixture with these elements, so as completely to burn them individually and in detail, is the important problem, the solution of which has been the study of engineers. The mode of so introducing and mixing the air depends on the circumstances of the furnace. If the grate be very large, and the combustion very slow and uniform, as is usual in the practice of Cornish pumping-engines, all or nearly all the air needed for effecting the complete combustion of the fuel may be passed through the grate. If, on the contrary, the grate be small, and the combustion rapid and irregular, as in locomotive practice, a large proportion of the air needed to accomplish the entire combustion of the fuel must be introduced above the fuel, there to mix with and consume the gases. The introduction of air through the grate is, in ordinary practice, the fundamental condition; the admission of air otherwise above the fuel is auxiliary or supplementary to it, supplying just the additional quantity of air requisite to complete the combustion.

Again, the temperature should be maintained at a sufficient elevation, or, more correctly, it should not be lowered by external causes, during the combustion of the hydro-carbon gases, in order to effect the union of the carbon element with its full proportion of oxygen. In chemical order, the hydrogen discharges the associated carbon, and unites with oxygen; by this union intense heat is generated, which envelopes the separated carbon-particles, and raises them to a white heat. Becoming thus luminous, and being the matter of flame, the carbon, in its intensely heated state, is prepared to unite with its saturating proportion of oxygen, and the union is effected the instant they meet, should the carbon retain its temperature until it gets into contact with oxygen. Upon this contingency depends the final condition of the precipitated carbon, whether as unburnt, uncombined particles, the colouring matter of smoke, or as the product of combustion, carbonic acid. Should the carbon-particles miss the opportunity of uniting with oxygen whilst yet at the high temperature which qualifies them to unite, it becomes practically impossible to restore them to the combining condition, and they inevitably pass away as smoke.

It follows, further, as a condition essential to the complete combustion of coal, that the combustible gases should be thoroughly mixed with their supply of air. When the streams or columns of hydro-carbon gases rise, undisturbed or unbroken, from the body of the fuel, they are decomposed in bands or films at what may be conceived as their surfaces of contact, when the oxygen of the surrounding air unites, in the first place, with the hydrogen of the decomposed distillation, and, in the second place, with the carbon-particles. So far the combustion is complete. Watery vapour and carbonic acid are generated as the results of the union of the distilled gases and the oxygen. At this stage, however, a contingency arises, and a partial re-action may ensue; for in the ordinary course of the circulation of the gases, the film or stratum of burnt gas mixes with and loses itself amongst the neighbouring hydro-carbon gases, and should there not be present a sufficiency of fresh atmospheric oxygen to continue the combustion in that quarter, the newly formed carbonic acid would be attacked by the hydrogen of the hydro-carbon, and resolved into its elements, of which the oxygen would be appropriated by the hydrogen, and the carbon would be re-precipitated simultaneously with the carbon separated from the newly formed hydrogen. It may be observed, however, that notwithstanding such occasional action and re-action to which the carbon is subjected, and chargeable to the superior affinities of the associated hydrogen, the carbon may be in condition, as at first, to again unite with oxygen, and to be ultimately and completely burned:—in the condition, namely, of a sufficiently elevated temperature. It is clear that a continuous process of intermixture is necessary to the completion of the combustion of coal, bringing together successively fresh portions of the combining elements, and throwing the separated carbon in the way of fresh oxygen for its own proper combustion.

The complication that usually characterizes the burning of coal is, then, both physical and chemical; physical, be-

Physical Conditions of the Combustion of Coal.

cause an intimate mixture, and a suitable proportion of the elements concerned, is essential to the completeness of their conversion; chemical, because, unfortunately for the special object of the furnace, which is to generate heat, the least important element, hydrogen, is precisely that which commands the preference, and must have its share of oxygen before the claims of the staple element, carbon, can be really entertained and satisfied. The hydrogen must be driven off before the main business of the furnace commences. The occasional presence of oxygen and nitrogen in considerable quantity further complicates the process, as they must be volatilised and driven off in the due course of distillation.

Nevertheless, both coal and coke are, in good practice, effectually burned in furnaces properly formed. The completeness of the combustion of coke in locomotive boilers has been proved by chemical and by mechanical analysis. The combustion of coal has been for many years diligently studied and practised by Mr Charles Wye Williams, and has been by him reduced to successful and varied practice. His leading principle, as published in his *Treatise on the Combustion of Coal*, is the introduction of air above the fuel, to mix with and consume the combustible gases, on the principle of the argand lamp, through a great number of small orifices in the furnace-door, or at the bridge, or otherwise. In its application, of course, the details are various, and in some classes of furnace having powerful draught, as locomotive fire-boxes, it has not been found necessary to subdivide the air so minutely as Mr Williams' practice indicates.

On the system of steam-inducted air-currents, the air is introduced in several streams, which, when necessary, are propelled into the furnace amongst the smoke, by means of jets of steam properly directed through the apertures, which are quite efficient in effecting the object.

There is an opinion that there is advantage in burning fuel in furnaces with long flues, slightly moist, and that ash-pits should be supplied with water, from which steam may be generated by the radiant heat from the fire, and passed through the grate. There is no actual gain of heat by this expedient; but it may be that the radiant heat, otherwise lost, is utilised in making steam, which may increase the efficiency of the fuel. The access of water to the fuel lessens the "glow-fire" or flameless incandescent fuel, and increases the quantity of flame by forming carbonic-oxide and hydrogen gases in its decomposition into its elements, oxygen and hydrogen, and the reduction by the oxygen of the carbonic acid already formed in the furnace. The presence of moisture, even in coke, creates flame, and reduces the intensity of the heat in the "glow-fire;" on the same principle of deferred or distributed combustion, moist bituminous coal is found to be most effective in furnaces with long flues, as in Cornish boilers, where they are 100 or 150 feet in length. These considerations point to the distinctive qualifications of coke and coal in furnaces. Whilst, under steam-boilers, coal and coke may be rendered equally efficient in the generation and communication of heat, per pound weight; on the contrary, it has been found, as recorded by Mr Apsley Pellatt, who gives the results of many years' practice, that in glass furnaces, where intense local heat is required, 13 cwt. of coke is practically equivalent to 21 cwt. of coal. Coke is of the most effective value where local intensity of heat is needed, as in glass furnaces, and in others with short flues and rapid draft, where the flame cannot be used. Coal is generally more effective where carried heat is in demand, the process of combustion being deferred and distributed, and the active development of flame and heat being sustained in the flues; and the benefit of a limited proportion of moisture in the coal depends upon the length of the flues and the time allowed for combustion, when the heat taken up in the glow-fire is given out again in the flame.

Efficiency of Steam-Boilers.

The circumstances under which coal is burned under steam-boilers are as various as the qualities of coal itself. The rate of combustion varies from 2 lbs. to 120 lbs. of fuel per square foot of fire-grate surface per hour; the combustion may be equally perfect for all rates, and in good practice it is so. The rate depends chiefly on the strength of the draught, which, if by chimney, does not, at its best, enable the furnace to consume above 30 lbs. of coal per square foot of grate per hour. For higher rates of combustion, the blast-pipe or the fan is employed. The rates of combustion in boiler furnaces may be thus classified:—

	lbs. per Square Foot per Hour.
1. The slowest rate of combustion in Cornish boilers with Welsh coal	2 to 2½
2. The slowest rate of combustion in Cornish boilers with Newcastle coal	4
3. Factory boilers	12 to 16
4. Marine boilers	16 to 24
5. Dry coal, quickest rate	20 to 23
6. Caking coal, „	24 to 27
7. Locomotives	40 to 130
8. Do. ordinary variations	50 to 100

The temperature of the products of combustion at the instant of their formation varies of course with the quantity of cold air in dilution. Professor Rankine estimates the temperature to be as follows:—

	Carbon.	Olefiant Gas.
Fuel, undiluted with air	4580°	5050°
If diluted with an excess of half the air consumed	3215°	3515°
If diluted with an excess equal to all the air consumed	2440°	2710°

The temperature of the escaping products of combustion in the chimney does not usually exceed 600° Fahr.; it is frequently lower, occasionally not above 300°, and at times barely sufficient to boil water. But this sort of excellence is not to be found except with the largest class of boilers and the slowest combustion. In passenger-locomotives on ordinary duty, the temperature usually rises to 600° and upwards, and in goods locomotives it probably reaches to 1000°.

CHAP. V.—THE EFFICIENCY OF STEAM-BOILERS.

Of the total heat of combustion of fuel, perfectly consumed in the furnace, a portion is absorbed through the heating surface of the boiler, and the remainder passes off without being utilised in the formation of steam. The proportion of utilised heat, or the efficiency of the boiler, varies with every circumstance, but it is regulated chiefly by the area of the fire-grate, the area of the heating surface, and the rate of combustion per unit of grate-surface, say per square foot of grate. If the grate be large and the combustion slow, a greater extent of heating surface is necessary to insure the same efficiency, than if the grate were small and the combustion quick, supposing in the two cases the same total quantity of fuel be consumed per hour. The reason is, that the intensity of combustion increases with the rate at which it proceeds per square foot of grate, the general temperature is higher, as there is a less excess of air in dilution, the radiant heat is also greater, and consequently there is a more rapid absorption of heat into the boiler. The importance of the last condition as to radiant heat is proved by the experiments of Peclet, who found that more than half of the heat of incandescent fuel is radiated from the mass. The relative proportions of the grate area, the heating surface, and the rate of combustion, constitute a question of great practical importance. It was investigated with respect to locomotive-boilers, and the results published in *Railway Machinery*, in 1852, and also in the *Proceedings of the Institution of Civil Engineers*, in 1853, when it was shown that, in order to insure the same efficiency, the following rela-

Efficiency of Steam-Boilers.

tions must be observed:—1*st*, For a given area of grate, the total hourly consumption of fuel should vary as the square of the total heating surface; that is to say, for example, if the heating surface were doubled, the total consumption of fuel might be increased to four times, whilst the same evaporative efficiency would be maintained. 2*d*, For a given extent of heating surface, the total hourly consumption should vary inversely as the area of grate; for example, if the grate-surface were increased to twice the area, the total hourly consumption of fuel should be absolutely reduced to one-half, in order to maintain the same efficiency. 3*d*, For a given hourly consumption of fuel, the area of fire-grate will vary as the square of the heating surface, in maintaining the same efficiency; for example, if twice the heating surface be employed, the grate may be extended to four times; conversely, if half of the heating surface be removed, the grate must be reduced to one-fourth of its area.

The mutual relations of heating surface, grate-area, and consumption of fuel, thus announced, are remarkable; and they bear upon the well-known sensitiveness of furnaces to superfluous enlargement of grates, in the reduction of efficiency. For it appears, that if a grate be doubled in area, only half the fuel can be burned on it, and only half the steam generated, if the same degree of efficiency, or evaporative power of the fuel, is to be maintained; so that only a fourth of the fuel can be, with equal utility, burned upon a square foot of the enlarged grate. It is apparent, then, that a superfluous size of grate is detrimental to the power of the boiler, unless at a sacrifice of fuel. On the contrary, an extension of heating surface adds in a still greater proportion to the power of the boiler, whilst the same efficiency of fuel is maintained. The general equation embodying these relations is,

$$F = C\frac{H^2}{G},$$

in which F=the quantity of fuel consumed per hour, H= the area of heating surface, G=the area of fire-grate, and C=a co-efficient, which is constant for similar boilers, but may vary for different kinds of boilers. Let the fuel be expressed in pounds, and the areas in square feet, and let the efficiency be represented by the evaporation of 9 pounds of water per pound of fuel, then the constant for locomotive-boilers, burning good coke, is equal to ·0154, and the formula becomes

$$F = \cdot 0154\frac{H^2}{G}.$$

Assuming 10 square feet area of grate, the hourly consumption of fuel, for different heating surfaces, capable of evaporating 9 lb. of water per pound of coke, are as follow:—

Area of Grate.	Area of heating surface.	Consumption of coke per hour. Efficiency=9 lb. of water per lb. coke.
Square feet.	Square feet.	lb.
10	450	312
10	500	385
10	600	554
10	700	755
10	800	985
10	900	1247

If the consumption be expressed at per unit of grate area, one square foot, the expression in the general formula becomes

$$F_1 = C\frac{H^2}{G^2} = C\left(\frac{H}{G}\right)^2 = Cr^2,$$

in which r = the ratio of the heating surface to the grate, and showing that the consumption of fuel, for constant efficiency, per square foot of grate, varies as the square of that ratio; in which case the formula for locomotives, as before, is

$$F_1 = \cdot 0154\, r^2.$$

The relative consumption of water evaporated is nine times the weight of coke, or $\cdot 0154\, r^2 \times 9 = \cdot 1384\, r^2$. The following are examples of the relative quantities, reduced to units of measure:—

Ratio of heating surface to fire-grate.	Consumption of coke per square foot of grate per hour.	Evaporation of water per square foot of grate per hour.		Evaporation of water per square foot of heating surface per hour.
Grate=1.	lb.	lb.	Cubic feet.	lb.
45	31	280	4·5	6·2
50	38	346	5·6	6·9
60	55	498	8·0	8·3
70	75	678	10·9	9·7
80	98	886	14·0	11·1
90	125	1121	18·0	12·5

This statement shows how very much the active value of the heating surface, per unit of its area, in evaporating water with the same degree of efficiency, may be increased by relatively reducing the grate, or by extending the heating surface itself. These results are based upon the conditions of the ordinary locomotive-boilers, with fire-box and small flue-tubes, about 2 inches diameter, and with sufficient clearance between the tubes, say ⅝ or ¾ inch for 160 tubes, and, of course, under good management. The same proportions stand good for coal in the locomotive. The evaporative standard of 9 lb. of water per pound of fuel is assumed, which would be equivalent to the utilisation of, say, 10,000 units of heat per pound of fuel, or about ⅘ths of the total heat of combustion. For other evaporative standards, though, no doubt, the same general equation is appropriate, different co-efficients would be required; and with respect to locomotive-boilers, it may only now be remarked, that, generally, within certain limits, the greater the rate of combustion on a given area of grate, with a given heating surface, the less is the evaporative efficiency. In locomotive boilers, an evaporative efficiency of above 10 lb. of water per pound of fuel has been attained. It must be admitted, however, that in general practice, an evaporation of only 8 lb. of water per pound of fuel is effected; and the efficiency fluctuates within the ordinary limits of 7 lb. and 9 lb. per pound of fuel. In locomotive practice the fuel is very commonly consumed at a rate varying from 60 lb. to 80 lb. per square foot of grate; but it descends as low as 40 lb. per foot of grate, with passenger-trains, and amounts to 100 lb., 120 lb., and even above that, per foot of grate per hour, in working goods-trains.

It follows, that the "long-boiler" type of locomotive-boiler, introduced and made by Messrs Robert Stephenson and Co., with a moderate grate, and long flue-tubes, is in general the most efficient in evaporative performance.

The general equation of efficient evaporative power is applicable to all classes of boilers, the value of the co-efficient probably differing for each class, and, of course, for each sort of fuel. The doctrine is powerfully illustrated in the practice of Cornish boilers, in which, with very large grates, the rate of combustion, as practised in Cornwall, is only from 2 to 4 lb. of fuel per square foot of grate. It is by slow combustion, they say, that they obtain their economical results, namely, a high evaporation of water—about 10 lb. per pound of coal. The system, of course, demands immense boilers, with long flues and extensive heating surface, to absorb at leisure the heat produced so languidly from the grate. The very low rate of combustion practised is in accordance with the nature of the fuel, commonly in small pieces, and in the form of dross; it requires to be deposited in layers on the grate and left undisturbed, so as to burn off gradually and uniformly. If forced, or disturbed, the smoke is disengaged, and there is a loss of efficiency.

Strength of Steam Boilers.

Thus there is a necessity for a large grate, in order to effect the complete combustion of the fuel; and there is a necessity for a large boiler and extensive surface, in consequence of the large grate, in order to absorb the heat.

Professor Rankine has announced the following approximate formula for expressing the efficiency of a furnace:—

$$\frac{E'}{E} = \frac{BS}{S + AF},$$

in which E denotes the theoretical evaporative power, and E′ the available evaporative power of 1 pound of a given sort of fuel; S the area of heating surface in square feet per square foot of grate, and F the number of pounds of fuel burned per foot of grate per hour; A, a constant, which is to be found empirically, probably proportional approximately to the square of the quantity of air supplied per pound of fuel; B, an empirical constant. In applying the formula to different classes of boilers, different values of A and B are proposed; for locomotive-boilers Professor Rankine computes the values of S and F from Mr Clark's formula, and arrives at near approximations for rates of consumption of about 60 lb. of fuel per square foot of grate per hour.

With respect to forcing a boiler, that is, urging the fire by frequent stirring and poking, discharging smoke and wasting fuel—a practice strongly deprecated by Mr Fairbairn—Professor Rankine justly observes that "the economy of fuel depends very much on the proper adjustment of the rate of combustion per square foot of grate to the draught of the furnace;" and that "it is best, in practice, to make the grate-area at first rather too large, and then to contract it by means of fire-bricks, until the smallest area is obtained upon which the required quantity of coal can be burned without incomplete combustion."

CHAP. VI.—STRENGTH OF STEAM-BOILERS.

English boiler-plates of iron are usually classed as Yorkshire plates, and Staffordshire, indicating the localities where they are manufactured. Cast-steel plates, also, are successfully manufactured of great strength, tenacity, and toughness; and good boilers may be made of that material. American boiler-plate appears to be made generally of superior quality. The following are the average ultimate tensile strengths of boiler-plate; that is to say, the weights necessary to tear the material asunder, per square inch of section:—

	Per square inch.	
Yorkshire iron plate, best quality	25	tons.
Staffordshire iron plate, do.	20	„
American iron plate, do.	31	„
Do. do. ordinary	27	„
Cast-steel plates	40	„

The breaking or ultimate tensile strengths of welded and riveted joints, making that of the solid plate = 100, are as follow:—

1. The solid plate	100
2. Scarf-welded joint	100
3. Double-riveted double-welt joint	80
4. Double-riveted lap-joint	72
5. Lap-welded joint	66
6. Double-riveted single-welt joint	65
7. Single-riveted lap-joint	60

It thus appears that scarf-welded joints are equal in strength to the solid plate, and that lap-welded joints, or such as have the edges of the plates merely superposed, have only $\frac{2}{3}$ds of the strength. Double and single riveting, as the terms imply, signify the union of two plates by two rows or by one row of rivets, respectively. A welt is a band of metal applied over the seam on one side; a double-welt is applied on both sides. The above proportions are to be accepted as correct, for plates not exceeding $\frac{3}{8}$-inch in thickness; for thicker plates the relative strengths are smaller, and in some cases thicker plates are positively weaker at the joints than thinner ones. The "working strength" is measured by the maximum strain prescribed by cautious engineers for practice, and does not usually exceed one-sixth of the ultimate strength, though occasionally one-fifth.

To apply these data for finding the strength of a cylindrical boiler—for example, one of 6 feet in diameter, and Staffordshire plates $\frac{3}{8}$-inch thick; the strength is to be expressed in lbs. per square inch. The united thickness of two opposite sides of the boiler is $\frac{3}{8} \times 2 = \frac{3}{4}$-inch, and there is $\frac{3}{4}$ square inch sectional area of metal to resist the strain on 1 inch length of the boiler. The ultimate strength of Staffordshire plate is 20 tons per square inch, or 15 tons on $\frac{3}{4}$ square inch. In 6 feet diameter there are 72 inches, and 15 tons $\div$ 72 = 466 lb. per square inch, the ultimate strength of the solid metal of the boiler expressed in steam-pressure; and 466 $\div$ 6 = 78 lb. per square inch, the working strength of the solid metal. If the plates be united by single-riveted lap-joints, of which the strength is only 60 per cent. of that of the solid plate, then $78 \times \frac{60}{100} = 47$ lb. per square inch is the working pressure per square inch.

Large iron tube flues are not capable of resisting so great a pressure externally against a collapse as they can bear internally, and they require careful staying to prevent collapse. Mr Fairbairn has worked out that question successfully, and he finds that the power of resistance of a plain tube to external pressure varies inversely on the unsupported length of the tube, inversely on the diameter, and inversely on the square of the thickness. The application of angle-iron ribs for stiffening long flues, recommended by Mr Fairbairn, is shown in his double-flue boiler, already described, Plate XX.

Ruptures and Explosions of Boilers.

CHAP. VII.—RUPTURES AND EXPLOSIONS OF BOILERS.

A steam-boiler fails, when the internal pressure of the steam overpowers the strength of the boiler to withstand the pressure. The boiler is said to rupture when the failure is not accompanied by a sudden or extraordinary development of elastic force; the material of the boiler giving way, by cracking or splitting open, and affording an outlet for the contained water and steam. The boiler is said to explode when the failure is accompanied by an extraordinary development of elastic force; the boiler being rent and torn asunder at strong places and weak places, frequently without distinction. When merely ruptured, a boiler rests in its place; when exploded, it is usually torn from its bed and projected—more or less entire, or in fragments—to considerable distances from its bed, carrying with it, or repelling, whatever opposes its progress, moving large masses, and affording other evidences of the enormous power suddenly developed as a consequence of the failure of the boiler. Various theories of explosions have been proposed; but though, to a greater or lesser extent, they serve to explain special phenomena, yet, by none of those hitherto proposed has the essential distinction between ruptures and explosions been accounted for. Many of them are based upon considerations derived from the sciences of electricity, magnetism, and chemistry:—electrical discharges, and the decomposition of steam into its elementary gases, oxygen and hydrogen; and the subsequent explosion of the hydrogen. Suffice it for the present to say, that discharges of electricity have only been proved to take place outside boilers, not inside; that steam can only be decomposed at a temperature equal to that of iron at a white heat, and that when decomposed, the oxygen unites with the material of the boiler, forming a metallic oxide, and the hydrogen alone remains. But without a sufficient combining equivalent of free oxygen, which is nowhere to

Ruptures and Explosions of Boilers.

be had within a boiler, an explosion of hydrogen cannot take place.

The ordinary explanation of explosions assign them to original weakness of boilers; to weakness produced by gradual corrosion of the material of which the boiler is made; to wilful or accidental obstruction or overloading of the safety-valves; to the sudden production of steam of a pressure greater than the boiler can bear, in a quantity greater than the safety-valve can discharge, of which the primary cause is said to be the overheating of a portion of the plates of the boiler, uncovered by water, and exposed to the intense heat of the furnace, so that a store of heat is accumulated, which is suddenly expended when water is suddenly placed in contact with the overheated plates, in the production of a large quantity of steam at a high pressure. These arguments, of course, point generally to the existence of overpressure—excessive with relation to the strength of the boiler to resist it, as the general cause. Mr Fairbairn, in his *Useful Information for Engineers*, takes the same view of the causes of the failure of boilers. The argument of simple overpressure, however, backed by the weighty authority of Mr Fairbairn, fails to explain the generic distinction between the causes of ruptures and those of explosions.

The essential distinction appears to be indicated by the symptoms, namely, the non-production of extraordinary elastic force in the case of ruptures, and the obvious production of it in the case of explosions. The phenomena of explosions are to be ascribed *to the projectile force acquired by the particles of water and steam within the boiler*, by reason of the suddenly developed expansive force of the steam, spontaneously generated in the boiler, concurrently with the sudden fall of pressure produced by the sudden escape of steam from the boiler, at the locality of the original failure; or by its enlargement of volume from any cause, as the collapse of a flue, for example. The particles of water and steam are projected against the shell of the boiler at an enormous velocity, like as many bullets, or small shot, making up in velocity what they want in mass or weight; and they communicate their centrifugal momentum to the material of the boiler, necessarily straining it, and when powerful enough, tearing it asunder, and thus effecting an explosion. Space, or latitude, is required for the generation of such projectile velocity, and the momentum due to the velocity; and if the water were confined within tubes entirely filled by it, there would be no projection of particles, and no explosive momentum, until the level of the water descended below the point of rupture, which explains the fact of the greater safety of water-tube boilers. The action of the projectile force in question is manifested by the bulging outwards of the flue-tubes usually to be observed in exploded locomotive boilers, due to the sudden generation of steam amongst the tubes; and the new theory affords an explanation of the frequent explosions of boilers that occur immediately after the starting of the engine, when, in the first place, the pressure in the boiler is lowered by the sudden admission of steam to the engine, and its rapid consumption by condensation in blowing through condensing engines, succeeded by the immediate spontaneous generation of fresh steam, and a discharge of projectiles within the boiler. The famous explosion on board the Great Eastern steamship may be similarly explained: the feed-water heater consisted of a cylinder surrounding the chimney, forming an annular space, filled with water and steam at a high temperature and pressure. The chimney, being unstayed, collapsed like a flue, under the pressure on its outer surface, and thus occasioned a sudden enlargement of volume within the heater, and a simultaneous reduction of pressure; the steam suddenly and spontaneously generated, expanded against the collapsed flue, and rebounded on the casing, projecting water with it; the moving mass of steam and water thus suddenly arrested, expended its momentum on the casing, and rended it asunder.

Explosions are probably in many cases preceded by ruptures. Circumstances determine whether a rupture shall be followed by an explosion. The limits of this article forbid the extended discussion of such circumstances, but perhaps the occurrence of an explosion, in ordinary cases, mainly depends upon the locality of the rupture, *under water*, or *above water*. If under water, water only is expelled, causing very little enlargement of volume, reduction of pressure, or internal commotion, and therefore unlikely to incur explosion. If, on the contrary, the rupture takes place above water, steam issues with the enormous velocity due jointly to its comparative lightness and its tension—1800 to 2000 feet per second—which, of course, would cause the evacuation of the steam-room of an ordinary boiler instantaneously through a very small opening, and, therefore, an instant fall of pressure and an instant generation of steam, and the projection of water and steam at the rate of many hundred feet per second within the boiler.

This new theory, which may be called *the projectile theory of explosions*, is susceptible of a variety of illustrative, collateral, and confirmatory evidence; and whilst it is compatible with other and more partial theories, it serves to account for much that remains otherwise unexplained, with respect to the various forms of the failure of boilers.

For the prevention of explosions, proper precaution must be exercised in the choice of materials, and the design and construction of the boiler. It should be subjected to frequent and careful inspection, and should have a sufficiently free action of the safety-valves, one or more of which should be placed beyond the control of attendants, and should suffice to liberate surplus steam sufficiently freely to prevent an excessive rise of pressure, under all ordinary circumstances. The sudden production of steam, in excess of the ability of the safety-valves to discharge the surplus, is most likely to be prevented by avoiding the forcing of the fires, which makes the boiler produce steam faster than the rate suited to its size and surface; by a regular, constant, and sufficient supply of feed-water; and by abstaining from the sudden introduction of feed-water, should the plates have become overheated, which would produce an explosion, and by drawing the fires, so as to allow the boiler and its contents to cool down, before refilling it with water.

CHAP. VIII.—DEPOSITS IN BOILERS.

Deposits in Boilers.

The impurities of the feed-water are precipitated and deposited on the internal surface of a boiler; sometimes as a hard crust of the minerals contained in the water, chiefly sulphate of lime; sometimes as mud or sediment, which settles loosely. Hard deposits, by resisting the conduction of heat, impair the efficiency of the boiler, as well as its durability and safety; and they may be prevented, either by administering chemical re-agents with the water, neutralising the ingredients of the water, or converting them into innocuous or loose compounds, which fall as sediment; or, what is better, by purifying the water before it is admitted into the boiler. The practice of surface-condensation in steam-engines, by which the condensed steam may be collected and returned to the boiler, insures a supply of pure water. (D. K. C.)

(Besides the authorities mentioned in the body of the foregoing article, the following have been consulted:—*The Engineer; Proceedings of the Institution of Mechanical Engineers;* Bourne's *Catechism of the Steam-Engine.*)

STEAM NAVIGATION.

Steam Navigation.

Of all the triumphs of man's ingenuity for which this age is so remarkable, none, perhaps, has conduced more to the wellbeing and happiness of the human race than the art of Steam Navigation. This is apparent when we consider the vastly extended means of communication which we now enjoy with the most distant parts of the globe; the fresh impulse given to commercial undertakings by the rapidity, the safety, and the certainty of steamships, as compared with sailing-vessels; and the increasing spread of civilization and Christianity attendant upon our intercourse with distant and semi-barbarous nations. It is not wonderful, therefore, that the merit of having invented an art so pregnant with interest to mankind should be claimed for many different individuals; and we accordingly find the names of ingenious men of all countries associated, more or less, with its origin.[1]

Paddle-wheels used by the ancients.

The use of paddle-wheels, propelled by manual or animal power, dates back to a very remote period, these having been employed by the ancient Egyptians, the Romans, and other nations of antiquity, for propelling their war-galleys; but it is doubtful whether any advantage was thus obtained in economy of labour, as compared with the use of oars. It is not, therefore, until the gradual development of the steam-engine, and its introduction as a motive power, that we can hope to find any advancement in the long-sought-for art of navigating ships against adverse winds and currents. The first historical notice we meet with of such a combination—a steam-engine placed on board a vessel to act as the propelling agent—occurs in the year 1543, when we are informed that Blasco de Garay, a sea-captain in the service of Charles V. of Spain, succeeded in propelling a ship of 200 tons burthen in the harbour of Barcelona, at the rate of a league (or three miles) an hour. No information is afforded us of the nature of his apparatus, except that it comprehended a boiler, which, it is stated, was liable to burst; that the power was transmitted through paddle-wheels, and that the vessel could be turned with much facility by means of the apparatus. We can only speculate as to the nature of this mysterious engine, but it seems probable that it owed its efficacy to the reaction of a jet of high-pressure steam, on the same principle as that famous classical toy, the Æolipile of Hero, invented B.C. 120. Notwithstanding that the scheme was commended by the emperor and his ministry, and its author promoted, we do not read of any second experiment being made, or of any further notice being taken of the invention. We may assume, therefore, that in this case the propelling power was found to be insufficient and unsatisfactory, and the experiment was worthless in its result.

Blasco de Garay, 1543.

In the year 1630, David Ramsey, "page of the king's bed-chamber," obtained a patent "*To make boats, ships, and barges goe against the wind and tyde*," but we do not hear of any experiments having been made by him. The patent office contains records of various similar suggestions made between the years 1630 and 1681, but nothing of any practical value appears to have been effected. At the latter date the ingenious Dr Papin, a Frenchman, described a method of propelling a vessel by steam. The only engine then known, however, being itself so crude and imperfect, the doctor experienced so much difficulty in reducing his scheme to practice, that it is believed no actual trial of it ever took place. His principal difficulty lay in obtaining the required rotatory motion from the reciprocating one of the piston, for which purpose he proposed to employ two cylinders, the piston of one of which should be ascending, while that of the other should be descending, the continuous rotative motion being obtained by means of racks attached to the extremities of the piston-rods, working *alternately* into a pinion on the paddle shaft. Although Dr Papin's schemes can only be viewed in the light of theoretical suggestions, he still deserves much credit both for his idea of the atmospheric engine, and for his proposal to employ it for working the paddles of a boat. Savery, on the other hand (who published his *Miner's Friend* in the year 1698), although a great actual improver of the steam-engine, and famous in his day as a clever mechanician, appears to have doubted the applicability of his engine to the propulsion of ships, since he only alludes cursorily to the possibility of such a thing.

Dr Papin, 1681.

Newcomen, 1705.

In the year 1705 Newcomen, having adopted Papin's suggestions of the cylinder and piston, and Savery's method of condensation, first completed the atmospheric engine, and made it *capable* of becoming, in practical hands, an efficient propelling power; and it is worthy of remark, that even at the present day, we have several excellent paddle-wheel steamers which are most satisfactorily propelled by modern atmospheric engines, constructed by the late Mr Seaward. The great engineering difficulty at this period was how to convert the reciprocating motion of the piston into the rotary motion of the shaft; for although, to our eyes, the *crank* may appear a very simple and almost self-evident expedient for this purpose, it was not till long afterwards that we find it introduced.

In the year 1730, Dr John Allen proposed to propel a vessel by the re-action of a jet of water forcibly expelled from the stern—a scheme which has been repeatedly revived since his time, and which has recently been attended with a considerable amount of success in the hands of Mr Ruthven of Leith. Six years after Dr Allen's proposal, Jonathan Hulls obtained a patent for his "*Invention of a machine for carrying ships and vessels out of or into any harbour or river against wind and tide, or in a calm.*" His idea of a steam-boat was as follows; and however we may now be inclined to smile at his rude mechanism, in comparison with the beautiful machinery of a steamship of our own times, Jonathan Hulls undoubtedly deserves much credit for his ingenuity. In his boat two paddle-wheels were suspended in a frame projecting from the stern. In the body of the boat were two steam cylinders, whose pistons acted on the atmospheric principle; that is to say, they were impelled in one direction only, by the pressure of the atmosphere acting against a vacuum. To each piston one end of a rope was fastened; the rope was then carried round a grooved wheel or pulley on the corresponding paddle-wheel, the other end of the rope being allowed to hang free, with a weight attached to it. When one of the pistons descended in its cylinder by the pressure of the atmosphere, it pulled its rope, and consequently moved round the paddle-wheel in a degree due to the length of the stroke and the diameter of the pulley. While the piston was ascending in the cylinder, on the re-admission of the steam, the counter-balance weight at the end of the rope dragged the pulley round in the contrary direction; but the pulley being attached to the paddle-wheel by

Jonathan Hulls, 1736.

[1] The historical portion of this article is indebted to Professor B. Woodcroft's *Sketch of the Origin and Progress of Steam Navigation* for some valuable facts.

Steam Navigation.

ratchet-work, it was so arranged that the paddle-wheel remained stationary during the retrograde motion of the pulley. There being two cylinders and two paddle-wheels in the boat, one would be in motion whilst the other was stationary, and thus a continuous progressive movement was given to the boat. It is uncertain whether this plan was ever put in practice.

James Watt, 1780.

We now arrive at the era of James Watt, whose inventive genius removed most of the obstacles which had hitherto prevented the steam-engine from being effectively employed for propelling vessels. His main improvement, after his invention of the separate condenser, was the substitution of the double-acting in place of the single-acting or atmospheric engine, by which means the power of an engine of given size and weight was at once doubled, while the motion was at the same time rendered more uniform. About this time also (1780) the crank and fly-wheel were first patented by James Pickard. Although Watt's improvements rapidly paved the way for the successful adaptation of the steam-engine to the purposes of navigation, we do not find that he himself devoted much attention at first to this subject, confining his views to perfecting the rotatory-engine, and increasing its economy. Accordingly, we find that it was not till after the expiry of their patent in 1800 that Boulton and Watt's engines were applied to this use.

In the year 1781, the Marquis de Jouffroy constructed a steamboat at Lyons of the following dimensions:—140 feet long, 15 feet beam, and 3·2 feet draught of water. His experiments, which were made in the river Soane, were probably unsuccessful, as the subject was allowed to drop.

Leaving undescribed some abortive attempts of Ramsay and Fitch in America, and Serrati in Italy, which were attended with no practical result, we pass on to the first really successful attempts at steam navigation, which were made in 1788 by a Scottish gentleman, Patrick Miller of Dalswinston, in Dumfriesshire. Having previously experimented with boats propelled by the power of men and horses applied to paddle-wheels, he resolved to make the steam-engine do this work; but neither he nor Mr James Taylor, who resided in his family as tutor, and assisted him in his experiments, could devise a plan for applying the engine. In this dilemma Taylor suggested that they should call to their assistance an old schoolfellow of his, Mr William Symington, an engineer, at that time employed in endeavouring to adapt the steam-engine to wheeled carriages. Mr Miller accordingly saw Symington in Edinburgh, and, after examining the model of his locomotive carriage, was convinced of the perfect applicability of a similar engine to drive the paddle-wheels of a boat, and gave orders for one to be made under the direction of Symington and Taylor. This engine was accordingly made in Edinburgh, sent to Dalswinton, and put together by them in October 1788. The engine, in a strong oak frame, was placed on one side of a twin, or double pleasure-boat, on Dalswinton loch; the boiler was placed on the opposite side, and the paddle-wheels in the middle. In the same month of October the machine was put in motion, and the inventors had the gratification of witnessing the perfect success of their efforts. Although the cylinders of their engine were but 4 inches in diameter, this first steamboat attained a speed of 5 miles an hour on the waters of the lake.

Miller of Dalswinton, Taylor, and Symington, 1788.

Mr Miller, being now desirous of trying the experiment on a larger scale, commissioned Mr Symington to purchase one of the canal-boats employed on the Forth and Clyde Canal, and to have suitable engines constructed for her at Carron Ironworks. When this new machinery was ready, a trial took place on a straight reach of the canal of about 4 miles in length, on the 26th of December 1789, when the vessel moved at the rate of about 7 miles an hour. Many other experiments followed with a similar result, and the following notice of them was sent by Lord Cullen to several of the Edinburgh newspapers:—

"It is with great pleasure I inform you that the experiment which some time ago was made upon the great canal here by Mr Miller of Dalswinton, for ascertaining the powers of the steam-engine when applied to sailing, has lately been repeated with great success. Although these experiments have been repeated under a variety of disadvantages, and with a vessel built formerly for a different purpose, yet the velocity acquired was no less than from $6\frac{1}{2}$ to 7 miles an hour. This sufficiently shows that, with vessels properly constructed, a velocity of 8, 9, or even 10 miles an hour may be easily accomplished, and the advantages of so great a velocity in rivers, straits, &c., and in cases of emergency, will be sufficiently evident, as there can be few winds, tides, or currents which can easily impede or resist it; and it must be evident that, even with slower motion, the utmost advantages must result to inland navigation."

Although these experiments were thus partially successful, and their value well understood and appreciated, we find that Mr Miller's boat was soon afterwards dismantled and laid up at Carron, and nothing further was at that time attempted. This apparent apathy can only be accounted for by the fact (which was afterwards acknowledged by Mr Miller himself), that Symington's machinery at this time was not equal to the task of propelling a boat with the degree of certainty and regularity necessary to insure commercial success. Hence, although the great principle of the possibility of steam navigation was thus apparently settled by Mr Miller's experiments in 1788 and 1789, it was not till the year 1801 that a really practical steamboat was first produced in Scotland. In this year Thomas Lord Dundas, who was well acquainted with Miller's experiments, and who was a large proprietor in the Forth and Clyde Canal, engaged Mr Symington to undertake a series of experiments on this subject, with the view of employing steamboats for towing on the canal in place of horses. The result was the production of the Charlotte Dundas, named after his lordship's daughter, and which, from the simplicity and practical nature of its machinery, may be justly considered as the "first practical steamboat." The superiority of this boat over its predecessors lay in Symington's more judicious arrangement of the machinery, which consisted of Watt's double-acting engine, working a connecting-rod and crank, which turned a single paddle-wheel, revolving in a well-hole near the stern of the vessel. This engine had one horizontal cylinder, 22 inches in diameter and 4 feet stroke. In March 1802 Lord Dundas, Mr Speirs of Elderslie, and several other gentlemen, being on board, the Charlotte Dundas "took in drag," says Mr Symington, "two loaded vessels, each upwards of 70 tons burthen, and with great ease carried them through the Long Reach of the Forth and Clyde Canal to Port-Dundas, a distance of $19\frac{1}{2}$ miles in six hours (being at the rate of $3\frac{1}{4}$ miles per hour), although it blew so strong a gale right ahead that no other vessel on the canal that day attempted to move to windward." Notwithstanding this favourable result, the scheme was doomed a second time to disappointment, in consequence of some of the proprietors of the canal becoming alarmed at the destructive effects of the wash of the steamboat upon the banks. The boat was therefore laid up in a creek of the canal, where it remained an object of curiosity merely for several years. It may be remarked, that this production of Symington's possessed every necessary qualification which is considered requisite, even at the present day, to make a good and useful steamer; and in proof of the confidence it inspired in its own time, we may observe that the Duke of Bridgewater actually ordered eight steamers from Symington for use on the Bridgewater Canal, to be built on the model of the Charlotte Dundas. His grace dying, however, shortly afterwards, this order was never executed.

The Charlotte Dundas, 1801.

Steam Navigation.

We now arrive at the period when American enterprise stepped in to avail itself of the painful and laborious results of these costly experiments, which although made and perfected in this country, had not yet been turned to good account. About a year after Symington's experiment with the Charlotte Dundas, Fulton, the American engineer, made a similar though less successful experiment on the Seine, for the weight of his engine broke the vessel in two, and the whole went to the bottom. He persevered, however, and in August 1803 he completed another vessel with its machinery. This boat was 66 feet long and 8 feet wide, and moved so slowly that his experiment is described as having been a failure. He afterwards came to Scotland, and saw Symington's steamboat on the Forth and Clyde Canal, his visit being thus recorded by Mr Symington:—

Fulton, 1803.

"When engaged in these experiments I was called upon by Mr Fulton, who told me he was lately from North America, and intended returning thither in a few months, but having heard of our steamboat operations, could not think of leaving this country without first waiting upon me, in expectation of seeing the boat, and procuring such information regarding it as I might be pleased to communicate, observing that, however advantageous such an invention might be to Great Britain, it would be still more valuable in America, where there were so many great navigable rivers. In compliance with his earnest request, therefore, I caused the engine-fire to be lighted up, and, in a short time thereafter, put the steamboat in motion, and carried him 4 miles west on the canal, returning again to the point from which we started in one hour and twenty minutes (being at the rate of 6 miles an hour), to the great astonishment of Mr Fulton and several gentlemen, who, at our outset, chanced to come on board. During the trip Mr Fulton asked if I had any objection to his taking notes regarding the steamboat, to which I made no objection, as I considered the more publicity that was given to any discovery, intended for general good, so much the better; and, having the privilege secured by letters-patent, I was not afraid of his making any encroachment upon my right in the British dominions, though in the United States I was well aware I had no power of control. In consequence, he pulled out a memorandum-book, and, after putting several pointed questions respecting the general construction and effect of the machine, which I answered in a most explicit manner, he jotted down particularly every thing then described, with his own observations upon the boat during the trip."

Fulton having thus obtained what information he could, returned shortly afterwards to America, and, in conjunction with Mr Livingstone, obtained a patent securing to them the prospective advantages of steam navigation in America, by what they were pleased to call "their invention of steamboats." They very wisely got all their machinery from England; so that in the year 1807 the first steamboat in America was launched, and fitted with a pair of engines constructed by Boulton and Watt.

The Clermont, 1807.

This vessel, called the Clermont, though probably fitted with superior machinery to that in Symington's boat, was barely as fast, making under five miles an hour. Her dimensions were 130 feet long, $16\frac{1}{2}$ feet beam, and 7 feet deep; the boiler 20 feet long, 7 feet deep, and 8 feet broad; the steam-cylinder (one only) was 24 inches in diameter, and 4 feet stroke; burthen 160 tons. Her paddle shaft was of cast-iron, with no outer support beyond the sides of the ship. The diameter of the paddle-wheels was 15 feet, the boards being 4 feet long, and dipping two feet in the water. She was subsequently lengthened to the extent of 140 feet keel. In the beginning of the year 1808 the Clermont was placed for regular work on the Hudson River, between New York and Albany, a distance of 125 geographical miles, and was crowded with passengers, her speed after the alteration being at the rate of 5 miles an hour. This was, therefore, the first steamboat that ever ran continuously for the accommodation of passengers, and the first that ever remunerated her owners, and to this the Americans may justly lay claim; but that Fulton was the "inventor" of the present system of steam navigation, as asserted by some American authors, cannot be admitted; nor, indeed, did he "invent" any single improvement in the construction either of the machinery or the vessel. The success of their first steamer induced Messrs Fulton and Livingstone to build two other vessels, the Car of Neptune, of 300 tons, and the Paragon, of 350 tons, also supplied with Boulton and Watt's engines.

Stevens, 1808.

The first person who ever took a steamer to sea was also an American, R. L. Stevens of Hoboken, who had been associated with Livingstone previously to the connection of the latter with Fulton, and had brought his experiments to a successful issue nearly as soon. As Fulton, however, had secured to himself the exclusive privilege of navigating by steam in the state of New York, Stevens boldly took his vessel round by sea from the Hudson to the Delaware. To him are due many of the present peculiarities of American steamers. He it was who first adopted the long stroke; the upright guides for the piston-rod; the beam overhead, raised on a high framework of wood, working above the deck; and the connecting-rod, descending thence to the paddle-shaft, all characteristic of American steamers to the present time. He also improved the form of the American boats, by substituting a fine entrance and run for the old bluff bow and stern, as well as by increasing their relative length to eight or ten times the beam. Stevens is believed to have been the first engineer who constructed a "tubular" boiler, though these did not come into general use till long after his time.

Comet, 1812.

Although steam navigation had been thus early introduced on the American waters, it was not till the year 1812 that the first regular passenger-steamer made its appearance in this country on the Clyde. This was the Comet, built for Mr Henry Bell, the proprietor of the Helensburgh Baths on the Clyde, and who had long been a most zealous advocate of steam propulsion. This little vessel was 40 feet long on the keel, and 10 feet 6 inches beam, propelled by a steam-engine of three or four horse-power, with a vertical cylinder, and working on the bell-crank principle—the engine being placed on one side of the vessel, and the boiler (of wrought iron) on the other. The Comet made her first voyage in January 1812, and continued to ply regularly between Glasgow and Greenock, at a speed of about 5 miles an hour. She was propelled by two small paddle-wheels on each side, each wheel having four boards only. She was afterwards transferred to the Forth, where she ran for many years between the extremity of the Forth and Clyde Canal and Newhaven, near Edinburgh. The distance is 27 miles, which is stated by Mr Bell to have been performed, on the average, in $3\frac{1}{2}$ hours, being at the rate of above $7\frac{1}{2}$ miles an hour.

Henry Bell.

Mr Bell had on several occasions brought his projects for steam navigation under the notice of the British government, but always without success; and it was not till the year 1819 that the admiralty of the day became impressed with the importance of steam-power for towing men-of-war, chiefly through the representations of Lord Melville and Sir George Cockburn. The first steam-vessel in the royal navy was then built, and was also named the Comet. She is still in existence, and measures 115 feet in length, 21 feet in breadth, and draws 9 feet water, being propelled by a pair of engines, by Boulton and Watt, of 40 horse-power each.

But to return to Mr Bell's steamers on the Clyde. The Comet was so successful, that two other steamers, of increased size and power, were constructed; and, in 1814, Mr Cook, of Glasgow, built a fourth, called the "Glasgow," which, in point of power and efficiency, became the standard at that time for river-steamers. The marine engines hitherto constructed had all been applied *singly* in the vessel; but in 1814 Messrs Boulton and Watt first applied *two*

Steam Navigation.

condensing engines, connected by cranks set at right-angles on the shaft, to propel a steamer on the Clyde. This was found to be a great improvement, and thenceforward almost all steamers have been fitted with two engines.

In the year 1815 a small vessel, with a side lever-engine of 14 horse-power, by Cook of Glasgow, made a voyage from Glasgow to Dublin, and thence round the Land's End to London. It then ran with passengers between London and Margate with some success, though encountering great opposition from the Thames watermen.

David Napier, 1818.

In 1818 Mr David Napier, to whom we owe the introduction of British coasting steamers, as well as of steam-packets for our post-office service, first established between Greenock and Belfast a regular steam communication by means of the Rob Roy, a vessel of about 90 tons burthen and 30 horse-power, built by Mr William Denny of Dumbarton. For two winters she plied with great regularity and success between these ports, and was afterwards transferred to the English Channel, to serve as a packet-boat between Dover and Calais. Soon after this Mr Napier had the Talbot built for him by Messrs Wood. She was 120 tons burthen; and when fitted with two of Mr Napier's engines, of 30 horse-power each, this vessel was in all respects the most perfect of her day. She was the first steamer that ran between Holyhead and Dublin. About the same time, also, he established the line of steamships between Liverpool, Greenock, and Glasgow, for which traffic he built the Robert Bruce, of 150 tons, with two engines, of 30 horse-power each; the Superb, of 240 tons, with two engines of 35 horse-power each; and the Eclipse, of 240 tons, with two engines of 30 horse-power each. All these were established as regular coasting traders before the year 1822.

The James Watt, &c., 1822.

In the latter year the steamer James Watt was built by Messrs Wood, to ply between Leith and London. She was the largest steamer that had yet been built, being 448 tons measurement, and fitted with two engines of 50 horse-power each, by Messrs Boulton and Watt. The Soho followed on the same line, and was equally successful. The next great advance made was in 1826, when the United Kingdom was constructed, this vessel having been regarded in her day with as much wonder and interest, from her (so-called) gigantic proportions, as were afterwards the Great Western, the Great Britain, and, more recently, the Great Eastern. The United Kingdom was 160 feet long, $26\frac{1}{2}$ feet beam, and 200 horse-power; the ship being built by Mr Steele of Greenock, and the machinery by Mr David Napier. Prior to this time many improvements had been made in the arrangement and construction of the marine engine by Boulton and Watt, Maudslay and Field, Penn, and others of our eminent mechanical engineers; the expansive action of steam in the cylinder having already been taken advantage of by Messrs Maudslay and Field in their engines, which were also fitted with escape-valves on the cylinders, and other improvements.

The Savannah, 1819.

The first steamer which crossed the Atlantic was the "Savannah," an American vessel, of 300 tons burthen, which arrived at Liverpool in the year 1819, direct from the United States, in 26 days, partly steaming and partly sailing. Being fitted with engines of small power, and the vessel being otherwise unsuited for ocean navigation, this must be regarded rather as a bold experiment (and not a very successful one) than as establishing the practicability of a rapid and regular steam communication between this country and America; for it is only in the combination of these two qualities that the steamship excels the sailing vessel. In 1829 the Curaçoa, an English built vessel, of 350 tons and 100 horse-power, made several successful runs between Holland and the Dutch West Indies. Men of science, however, plainly demonstrated, to their own satisfaction, that the navigation of the Atlantic by steam-power alone was impracticable; and it was not till the Sirius and the Great Western had shown the fallacy of their reasoning, that the public mind was disabused of this idea. The Sirius was not built expressly for transatlantic navigation; she belonged to the St George Steam-Packet Company, and had run with a good reputation between London and Cork. Her tonnage was about 700 tons, and her horse-power 320. She started from London on the morning of the 4th of April 1838, with 94 passengers. Though first in the race, she was only three days in advance; for on the 7th of the same month the Great Western, built and fitted at Bristol expressly for the purpose, followed her. The Sirius arrived at New York on the 22d, being 17 days clear on the passage, and the Great Western (sailing from Bristol) on the 23d, being 15 days. The Sirius again sailed on her homeward passage on the 1st of May, and the Great Western on the 7th of May, and they arrived, the first on the 18th, and the second on the 22d, being 16 and $13\frac{1}{2}$ days respectively. The average speed of the Great Western on this voyage was thus 8·2 knots on her outward passage, and nearly 9 knots on her homeward, reckoning the distance at 3125 knots for the one, and 3192 for the other. She consumed 655 tons of coal going out, having still 205 tons remaining in her coal-boxes upon her arrival at New York. Coming home her consumption was 392, having 178 tons remaining on her arrival at Bristol. Her average daily consumption varied from 27 tons, with expansive gear in action, to 32 tons without it. As the Great Western possesses considerable historical interest, some of her principal dimensions are here subjoined. She was designed and built by Mr Paterson of Bristol, and fitted with machinery by Messrs Maudslay, Sons, and Field of London. She is 212 feet long between the perpendiculars, 35 feet 6 inches beam, and 23 feet 3 inches depth of hold, drawing from 16 to 18 feet of water. Her tonnage is 1340 (builders' O.M.), and her engines (on the side-lever construction) are 440 horse-power. Her cylinders are $73\frac{1}{2}$ inches in diameter, and 7 feet stroke, making 12 to 15 revolutions per minute. Her complete success was doubtless mainly attributable to the fact, that she was especially fortunate both in her designer and in her engineers, who are still, perhaps, the most eminent of the present day in their respective departments.

The Sirius and Great Western. 1838.

The practicability of transatlantic steam navigation being thus triumphantly established, the British Queen, the President, and other large steamships, were built in rapid succession, as well as many steam-vessels of war.

The screw-propeller introduced, 1837.

Up to this time the paddle-wheel was the only propelling agent employed; but in 1837 the rival system of propelling ships by means of the screw-propeller first came prominently into notice, through the successful experiments of Captain Ericsson and Mr F. P. Smith. Captain Ericsson's small vessel, of 45 feet in length, 8 feet beam, and but 2 feet 3 inches draught of water, towed the American ship Toronto, of 630 tons, on the Thames, on the 25th of May 1837, at the rate of $4\frac{1}{2}$ knots an hour, against the tide, as authenticated by the pilot; and also towed the admiralty barge, with their lordships on board, from Somerset House to Blackwall and back, at the rate of about 10 miles an hour. Later in the same year Mr Smith made some very successful trips with his small boat and screw-propeller between Margate and Ramsgate. The next screw-vessel was the Robert Stockton, built in 1839 by Messrs Laird for an American gentleman, who had witnessed Captain Ericsson's experiments. This boat was also perfectly successful; but the Board of Admiralty still failed to recognise the peculiar applicability of this means of propulsion for vessels of war. The next year, however, in 1840, Mr F. P. Smith, having obtained the support of some influential mercantile men, brought out the Archimedes, a screw-vessel of 232 tons burthen and 80 horse-power. The success of this vessel was so complete, that the Admiralty were at length induced

The Archimedes, 1840.

Steam Navigation.

to make a trial of the screw in the royal navy, and the Rattler was ordered to be built on the same lines as the Alecto paddle-wheel steamer, and to be fitted with engines of the same nominal power. The next screw-steamer worthy of notice was the Dove, an iron boat, constructed under Mr Smith's direction. Her speed, however, proved so unsatisfactory to her owners, that they ordered her to be changed into a paddle-wheel boat; and as it happened that she had been built with very fine after-lines, her constructor unfortunately charged her deficiency of speed to this circumstance, and adopted the theory that full stern-lines were the most advantageous for the action of the screw. The Rattler was now tried; and her trials having fully satisfied the Board of Admiralty, they ordered the construction of several screw-vessels, which were all built with full sterns. This idea having at length been proved, by further experiment, to be erroneous, and that, on the contrary, fine after-lines were absolutely required for the proper efficiency of the screw-propeller, so as to allow of a ready access and escape of the water, the whole of these vessels were deficient in speed, and some of them were altered at great cost.

The Rattler, 1842.

The screw had meanwhile advanced rapidly into favour as an auxiliary power for fast sailing vessels in the merchant service; and more recently it has been extensively employed for full powered steamers of the very largest class (in preference to the paddle-wheel) by several of our great mail-packet companies, the Peninsular and Oriental Company taking the lead in this respect.

The requirements of the great navigable rivers of America have naturally led to the supremacy of that nation in the art of *river* navigation. The description of the large American river-steamer, The New World, given in another part of this article, as a type of her class, will be found both novel and interesting.

This rapid sketch of the rise and progress of steam navigation would not be complete without referring specially to the wonderful development it has lately received in the construction of the Great Eastern, whose giant bulk is even now struggling into life under peculiarly depressing circumstances. In addition to the interest naturally excited by the immense size of this vessel (whose proportions will be given hereafter), she is destined to solve another problem in marine engineering, namely, the desirability of combining screw-propeller and paddle-wheels in the same steamship.

A statistical table is subjoined, showing the progress of steam navigation in the British Empire, from its first introduction in 1814, down to the most recent times for which returns have been received.

Explanation of statistical table.

It should be observed that the "register" tonnage here given is exclusive of the tonnage of the engine-room, which in a well-powered steamer generally amounts to one-half, or more, of the registered tonnage. An addition of one-third should therefore be added for the gross tonnage of this table. To take an example. The Shannon, West India mail packet, has

Register tonnage	2187·24	H.-P. 775
Engine-room do.	1284·57	
Gross do.	3471·81	

The horse-power (nominal) averages about one-third of the register tonnage; so it may be fairly assumed that this country now possesses a fleet of 2150 merchant-steamers, having an aggregate gross tonnage of 670,000 tons, and a nominal horse-power of 165,000 horses.

The steam navy of this country consists at present of about 468 vessels, having an aggregate tonnage of 470,000 tons, and a nominal horse-power of 110,000 horses.

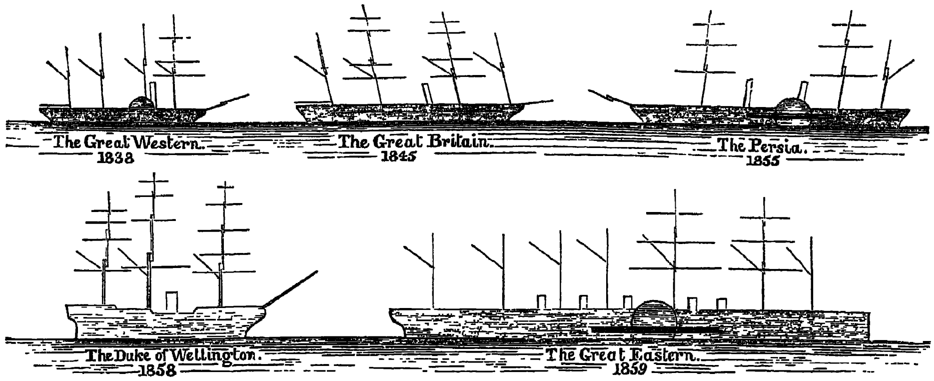

Fig. 1.—Comparative sizes of the above Steamers.

In constructing a steam-vessel three things require to be specially considered, each of which is a sufficiently complex study in itself; namely, the ship, the engines and boilers, and the propeller. To combine these in such a manner as to produce a perfect whole is one of the most difficult problems of modern engineering, demanding at once the theoretical attainments of the natural philosopher, and the laboriously acquired knowledge and shrewd sagacity of the practical mechanician. As the limits of this article must preclude the pursuit of theoretical investigation, it is proposed to confine it almost exclusively to the practical part of the subject, and to a record of the results of actual and approved performance.

The marine engine.

The marine steam-engine, although acting on the very same principles as the ordinary land condensing-engine, and provided with the same integral parts, differs from it essentially in the particulars of weight and form, being necessarily made as light, and as compact, as possible. These requirements throw many obstacles in the way of the marine engineer which are not encountered on shore, both as regards the engines and boilers; and his difficulties are increased by the stern necessity which exists on board ship for the utmost economy in the consumption of fuel, the value of which is there immensely enhanced.

Side-lever engines.

The oldest type of the marine-engine is the side-lever variety, which, till within the last ten or twelve years, was almost universally employed in steamers; and which is, indeed, still preferred for paddle-wheel steamers, by at least two large mail-packet companies—viz: Cunard's and the West India Mail Company (fig. 2). There are several

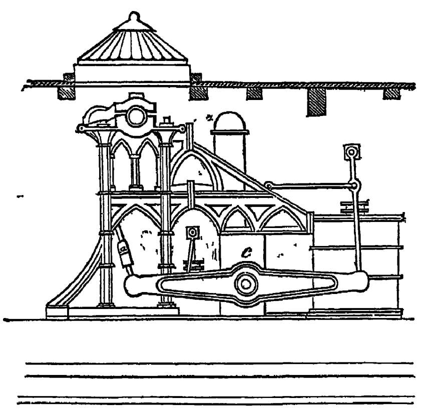

Fig. 2.
Side-lever Engine.

good reasons why this form of engine should be thus favoured. In the first place, the working parts are well balanced on either side of the main centre (*c*, fig. 2), so that the engine will stand in any position without the piston having a tendency to fall by its own weight, thus enabling the crank to be kept in the most advantageous position for giving prompt motion to the shaft immediately that the engine is started. Direct-acting engines are often very troublesome in this respect. Another advantage of the parts being nicely balanced is, that the engine works with little friction, and consequently less strain, and tear and wear of the brasses and moving parts of the machinery. Hence the side-lever engine is very economical in maintenance and repairs, as well as in the quantity of oil and tallow required for lubrication, no mean item in the expenditure of some engines. Again, this form of engine admits of a good long stroke and connecting-rod, by which means the steam may be used to best advantage in the cylinder, while, at the same time, the thrust of the piston is transmitted to the crank in the most equable and effective manner. Many pairs of side-lever engines are still doing their work well, after more than twenty years' service, and have cost less for repairs than most direct-acting varieties in half that time.

Direct-acting engines.

But although it may be quite true that side-lever engines are thus economical in their working, it does not necessarily follow that they are the best form of engine for passenger-steamers. On the contrary, when we consider the

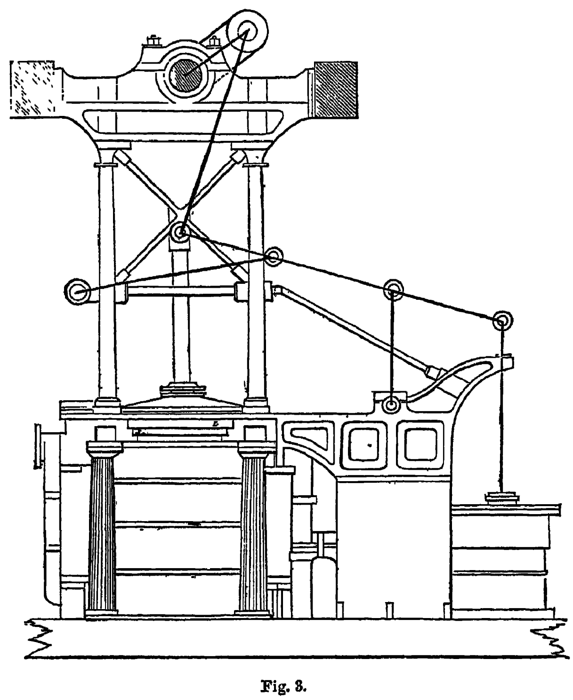

Fig. 3.
Direct-acting Engines in Gorgon, &c. (Seaward.)

value of space and weight in a first-class merchant-steamer, it appears probable that they are really more expensive

Steam Navigation.

than the lighter and more compact forms of direct acting-

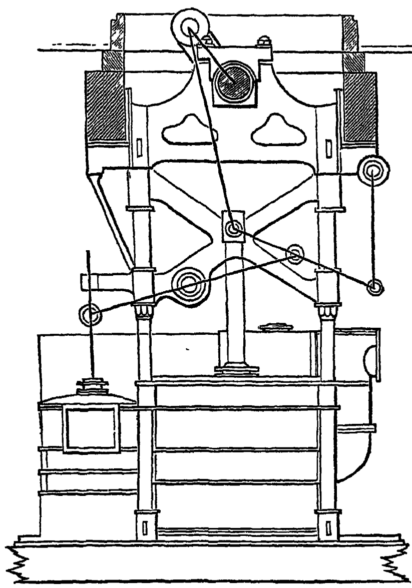

Fig. 4.
Direct-acting Engines in Vulture, &c. (Fairbairn.)

engines which have now so generally come into use, and by

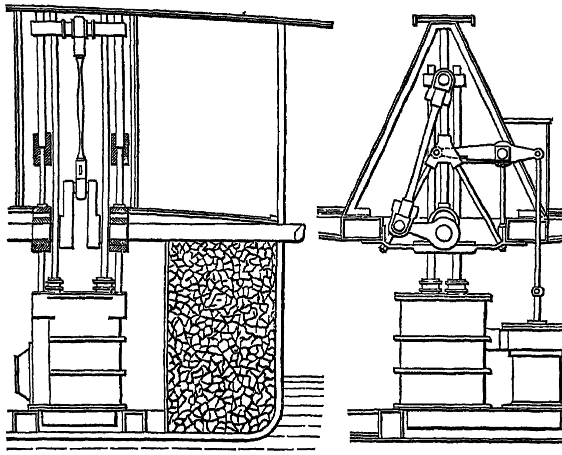

Fig. 5.
Direct-acting Engines for shallow draught. (Maudslay and Field.)

employing which we may save at least 20 feet in the length of the engine-room, and 100 tons of displacement, in engines of 500 nominal horse-power. Direct-acting engines, being susceptible of great variety of form, have assumed as many different shapes as there are manufacturing engineers ready to invent, adapt, or distort them, as the case may be; and the now very general use of the screw-propeller has, of course, varied and modified these forms still more). In the merchant service, the height of the machinery is not of much moment, provided only that it does not raise the centre of gravity of the vessel too high; but in the steam-navy it is considered essential that the whole of the engines and boilers should (if possible) be kept under the water-line of the ship, as a protection from shot; which, in the case of screw-vessels, is now generally accomplished (see fig. 15).

Varieties.

Direct-acting paddle-wheel engines may be classed under four heads; namely, those which preserve the parallelism of the piston-rod by means of the system of jointed rods called a parallel motion (figs. 3 and 4); those which use guides or sliding surfaces for this purpose (figs. 5 and 7); oscillating engines (fig. 6), in which the cylinders are hung upon pivots, and follow the oscillations of the crank; and

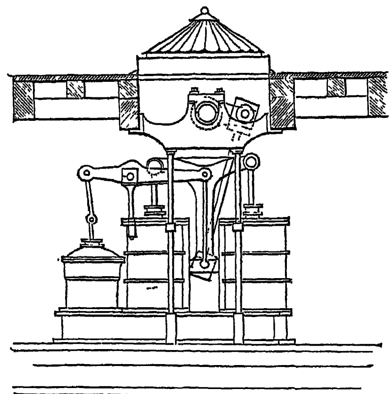

Fig. 7.
Direct Double-cylinder Engines, suitable for large power. (Maudslay.)

those denominated "trunk-engines" (fig. 8), in which a hollow cylindrical trunk is attached to the piston, and passes, steam-tight, through the cylinder cover. Several of these varieties have their distinctive appellations, being known as the "steeple-engine" (which is a favourite form on the Clyde); Maudslay's double-cylinder engine (fig. 7); the annular-piston engine (with two piston-rods); the atmospheric engine; the combined-cylinder engine (Plates XXXIV. and XXXV.); and several others. As verbal description is of little value in making these forms intelligible to the reader, sketches of the more characteristic of them are subjoined, as well as detailed plates of approved examples (see Plates). These engines are generally made with two cylinders, but in the case of screw-engines there are sometimes three, and sometimes four cylinders

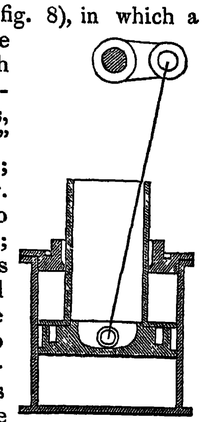

Fig. 8.

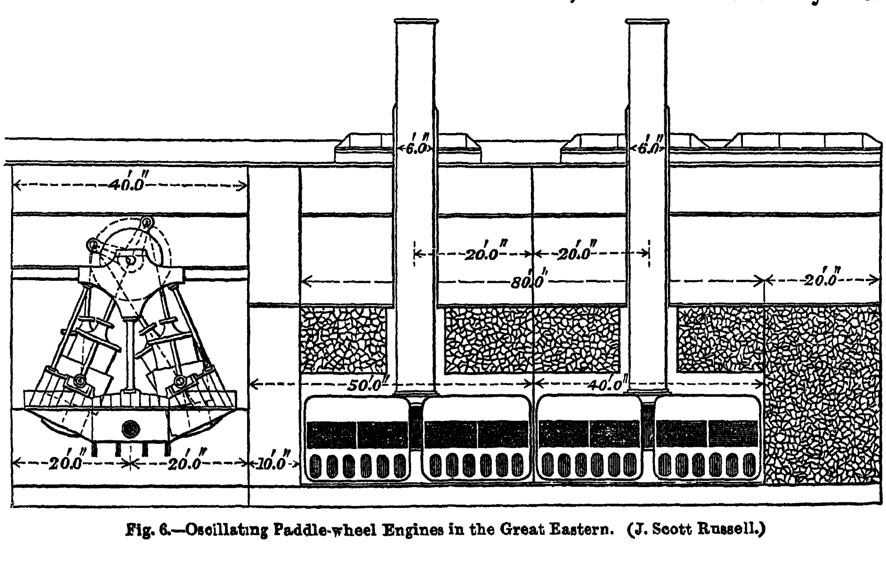

Fig. 6.—Oscillating Paddle-wheel Engines in the Great Eastern. (J. Scott Russell.)

placed in all possible positions; being found upright, inverted, horizontal, and inclined.

Screw-engines.

Screw-engines are made either with or without gearing. The use of geared wheels intervening between the engine and the propeller admits of a slow speed of piston with a high velocity of screw, and is so far beneficial, but in practice there are several disadvantages attending it.

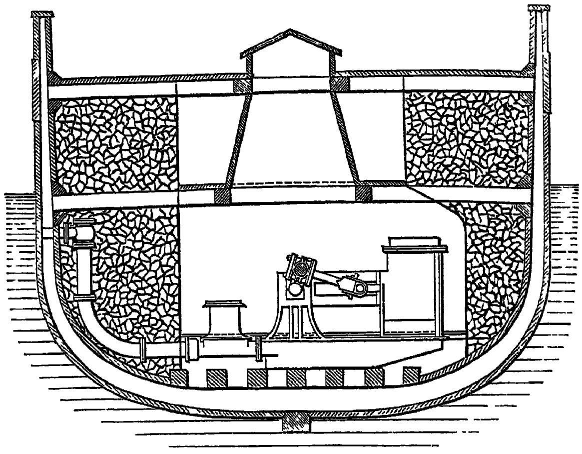

Fig. 9.
Horizontal Screw-engine (Direct), adapted for the Royal Navy, &c.

The driving-wheel is necessarily very large and cumbrous, while the wooden teeth with which it is fitted are subject to unequal wear, and are liable to be "stripped," or broken off, by a sudden stroke of the sea upon the screw. Their revolution is also attended with a loud rumbling noise, from which there is no escape on board-ship. In steam-vessels of war it is difficult to keep the top of the large wheel sufficiently low, while at the same time their draught of water admits of the use of a screw of great diameter and pitch, by which means the necessary speed may be obtained for the ship without unduly increasing the velocity of the piston. Hence there are comparatively few geared screw-engines in the Royal Navy. In the case of full-powered screw-engines in the merchant service, the use of gearing is generally found to be necessary (fig. 10),

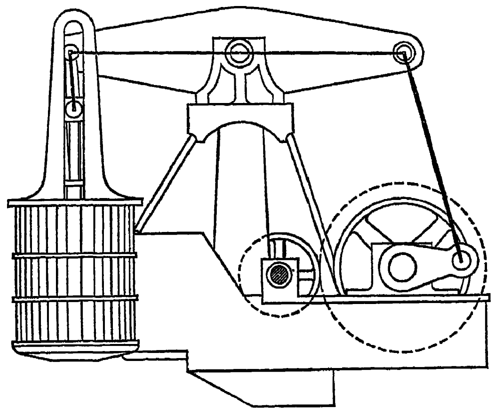

Fig. 10.
Vertical Screw-engine (Geared), adapted for the Merchant Service.

but it may be advantageously dispensed with wherever the power of the engines is not calculated to give a very high speed to the ship. The velocity of piston in actual use in different classes of steamers will be hereafter noted.

The following (Figs. 11 *to* 16) *are other examples of Screw-engines:—*

Steam Navigation.

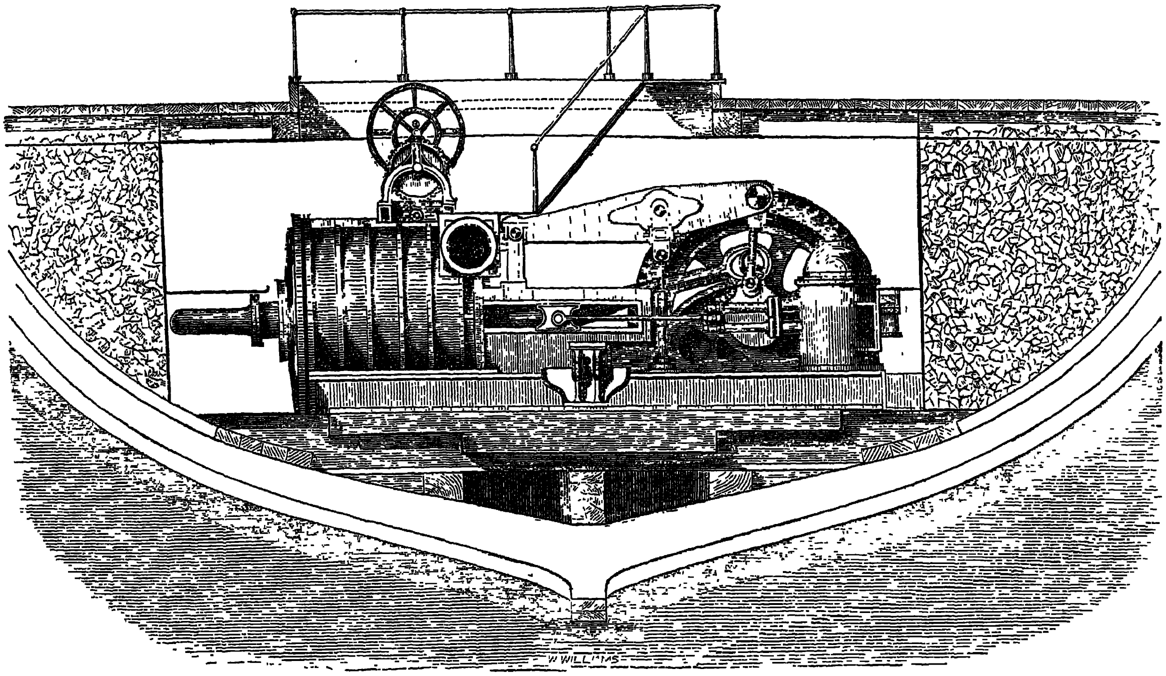

Fig. 16.—Screw-engines in the Royal Navy, Geared.

Nominal horse-power.

The cylinder of the steam-engine, being that portion of the machine in which the power is developed, must be considered as its principal member. Upon its dimensions depend, in some degree, the size of all the other parts of the engine, as well as its reputed powers, being called an engine of 100 or of 200 horse-power according to the diameter of the cylinder, modified to a small extent by the length of the stroke. This, called the nominal horse-power, is obtained by the formula—

$$\text{H.P.} = \frac{\text{Area of cylinder} \times \text{effective pressure} \times \text{speed of piston}}{33{,}000}.$$

In this formula the area of the cylinder is taken in square inches; the "effective pressure" is assumed at 7 lb. (by some makers at $7\frac{1}{2}$ lb.) to the square inch; and the speed of the piston (according to the arbitrary rule adopted by the admiralty), is presumed to vary with the length of stroke, as shown in the following table:—

Stroke.	Speed of piston.	Stroke.	Speed of piston.
Ft. In.	Ft. per min.	Ft. In.	Ft. per min.
3 0	180	6 0	221
3 6	188	6 6	226
4 0	196	7 0	231
4 6	204	7 6	236
5 0	210	8 0	240
5 6	216	9 0	248

It is at once apparent that the power thus calculated cannot be the real power of the engine, since it is wholly irrespective of the pressure of steam in the boiler, the perfection of the vacuum in the condenser, the actual number of reciprocations of the piston, and the varying loss by friction depending upon good or bad workmanship, and the general plan of the engine. For the sake of convenience, however, the nominal horse-power is still retained, since it defines, with tolerable accuracy, the actual *size* of the engine, and its commercial value, in so far as the latter is dependent upon the dimensions of the cylinder. To remedy, in some degree, the uncertainty attending the use of this term, it is now becoming usual for the purchaser of a steam-engine to insert a clause in his contract, binding the manufacturer to show a certain specified amount of indicated horse-power.

Indicated horse-power.

The indicated horse-power of an engine is obtained by the aid of a valuable little instrument called an indicator, consisting mainly of a small cylinder placed in connection with the cylinder of the engine, both above and below the piston. This little cylinder is open at the top, and is fitted with a piston which presses against a spiral spring. The cock which connects the indicator with the cylinder of the engine being opened, steam is admitted under the piston of the indicator during the one stroke, and vacuum during the other, precisely as in the large cylinders; thus causing the little piston to push and pull alternately against the spiral spring. If the pressure were uniform throughout the stroke, the indicator-piston would start at once from top to bottom, and *vice versâ*, remaining stationary until acted upon by the opposite pressure; but since the pressure within the cylinder of a steam-engine is constantly varying during every portion of the stroke, it follows that the pressure on the spiral spring of the indicator, and the corresponding movement of the indicator-piston, must be variable too. If a pencil be fixed to the piston-rod of the instrument, it will register the fluctuations of pressure upon a piece of paper held close to it; but unless some provision be made for allowing the pencil a clear space on the paper at each successive instant of time, it will only move up and down in the same vertical line, and the markings due to fluctuation of pressure will be undistinguishable. To obviate this, the paper receives a circular motion in one direction during the down-stroke of the piston, and a reversed circular motion during the return-stroke, the result being that, as the pencil moves vertically up and down, a continuous curved or sloping line is traced on the paper. By this line an oblong space is inclosed, called the indicator-figure, card, or diagram, the vertical ordinates of which will then represent the effective pressures at the corresponding portions of the stroke, and their mean length will therefore indicate the average pressure in the cylinder during the whole period of the stroke.

Description of the indicator.

Indicated and effective horse-power.

To find the indicated horse-power, therefore, we must take the area of the cylinder in square inches, multiply it by the average pressure as found from the indicator-figure, and again by the actual number of feet through which the piston is travelling per minute; when the product, divided by 33,000, is the indicator or gross horse-power of the

Steam Navigation.

engine. This must not be confounded, however, with the *effective* power of the engine, or that actually available for the purpose for which the engine is used. To obtain this, a considerable deduction (about 25 per cent., it is believed) must be made for the friction of the moving parts, and for the power required to work the valves, air-pump, feed and bilge pump, &c.; but as this would be nearly alike for all well-constructed engines of equal power, and no ready means exist for testing it, the gross or indicated horse-power is taken as the measure of the power in all ordinary cases.

Proportion of indicated to nominal horse-power.

An example of a set of indicator-diagrams (fig. 17) is subjoined, to show the manner in which they are usually worked out; and it will be seen that, in this instance, a pair of engines of 500 *nominal* horse-power were actually exerting an *indicated* horse-power of more than 2000 horses, or four times the nominal. This may be taken as the usual proportion now existing between nominal and indicated horse-power in modern engines by the best makers, while using steam of from 15 to 20 lb. pressure; but the average performance of existing engines is still very much below this, not exceeding from 2 to 2·5 times the nominal horse-power.

[The dynamometer is an instrument used to measure the force actually expended in propelling the vessel; or, in other words, for showing the effective horse-power of the engines. It is fitted occasionally on board of a screw-steamer, the thrust of the propeller being transmitted through a series of levers to a Salter's spring-balance; but it is difficult to obtain true indications from this instrument, which is liable to many disturbing influences. There is a fixed dynamometer at some of H.M. dockyards, by means of which the pull of any steamer, whether paddle or screw, may be obtained in tons.]

Fig. 17.

Indicated horse-power depends mainly on the boiler.

The size of the boiler is obviously a very important element in determining the indicated horse-power of an engine, inasmuch as the speed of the piston (or the number of revolutions per minute) depends mainly upon the supply of steam from the boiler. The power of an engine may thus always be increased by adding to the size of the boiler, provided the steam-passages are large enough to admit of the increased flow of steam without its becoming throttled or "wire-drawn." A large boiler, however, implies a large consumption of coal as a necessary attendant upon any increase of power in the engines, or velocity in the ship; so that in practice it is generally found inconvenient for sea-going steamers to urge their engines to the utmost duty of which they are capable, as tending to limit the distance which it is possible to run with a definite weight of coals. Hence it follows, that while vessels making short runs (such as the Holyhead packets) will show an indicated horse-power of four, or even five times their nominal, a transatlantic steamer cannot afford to do so, although her engines may be equally efficient.

Velocity of piston.

It will be understood, from what has been already said, that the speed at which marine engines are driven is very various, and also that it is liable to vary (even in the same vessel) according to circumstances; such as the steaming capacity of the boilers, the necessity for economizing fuel, and the dimensions of the paddles or screw. Apart from the proper or "calculated" speed, there is of course the additional consideration of the variable trim of the vessel, and the undulations of the sea, which affect the speed of the engines by throwing more or less work upon them, in proportion as the propelling agent is deeply or lightly immersed. The subjoined tables will convey some idea of the velocity at which pistons are driven (under the most favourable circumstances of *trim*) by some of the principal marine engineers of the day:—

Steam Navigation.

Speed of Pistons in Merchant-Steamers (Paddle and Screw).

Rattler	Maudslay and Field	40¼	4 0	25½	204	Double cylinder, geared.

All the merchant-steamers in this table have a speed of above 13 knots, and the government steamers of 10 knots.

Some of these speeds are nearly twice as great as would be sanctioned by the table previously quoted as embodying the practice of James Watt; and although, theoretically speaking, there may be no objection to such high velocities, they are inconvenient in practice, from the tendency of the working parts to heat by the friction, from the rapid wear of the parts, and their increased liability to accident or derangement.

Long and short stroke engines.

Although engineers are perfectly agreed as to the superior advantages of a long stroke for their engines, it will be seen by the preceding table how rarely in the case of screw-engines this desirable object can be accomplished. The cause of this is, that the *pitch* of the screw-propeller (by which term is implied the linear advance made by the screw during one complete revolution, supposing it to be working in a solid), cannot be effectively increased beyond a certain proportion, depending upon the diameter of the screw; and as this is necessarily limited by the draught of water, it follows that the only available means for augmenting the linear advance of the screw is by increasing the number of revolutions. For each revolution of the screw, two journeys of the piston (in a direct engine) are required, and to enable this to be done within the required time, the strokes must be short. The chief disadvantages attending a short stroke are the more frequent recurrence of the "dead points" of the crank (when the piston arrives at the top and bottom of the cylinder), at which times much of the momentum of the moving parts is destroyed; and the loss of a certain quantity of steam contained within the cylinder ports or passages at each stroke, which does not exert a direct pressure on the piston. It is natural to suppose, also, that short-stroke engines do not derive so much benefit from expanding in the cylinders as those having longer strokes.

Another desideratum for all kinds of steam-engines is a long connecting-rod, as tending to diminish the angular strain thrown upon the main crank, and thus avoid the loss of power arising from unnecessary friction. This action is

Long and short connecting-rods.

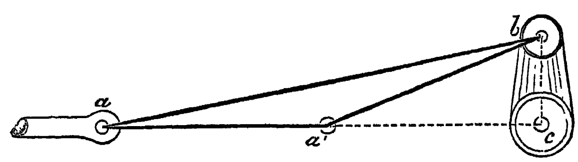

Fig. 18.

made apparent by the accompanying sketch (fig. 18), in which *a b* represents a long connecting-rod, and *a' b* a short one, their relative efficiency varying as the angles *a*, *b*, *c*, and *a'*, *b*, *c*. The defects of a short connecting-rod become sensible in practice by greater liability of the bearings to heat, by an increased wear of "brasses" and packings, and a larger consumption of oil for lubricating.

Cutting off the steam in the cylinder.

The cylinder of a steam-engine is never allowed a full measure of steam from the boiler, this being shut off at some part of the stroke according to the power it may be desirable to exert. A certain quantity of steam, varying generally from ⅙ to ⅛ of the contents of the cylinder, is always excluded by the slide-valve, which is made to close the steam-port before the end of the stroke. In most engines a further amount of steam is excluded by means of a separate valve, called the expansion-valve, which is so arranged that it may "cut off" the steam, or prevent a further supply, at any desired point, according as it may be wished to economize fuel, more or less, at the expense of velocity. Thus, some engines are worked with ¾ of a cylinder full of steam to each stroke, some with ½, and others with only ¼; or the same engine may be worked successively at the different "grades of expansion" corresponding to these quantities. This is called "working expansively," because the portion of steam thus shut in continues to expand in volume, and to give out elastic force, to the end of the stroke.

Steam Navigation.

Advantages of expanding steam in the cylinders.

Two advantages arise from cutting off the steam in this way. Firstly, it allows the stroke to be completed under a diminished pressure, so that the piston comes gently to rest at the top and bottom of the cylinder, without imparting a destructive jar to the machinery; and, secondly, it is economical of power (or, which is the same thing, of *fuel*), since it is found that the force actually exerted upon the piston by the isolated steam, during its expansion into the increased volume as the piston descends in the cylinder, is considerably greater than that due to the simple pressure of the same weight of steam acting at a uniform density.

It is found by calculation that when the steam is cut off at $\frac{1}{2}$ stroke, seven-tenths of the power already exerted in the cylinder is added by the subsequent expansion of the steam; when cut off at $\frac{1}{3}$, 2·1 times the power is added; and when cut off at $\frac{1}{4}$, 2·4 times nearly. According to the usually-received natural law regulating the pressure and elasticity of steam, it is assumed that the pressure is inversely proportional to the volume of the steam after it has expanded into the increased bulk, or, in other words, that when the steam has expanded to twice its original volume, its pressure will be reduced one-half; when it has expanded four times its volume, the pressure will be $\frac{1}{4}$th, and so on. The pumping-engines in Cornwall, which do their work so very economically, use steam of about 40 lb. pressure, cutting it off in the cylinder after $\frac{1}{6}$th or even $\frac{1}{8}$th part of the stroke has been made, the remaining $\frac{7}{8}$ths being performed wholly by expansion.

Fxpansion can be rarely pushed to its extreme limits.

It is very seldom, however, and that only when special means are provided for this purpose, that the principle of expansion can be beneficially carried out in marine engines to an extent nearly approaching that just mentioned. It is a well known property of all gaseous fluids, steam of course included, that any expansion of volume is necessarily accompanied with the loss of sensible heat, which is taken up in the latent form by the expanded gas or vapour. Hence, when the steam expands under ordinary circumstances within the cylinder of a steam-engine, a portion of it is compelled to part with its latent heat, to enable the rest to retain the gaseous form. This portion of steam, therefore, condenses into water of the same temperature, which forms a thin film over the interior surface of the cylinder. When the return stroke begins, and the watery lining of the cylinder is brought into connection with the condenser, it rapidly evaporates into steam of low tension. This steam, besides vitiating the vacuum, acts still more injuriously by robbing the cylinder of the heat which it required for evaporation; when the metal of the cylinder, being thus lowered in temperature, condenses the steam, upon its re-admission, to a serious extent. Thus it happens that the principle of expansion, when carried out to any great extent in cylinders which are only "clothed" in the usual way, has so frequently failed to realize the expected economy of fuel; and this has been most unjustly charged to a defect in the principle of expansion.

Advantage of a steam-jacket.

In the case of the Cornish engines already mentioned, where the steam is expanded to eight times its volume with known advantage, the cylinder is invariably surrounded with a "jacket" kept well supplied with dense hot steam from the boiler; by which means it is retained at a high and nearly uniform temperature during the entire stroke; and to this steam-jacket it is mainly due that so remarkable an economy attends the use of expansion in Cornwall. The cylinders of a marine engine, on the other hand, are protected from radiation by a clothing of felt and wood only; but in the few instances where a steam-jacket has been applied, the most beneficial results have followed.

Advantage of super-heating the steam.

Another mode by which the expanded steam may be protected from condensation in the cylinder is by previously imparting to it an extra dose of heat beyond that due to its pressure, or, in other words, by "superheating" it. It is apparent that this extra heat becomes available for the supply of the latent heat demanded by the expanding steam, which is thus saved from premature condensation.

Conditions under which the full benefit of expansion may be obtained.

In order to derive the utmost benefit of which the principle of expansion is capable, it is necessary that the initial pressure of steam should be considerable, that it should have plenty of space to expand into, and that the cylinder should be maintained at a high temperature. These conditions would seem to imply the use of a large jacketed cylinder of sufficient strength to bear the high initial pressure. As such a cylinder, however, would be very heavy and cumbrous, the plan has been occasionally adopted of using *two* cylinders, in which to utilize the steam, namely, a large and a small one. In this case the high-pressed steam from the boiler is admitted into the small cylinder only, and after expanding in that to twice or three times its volume (by which its pressure is reduced to one-half, or one-third), it is then admitted from the small cylinder into the large one, where the expansive process is finally completed under the most favourable circumstances.

Combined-cylinder engines.

This combination, called the combined-cylinder engine, has of late been brought prominently forward by the engineering firm of Randolph Elder and Co., of Glasgow. Plates XXXV. and XXXVI. represent the engines of the steamers Callao, Lima, and Bogotâ, made on this principle, and which have attracted much notice by their remarkable economy of fuel. Their principal dimensions will be afterwards given with the description of the plates. They were thus described by Mr Elder at the late meetings of the British Association—"These engines are constructed with the view of getting the greatest amount of power from a given quantity of steam at a given pressure, with less total weight of engines, boilers, and water, and occupying less total space than is found in the ordinary class of steam-engines on board of steamships. To accomplish these objects the following construction of engine has been adopted:—The cylinder capacity is so great as to admit of the steam being expanded to within 2 lb. of the pressure in the condenser at the end of the stroke, while the engines are working full power. In order to reduce the violent shock of steam at 42 lb. pressure on such a large piston, a cylinder with a piston one-third of the size is placed beside it. This small cylinder receives the steam direct from the boiler during one-third of its stroke, after which it is cut off. This steam is consequently reduced to one-third of its original pressure, or to 14 lb., at the end of the stroke, and it then enters the second or larger cylinder. Here it is expanded three times more, or down to $4\frac{2}{3}$ lb. Thus, the steam at 42 lb. is expanded to 14 lb. in the first cylinder, at which pressure it enters the second cylinder, and is further expanded down to $4\frac{2}{3}$ lb.; but as the second piston has three times the area of the first, the load will be the same on both pistons, and the piston-rods, cross-heads, and connecting-rods may be the duplicates of each other." The steam is super-heated in the boilers to about 400°, and the cylinders are steam-jacketed and clothed with felt and wood. The feed-water is heated before entering the boilers. It is stated that, although the engines worked with superheated steam, this was found inadequate to prevent condensation in the cylinders without the use of the steam-jackets in addition, the indicator diagrams taken from these engines showing a marked increase of power resulting from a free use of the steam-jackets, the supply of steam to which may be modified at pleasure.

Economy of fuel in Lima, Bogota, &c.

These vessels have all shown a minimum consumption of from 2 to $2\frac{1}{2}$ lb. of best Welsh coal per indicated horse-power per hour, their speed being at the same time $12\frac{1}{2}$ to 13 knots, which must be considered a very satisfactory result. Their consumption of coal at their usual working trim is about 3 lb. per indicated horse-power, the vessel making 11 knots; whereas the more usual consumption of modern marine engines varies from 4 to 5 lb. per indicated horse-power per hour, and the average consumption of all classes cannot be less than 6 lb.

Two cylinders not considered requisite.

It is not contended, however, that the system of expanding in two cylinders is essentially requisite towards the attainment of a great economy in the consumption of fuel, and there are many instances of single-cylinder engines in which the same beneficial results have followed a like judicious combination of means and appliances for this purpose. A case in point is supplied by the recent performances of the steamship Thunder, a vessel fitted with machinery of much the usual kind, by Messrs Dudgeon of London. Although supplied with steam of only 14 lb. pressure, her engines do not consume more than $2\frac{1}{4}$ lb. of coal per indicated horse-power per hour, the vessel making 13 knots. Her machinery

Steam Navigation.

is represented by Plates XXXIII. and XXXIV., and will be found fully described at page 668. An indicator-diagram from her engines is here subjoined (fig. 19).

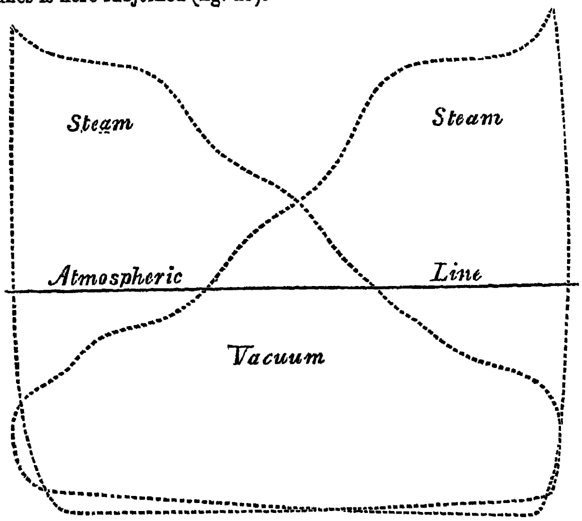

Fig. 19.

Stroke	36 „
Indicated horse-power, each cylinder, with expansion	= 348

Economy of fuel in steamer Thunder.

It may be stated that a consumption of $2\frac{1}{4}$ lb. of coal per indicated horse-power per hour would represent in Cornwall a "duty" of about 90,000,000 of pounds raised 1 foot high in an hour by a bushel (or 94 lb.) of coal, which is considered economical working even for a Cornish engine. The success achieved in the case of the Thunder appears to be due to the conjunction of the following good qualities in the machinery—viz., a perfect command of steam in the boilers, the super-heating and expanding the steam in "belted" or jacketed cylinders, and the allowance of an unusually large inlet and outlet for the steam by the main valves.

Economy of fuel in Omeo.

Another example of unusual economy in the consumption of fuel has been recently shown in the auxiliary screw-steamer Omeo, fitted with engines of 100 nominal horse-power, by Messrs Morrison of Newcastle. These engines use steam at 60 lb. pressure, which is expanded to a large extent in single cylinders, and afterwards condensed in the usual way, the cylinders being surrounded with steam-jackets. The engines work up to 426 indicated horse-power, while driving the ship at 9 knots, and burning only 2·4 lb. of coal per indicated horse-power per hour. As the use of high pressure steam necessarily implies a boiler of corresponding strength, the Omeo's boilers are cylindrical, with "coned" furnaces and upright "coned flues," fitted with a superheating chamber on the top. The employment of steam of this high tension, however, is not to be recommended for passenger-steamers.

Importance of the question of economy of fuel.

The question of economy of fuel is of vital importance even in a national point of view, as affecting the maintenance and extension of some of our great postal lines of ocean steamers, and it is now receiving a large share of attention both from steamship owners and engineers. The subject naturally divides itself into two heads—the production of steam in the boiler, and its subsequent employment in the engine.

The boiler.

1st, *The Boiler.*—It is a material point towards economical working that the boiler should be large enough to ensure a constant command of steam without the necessity for "forcing" the fires, or continually stirring them up. This acts prejudicially in more ways than one. In the first place, each time that the fire-door is opened the cold air rushes in through it, and mixing with the hot gases in the furnace, checks their perfect combustion, at the same time that it robs the interior of the boiler of much valuable heat. Again, if the boiler be deficient in heating surface, the fires must be kept *thin*, to promote rapid combustion; and as these fires are specially liable to "burn into holes," a quantity of cold air enters the furnace through them, and the same cooling effect is produced in the flues and passages. It may be also remarked that, however desirable it may be to "burn smoke" by admitting air into the furnace above the bars, it is seldom an *economical* process, and if not managed with great caution, is apt to become very much the reverse. The natural consequence of stirring the fire too much is, that a large quantity of small coal and cinder falls through the bars into the ash-pit, and as the boilers cannot supply the constant demand for steam unless the fires are kept bright and active, these cinders cannot be re-burned, probably, for fear of checking the formation of steam. They are thrown overboard, therefore, with the ashes, and a heavy expense is incurred.

Forcing the fires is expensive of fuel.

Smoke-burning not economical.

Stoking is not a mere mechanical operation.

It may be thought by some persons that stoking is a mere mechanical operation, easily acquired by the commonest labourer; but this is a great and vital error, which generally costs steamship owners many thousand pounds before they find it out. The stokers, in fact, may be wasting coals by the ton at the furnaces of the boilers for want of proper supervision, while the engineer is straining every nerve to save a few pounds weight by economizing steam in the engines, and possibly congratulating himself, at the same time, upon his able management. It is no unusual case for a difference of 20 per cent. in the consumption of fuel to arise simply from good or bad stoking, by which is meant the whole management of the fires and the draught. The *quality* of the coals is another important item in estimating the consumption per horse-power, and some remarks on this subject will be made hereafter. In large ships the mere labour of passing the coals along to the front of the fires is very severe, and some contrivance of slides or rails to enable the buckets to be easily run down the firing stage is recommended. The stoker's duty is, at the best, a most irksome one, and it is found in practice that any contrivance which adds to their comfort and convenience, whether it be by reducing the heat of the stoke-place, supplying them with a tap of cold distilled water, &c., is amply repaid by the increased attention bestowed on the fires. A marked reduction in the heat of the stoke-place in many of her Majesty's ships has attended the use of the double smoke-box doors, shown in the subjoined sketch (fig. 20),

The comfort of the stokers should be consulted.

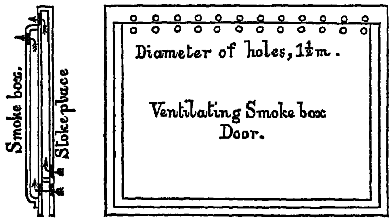

Fig. 20.

which are kept cool by a current of air passing between the double linings. It is very important, both as regards the coolness of the stoke-place and the steaming power of the boilers, that the draught of air to the fires should be encouraged as much as possible by means of large hatches, wind-sails, and air-tubes. It is found preferable, where rapid combustion is required, to allow two or more funnels to the boilers, if by this means the draught may be made more direct; for the question is not merely how to generate steam with the least possible consumption of fuel, but how to do this in the least possible time, and with a boiler of the least possible weight and capacity. It is comparatively an easy matter to evaporate water economically in a Cornish boiler, for instance, but a very difficult and complex one under the conditions imposed upon the marine engineer. The ordinary rate of combustion in the furnaces of marine boilers is about 15 lb. of coal burned on each square foot of grate-bar surface per hour; and the ratio existing between the absorbent or "heating surface" of the boiler and the grate-bar surface varies from 15 to 25 of the former to 1 of the latter. The furnace-bars are frequently made so thick as unnecessarily to impede the admission of air to the fires. They should not exceed $\frac{3}{4}$ of an inch for wrought-iron, or 1 inch for cast-iron, on the upper edge, and should have an air-space of from $\frac{7}{16}$ths to $\frac{1}{2}$ inch between them, while burning Welsh coal.

Draught to the fires.

Rapidity of combustion.

Heating surface.

The nature and arrangement of the heating surface in a boiler is very material, the chief points to be considered being, that the steam may have a ready escape from every part of the heated surface, that every portion of the interior of the boiler should be accessible for "scaling," or removing the crust of insoluble matter, which forms upon the plates and tubes, and that soot and ashes should not collect in any of the flues or passages. A large and high furnace is very desirable for facilitating the proper admixture of the combustible gases with the oxygen of the air. Brass tubes are much preferable to iron for rapidity of evaporation, as might be expected from their relative powers of conducting heat. Some recent experiments have shown, that the evaporative power of clean brass tubes is, to that of iron, as 125 : 100; and copper tubes as 150 : 100, nearly.

Use of salt-water in marine boilers.

Salt-water being necessarily used in the boilers of sea-going steamers, this is liable to become more and more saturated with

Steam Navigation.

salt and earthy impurities in proportion as the steam passes off to the engines. A twofold evil thus arises. The super-salted water, as it increases in density, demands more heat before it will part with its steam; and the insoluble imgredients it contains (chiefly the carbonates of lime and magnesia, and the sulphate of lime), gaining strength with the abstraction of the steam, are deposited inside the boiler, thus forming a non-conducting skin, which greatly impairs its efficacy, and subjects the plates to risk of injury from the fire. To remedy this, a certain portion of the water in the boiler is "blown off" into the sea, its place being supplied by the feed-pumps with a corresponding portion of the hot-water, which results from the condensation of the steam by a jet of sea-water. As the temperature of the "feed," however, does not exceed 100°, while that of the brine it replaces is probably about 230°, it is evident that much heat is thus lost, more especially as a good deal of steam is believed to escape with the water that is blown off.

Constituents of sea-water.

According to Dr Ure's experiments, the largest proportion of salt held in solution in the open sea is 38 parts in 1000 by weight, and the smallest 32. In a specimen brought from the Red Sea, 43 parts were found, the specific gravity of the water being 1·035. The Mediterranean contains about 38 parts in 1000, the British Channel 35·5, the Arctic Ocean 28·5, the Black Sea about 21, and the Baltic only 6·6.

The same authority states, that deep sea-water from the ocean (from whatever locality) holds nearly the same ingredients in solution, containing, on an average, in 1000 parts—

25·0	Chloride of sodium or common salt.
5·3	Sulphate of magnesia.
3·5	Chloride of magnesium.
0·2	Carbonates of lime and magnesia.
0·1	Sulphate of lime.
34·1	

Also a little sulphate and muriate of potash, iodide of sodium, and bromide of magnesium.

"Blowing-off."

It is now the usual practice to "blow-off" the requisite quantity of brine continuously, in the proper proportion to the amount of feed admitted, so as to keep the water in the boiler at a certain regular degree of saturation, at which it is found by experience that little or no deposition of "scale" will take place. Till within the last few years, boilers were always blown-off from the *bottom* only, it being not unnaturally supposed that the heaviest and most saturated water would be found there; but experience has now proved that the greater portion of the impurities from which the scale is formed are to be found on the *surface* of the water of the boiler (being carried upwards by the steam), and should be abstracted from thence. Mr Lamb, the superintending engineer of the Peninsular and Oriental Steam Navigation Company, was the first to introduce "surface blow-off," which is now very generally used in addition to blowing-off from the bottom, and is attended with a considerable improvement in the condition of the boiler-surfaces.

Surface blow-off.

Proper degree of saturation of water in boiler.

The rule adopted by this company is, that the feed and blow-off shall be so regulated, the one to the other, that the water in the boiler may be always at the degree of saturation marked 17 on the scale of their hydrometer, which represents a saturation of between $\frac{3}{32}$ and $\frac{4}{32}$ parts of salt.

The following table shows the boiling point and specific gravity of sea-water (at 60° Fahr.) of different degrees of saturation, expressed in parts of salt contained therein, the barometer indicating 30 inches of mercury:—

	Saltness.	Boils.	Sp. gr.	
Pure water.............	0	212°	1·	
Common sea-water......	$\frac{1}{32}$	213·2°	1·029	
Up to this point but	$\frac{2}{32}$	214·4°	1·058	
little deposit will be	$\frac{3}{32}$	215·5°	1·087	
formed............→	$\frac{4}{32}$	216·7°	1·116	
	$\frac{5}{32}$	217·9°	1·145	
	$\frac{6}{32}$	219·1°	1·174	
	$\frac{7}{32}$	220·3°	1·203	
	$\frac{8}{32}$	221·5°	1·232	
	$\frac{9}{32}$	222·7°	1·261	
	$\frac{10}{32}$	223·8°	1·290	
	$\frac{11}{32}$	225·0°	1·319	
	$\frac{12}{32}$	226·1°	1·348	saturated solution.

As a general rule, the atmospheric boiling point of the water should never be allowed to exceed 216°, when the barometer stands at 30 inches. The temperature must be ascertained by drawing off a small quantity of the brine, and boiling it in a deep copper vessel in the engine-room, a correction being made, as nearly as possible, for the state of the barometer.

The following table shows the height of the boiling point of pure water at different heights of the barometer:—

Barometer. Inches.	Boiling Point.	Barometer. Inches.	Boiling Point.
27	206·96°	29½	211·20°
27½	207·84°	30	212°
28	208·69°	30½	212·79°
28½	209·55°	31	213·57°
29	210·38°		

In testing brine by the hydrometer, care must be taken that it has the particular temperature for which the hydrometer scale was calculated. This is usually 200° Fahr. About 3° of temperature make a difference of ·0001 of the specific gravity, or ·036 of the usual hydrometer degree, or ·0036 of the density of sea-water. The steam raised from salt-water and fresh is precisely the same in every respect; but it has been found by experiment that water of the density which it usually acquires in marine boilers, demands about one-tenth more of heat to convert it into steam than if it were fresh-water, its "capacity for heat" being greater to this extent. It is needless to say, that salt itself will not be deposited until the brine arrives at its point of greatest saturation, or three times the density which the water should ever be allowed to acquire; but what the engineer has to guard against is, the deposition of a solid stone-like incrustation, composed of the sulphate and carbonate of lime, and the carbonate of magnesia. These are at first held in solution by the water, but are subsequently rendered insoluble, and become deposited on the plates and tubes of the boiler, partly from the free carbonic acid being expelled by the boiling of the water, and partly by its continued saturation.

Surface condensation.

Many, though hitherto unsuccessful, attempts have been made to obviate the necessity for this expensive process of blowing off. The only effectual remedy is the employment of fresh water in place of salt in the boilers; but this can only be accomplished by the adoption of "surface condensation." By this term is understood the condensation of the steam by contact with a large extent of cold metallic surface, instead of the usual method of condensing by a jet of sea-water. This principle, though repeatedly tried, has hitherto proved more or less inefficient, and the invention of an effective method of surface condensation is still a problem in marine engineering. It is believed that an economy of about 15 per cent. in consumption of fuel would result from the use of fresh-water in the boilers of marine engines, with a longer duration of the boiler, and the saving of much valuable time consumed in cleaning. The average duration of boilers using salt-water does not exceed six years, while those using fresh-water last eight or nine; but the life of a boiler is very uncertain, depending so much on the care and attention bestowed upon it.

Process of "scaling."

The process of "scaling" a boiler, or removing the deposit from the internal surfaces, is a very tedious and troublesome one, the scale being detached by hammers and chisels, after being loosened as much as possible by lighting fires in the furnaces of the empty boiler. In some recent experiments on this subject made at Portsmouth by Mr Lindsay, the boiler was filled with hot air at a temperature of 400°, which acted most successfully in detaching the scale by the rapid expansion induced. The boiler was afterwards filled for service, and so soon as a pressure of steam was obtained, the bottom blow-off cocks were opened, and most of the scale previously detached was "blown off" into the sea.

Donkey-engine.

Almost all boilers are now fitted with an auxiliary or "donkey" engine, for the purpose of keeping up the requisite supply of feed, while the regular feed-pumps attached to the large engines are not working. The "donkey" is also made useful for pumping water either from the sea or the bilge, and is an invaluable aid in case of fire.

Feed-water heaters.

In many steamers the feed-water is heated to a point considerably above the temperature of the condenser, by means of the waste heat of the boiler itself; being brought into contact either with the brine which is blown off, or with the hot air at the foot of the chimney. By this means its temperature may be raised from about 100° to 180° or 200°; and as modern practice shows the advantage of freshening the boiler by a plentiful admission of feed, it is very desirable that its temperature should be thus previously raised. Various modes of effecting this will be found mentioned in the descriptions to the plates accompanying this article. The feed-water heater of the Great Eastern has acquired an unfortunate notoriety from the sad consequences attending its explosion, though there is no inherent danger in the arrangement there adopted, which has been safely and successfully applied in many other vessels.

"Priming."

When the ebullition inside a boiler is so rapid and violent that the water rises with the steam in considerable quantity, and is carried over with it to the engines, or is blown up the waste steam-pipe, the boiler is then said to "prime." This is one of the most

Steam Navigation.

dangerous and troublesome propensities to which a boiler can be subject, as it may occasion a break-down in the engines by the shock of the piston upon the incompressible fluid (if escape-valves of sufficient capacity are not fitted), and in all cases it entails a great loss of heat carried off by the hot-water which boils over.

Causes of priming.

Priming may arise from a variety of causes, but the prevalent one, more especially in the government service, is a too contracted steam space over the water of the boiler. For where the reservoir of steam from which the engines are supplied is very small, there must be constant pulsations of pressure in the boiler; and each time that the surface of the boiling water is relieved of a certain amount of pressure by the rapid withdrawal of a cylinder full of steam, it boils up with great violence, and possibly overflows into the steam-pipe. The only remedy for this is an addition to the size of the steam-chest, and an increased height above the surface of the water to the steam-pipe orifice. Priming, however, is frequently the result of accidental causes, apart from the construction of the boiler. Water charged with mud or mucilage, which forms a viscid scum on the surface, is sure to induce it; also while the ship is passing from fresh-water into salt, and *vice versâ*. A new boiler with clean "raw" surfaces, is more liable to prime than after it has contracted a coating of scale, in consequence of the brisker ebullition going on, as well as from the dirt and grease left in a new boiler by the workmen. It is a usual practice to put tallow in a boiler as a preventive of priming, but this is not always attended with the desired effect. When the boiler primes very much, it is necessary to slow the fires, so as to prevent the too rapid formation of steam.

"Wet" steam.

All boilers are subject to the loss of a certain quantity of water, which rises with the steam in the shape of fine spray, and passes over with it into the cylinders of the engines. When much of this is present, the steam is said to be "wet;" but it is believed that all steam raised in the ordinary way is more or less charged with water in a state of fine subdivision. To evaporate and utilize this water is one of the principal incentives to the use of surcharged or "superheated" steam. The other advantage arising from its use, namely, the prevention of condensation in the cylinders, has been already referred to while treating of expansive working.

Superheating apparatus.

The steam in the boiler may be superheated in a variety of ways, but those methods seem preferable which use for this purpose the spare heat at the bottom of the chimney, which would otherwise be almost entirely lost. The accompanying sketch (fig. 21) explains the method

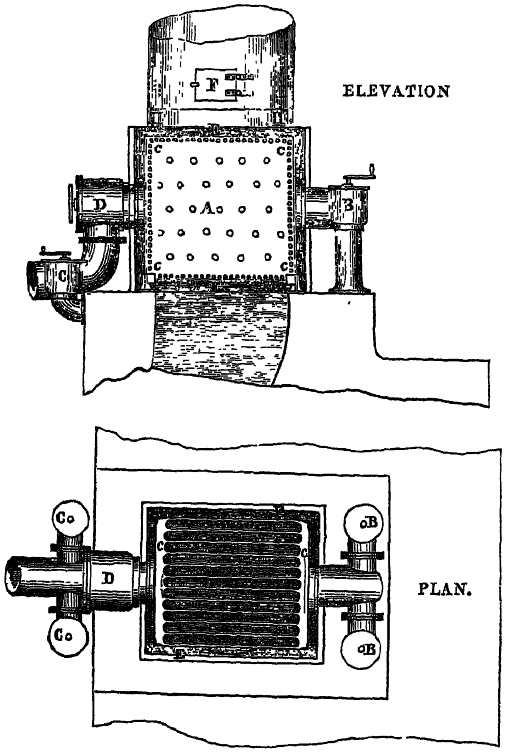

Fig. 21.
Lamb and Summers' Superheating Apparatus.

which has been already largely employed in the steamships of the Peninsular and Oriental Steam Navigation Company, those of the Union Steam Packet Company (carrying the Cape mails), and many others at Southampton, and which has been attended with the most undoubted success. It will be observed, that the steam in its way from the boilers to the engines passes through the superheating chest A, at the foot of the chimney, the steam occupying the narrow spaces between the sheet-flues through which the smoke and hot air pass.

BB are stop-valves for admitting the steam to the apparatus, or excluding it if necessary.

CCC are stop-valves for passing the steam direct from the boilers to the engines without going through the apparatus.

DD are stop-valves for admitting the superheated steam to the engines, or shutting it off when common steam only is used.

EE is a square casing enclosing the apparatus, and forming the foot of the chimney, the smoke and hot air of which entirely surround the superheating chest. Other casings of thin iron are fitted outside this to prevent the radiation of heat.

F is a door for getting into the chimney, and examining the flues of the apparatus.

The chimney is not rigidly fastened to the square casing, but ships over the projecting part HH, the space between being filled with clay. This mode of carrying the chimney is adopted, so that, in the event of collision, the loss of the chimney should not entail the destruction of the apparatus and its connexions.

It is found, from experience, that a heating surface of about 4 square feet per nominal horse-power of boiler is required to superheat the steam under ordinary circumstances. The temperature of the steam, when issuing from this apparatus, is generally found to be about 320° to 360°; and in the slide-jacket, from 20° to 30° less, according to the length of the steam-pipe.

A high temperature not required.

The saving of fuel in the steamships of the Peninsular and Oriental Company, by the use of this apparatus, is stated to vary from 20 to 33 per cent., without any injurious effects resulting to the piston-packings, &c. By this simple and inexpensive process the whole steam given off by the boiler is "superheated" from the temperature due to its pressure (which for steam of 15 pounds pressure would be 250°) to a temperature of from 350° to 380°, which has been proved to be amply sufficient for obtaining all the benefit derivable from the process. That much of the heat of superheated steam is really employed in evaporating the particles of water held in suspension seems to be proved by this fact, that its temperature will fall as much as 40 or 50 degrees, in some cases, during its passage from the boiler to the engine, though there is no perceptible escape of heat by radiation from the surface of the well-protected steam-pipe. The heat thus apparently lost is undoubtedly taken up (in the latent form) by the steam resulting from the vaporization of these watery particles, by which means the heat already contained in the water is turned to good account, and the evaporative power of the boiler is virtually increased.

Economy of the process.

A great many experiments have been made to test the actual economy of the process by comparison with the existing consumption of coal before the superheating apparatus was fitted, and in every instance there has been a perceptible improvement. This sometimes takes the shape of increased speed in the engines and vessel, sometimes a saving of fuel alone is effected, and in other instances both of these are combined in the same vessel in variable proportions. Where the speed of the vessel has been kept a constant quantity, there would appear to be an actual saving of from 15 to 25 per cent. of fuel, according to the nature and qualities of the boiler to which the process has been applied, and the amount of expansion in the cylinders. The high rates of economy are naturally shown by those boilers which were previously the worst to keep steam with, and which required very hard firing to do so. Those addicted to priming and wet steam rank next in apparent economy, while those boilers which show the least were originally the best specimens of their class. There is no question, however, but that the process is beneficial *in all cases*, though not equally so, and enables the steam to be raised in the boilers without "hard firing" being resorted to, being in this respect a great boon to the stokers.

Wethered's *mixed* superheated steam.

It is believed that not the slightest advantage over the ordinary methods of superheating the steam is due to Mr Wethered's system of mixing superheated and ordinary steam together at the point where they enter the valve-jacket. To this gentleman's patent, however, we owe, in a great measure, the general awakening of marine engineers to the undoubted advantages of the process, which have been till now so unaccountably overlooked.

Conservatism in marine engines.

The plan adopted by the government of contracting for their steam machinery with only a few favoured and old-established houses, has undoubtedly tended to promote conservatism in marine engines, and to repress innovations and improvements, the wholesome though often unpalatable principle of competition being, in their case, scarcely roused into action. These lordly manufacturers have nothing to gain, in fact, by breaking new ground, being well assured of their accustomed orders from the Admiralty, and not caring to raise the ques-

Steam Navigation.

tion whether their beautifully constructed machinery might not possibly be made to content itself with 60 tons of coal per diem in place of 80. In the case of those manufacturers, however, who have not the *entrée* at Whitehall, but who are dependent upon the custom of the great steam shipping companies, and other private owners of steam-vessels, who are fully alive to their own interests, there exists an active competition, and consequently a strong inducement to improve upon the economical performance of their machinery. We find, accordingly, that it is this class who have taken the lead in the recent steam reformation which has now fairly set in.

Marine boilers.

There are three principal kinds of marine boilers in use in this country, namely, the rectangular-flue boiler (which is now very generally discarded); the multitubular boiler, or, as it is more usually called, the *tubular* boiler; and the sheet-flue boiler.

The tubular boiler.

The tubular boiler (as shown in Plates XXXIII. and XXXIV.) is that in most general use. This construction enables a very large quantity of heating surface to be crowded into comparatively small space; while the form of the tubes, which vary from $2\frac{1}{2}$ to 4 in. in diameter, affords great strength, at the same time that the thinness of the metal composing them offers little impediment to the conduction of heat. They are attended with this inconvenience, however, that the flame arising from the combustion of the inflammable gases in the furnace is prematurely extinguished by the minute subdivision and rapid reduction of temperature to which it is exposed in passing through these small tubes.

It is well known that flame requires a very high temperature for its maintenance, and is easily extinguished by contact with a comparatively cool surface; as for instance, in passing through the wire-gauze of the miner's safety-lamp. A precisely similar effect is produced by the boiler-tubes, whose temperature, from their being surrounded with water, must be considered low when compared with that of the flame and hot gases passing through them.

Vertical-tube boiler.

The Americans have adopted a different form of tubular boiler (as shown in the accompanying wood-cut, fig. 22),

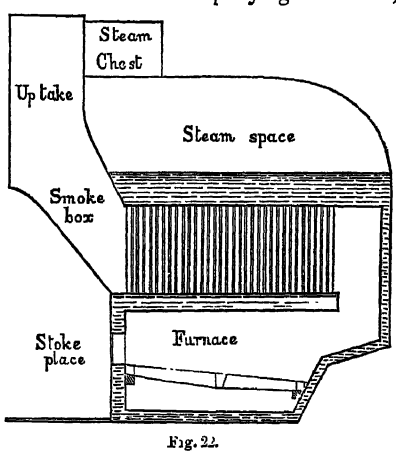

Fig. 22.
American upright-tube Boiler.

in which the tubes are disposed vertically, the smoke and flame passing round the *outside* of the tubes, and the water being contained *inside*. These vertical-tube boilers are very effective in generating steam, and partly for this reason, that the flame reaches further amongst their tubes than in the case of a horizontal boiler, in consequence of the greater space outside the tubes in which the flame may develop itself. The importance of this, while using the bituminous *flaming* coal of the northern coal-fields, is very great. The absorbent surface of the vertical-tube boilers is, of course, greater than that of the horizontal in proportion as the external diameter of the tubes exceeds their internal diameter, and the weight of water it is necessary to carry is much less.

Sheet-flue boiler.

Sheet-flue boilers are constructed with numerous flat, narrow water-spaces, alternating with flues of the same form in place of tubes. The width of the water-spaces in "Lamb and Summers' patent sheet-flue boilers" varies from $1\frac{1}{2}$ to 2 inches, and the flues from $2\frac{1}{2}$ to 3 inches. They are extensively used in the steamers of the Peninsular and Oriental Company, where they give much satisfaction from their durability, and economy in repairs.

Explosions of boilers. Causes.

When a marine boiler explodes, the presumption is, either that the safety-valve has not acted properly, or has been over-weighted, and the boiler has burst simply from excess of pressure; or that the water has been allowed to fall too low, and thus expose the tops of the flues or furnaces, or the boiler-tubes, which, getting red-hot by the action of the flame, have suddenly generated such a rush of steam, upon the re-admission of the feed, as to cause a rupture of the weakened plates. Explosions most frequently happen at the moment of opening or shutting a safety-valve or communication-valve, which shows that so long as the steam remains undisturbed within the boiler, it will sustain a very high pressure without bursting; but should a wave or pulsation be carried through it, the equilibrium is instantly destroyed, and a rupture takes place. The very act of suddenly opening a safety-valve, or a communication-valve to the engines, would cause the water to boil up with great violence, and an immense volume of steam to be instantly liberated, in consequence of the water being relieved from a certain amount of pressure.

Precautions, &c.

In the event, therefore, of the discovery being made that any portion of the boiler has become overheated from want of water, the engineer should neither open the safety-valve nor admit the feed, but throw open the fire-doors, close the dampers, and draw the fires, after which the safety-valves may be cautiously relieved, and the feed gradually admitted, until the overheated surfaces are covered with water.

In those parts of the boiler where the heat is most intense (as at the backs of the furnaces) the plates will gradually become oxidated and weakened by the fire, even although kept constantly in contact with water. This is probably owing to the rapid disengagement of steam from the surface, which interposes a non-conducting film of steam between the iron and the water, and thus permits the former to get overheated. Thick plates, or overlapped joints, in such a position, "burn out" quicker than thin ones, from the imperfect conduction of the heat through the métal, and this is of course much aggravated when the plates are coated with scale. Plenty of steam room is a safeguard to a boiler, as tending to diffuse and neutralize any dangerous oscillation or sudden accession of steam. The immense rush of steam which always follows an explosion is satisfactorily explained, when we consider that the instant the water contained in the boiler is relieved of pressure it throws off steam with great rapidity, and continues to do so until the whole mass of the water is reduced to the atmospheric condition of 212°Fahr. To make matters worse, the steam-chests of all the boilers are usually in communication.

Rarity of explosions in steamers.

It is gratifying to find that while explosions in America are so frequent, they rarely occur on board of steam vessels in this country—a result which is doubtless to be attributed, in a great measure, to the supervision of the Board of Trade. It is worthy of remark, also, that the majority of such accidents havè happened to tug-boats, which, from not carrying passengers, are exempt from government interference; and it will be remembered that the Great Eastern, when her feed-water heater exploded with such fatal consequences, had not yet received a certificate of sea-worthiness.

Requirements of the Merchant Shipping Act.

By the Merchant Shipping Act of 1854 the Board of Trade are empowered to enforce certain provisions of equipment of the vessel and her machinery, supposed to conduce to the safety of the passengers and ship. The principal points to which attention is directed by this act are, that the masters and mates of steamers shall

Steam Navigation.

have proper certificates of competency; that the hull and machinery generally shall be of sufficient strength; that the number of passengers carried shall be limited by the accommodation; that a sufficient number of boats be carried; that proper water-tight bulkheads be fitted, as well as pumps, fire-pumps and hose, life-buoys, lights, compasses, &c., &c. Each boiler is required to have one safety-valve, and recommended for further security to have two, the weights upon which have been sanctioned by the Board through their surveyor. One of these valves (called the government safety-valve) is left locked beyond the control of the engineer of the boat, the key being placed under the master's charge. Every passenger-steamer is required by this act to renew her certificate of efficiency or sea-worthiness twice a-year, after periodical surveys have been held upon her hull and machinery; and if such certificate is not granted, she is debarred from carrying passengers until the required provisions are complied with.

Qualities of coal.

It will now be desirable to convey some practical information regarding the coals used in steam-vessels. The qualities it is most desirable for steam-coals to possess may be summed up as follows:—1. They should have a high evaporative power, or, in other words, they should be capable of converting much water into steam with a small consumption of fuel. 2. They should not be highly bituminous, as such coals produce a dense black smoke which it is difficult to consume in the furnace, and the soot and tarry matter evolved are found to clog the tubes and flues, and detract from the evaporative power of the boiler. 3. The coal should light quickly, and be capable of a rapid combustion. 4. It should be sufficiently cohesive in its nature to bear the constant attrition it is subjected to without becoming broken into small fragments. 5. It should combine a considerable density with such a mechanical structure as may admit of its being stowed in the smallest possible space, this involving a difference of 20 per cent. 6. It should be as free as possible from sulphur, which induces progressive decay and spontaneous combustion.

Admiralty experiments on coals for the Royal Navy.

Table, showing an Abstract of the Principal Results obtained from the Best Coals of the United Kingdom, collated from the Admiralty Reports on Coals suited to the Steam Navy.

Name of Fuel.	Evaporative power or No. of lbs. of Water converted into Steam by 1 lb. of Coal.	Weight of cubic foot in lbs.	Space occupied by 1 ton in cubic feet.	Cohesive Power percentage of large Coals.	Evaporative Power after deducting for Combustible Matter in residua.	Evaporative Power per Hour per Square Foot of Grate surface.	Lbs. of Clinker per ton.

„ small	20·8	15·0

Average Chemical Analysis of 100 *parts of Dried Coal.*

Ash	2·24	4·32
Carbon	89·13	78·45
Hydrogen	4·23	5·11
Nitrogen	1·27	1·79
Sulphur	1·01	1·36
Oxygen	2·12	8·97

In the foregoing tables the "theoretical evaporative power" is deduced from the composition of each coal as determined by chemical analysis. It gives the maximum amount of heat which each coal could produce, calculated in terms of the number of pounds of water at 212°, which would be converted into steam at 212° by the complete combustion of 1 lb. of each variety of coal.

Evaporative power of coal.

1 pound of pure carbon (according to the most accurate experiments) emits, by its combustion, an amount of heat sufficient to evaporate 14·88 lb. of water at 212° into steam at 212°; and 1 lb. of hydrogen, when burned, emits heat enough to convert 63·56 lb. water at 212° into steam of the same temperature. It is found experimentally, that the quantity of water capable of being evaporated by any coal is (as nearly as possible) directly as the quantity of coke which can be produced from that coal; the fact being, that in the case of bituminous coals, as burned in an ordinary furnace, as much heat is required for liberating the volatile products of the coal as is afterwards produced by the combustion of these volatile products, taking into account the cooling effect of the air admitted to maintain their combustion. Hence the very high evaporative power of anthracite coal, which, unfortunately, has certain countervailing disadvantages, that preclude its use in the boilers of a steam-vessel under ordinary circumstances. It is not only very difficult to light, but when lighted can be maintained in active combustion only by the aid of artificial draught, when the heat evolved is so intense as rapidly to destroy the fire-bars, as well as the material of the boiler itself.

Anthracite.

Welsh coal.

Welsh coal, which holds an intermediate rank as to its evaporative power between anthracite and the bituminous coals of the northern district, is considered the most suitable for steamers in general, and is much more easily stoked than bituminous coal.

Treatment of bituminous coals.

As Newcastle and other bituminous coals demand careful and peculiar treatment in the furnace, it may not be out of place here to give some directions for stoking it. The fires should be kept at a uniform thickness of from 12 to 14 inches. When the furnaces of one boiler are being charged, the fresh coal should be thrown upon the right-hand half of each fire in succession for one charge, and then upon the left-hand half of each fire during the next charge, and so on alternately, so that the whole fire may never be covered with "green" coals at once. The green coal is to be thrown upon the front half of the fire only, and never at the back of the fire, but when necessary the red burning fuel must be pushed back by the shovel, to keep up the proper thickness of the fires at the bridge. Where no means are provided for admitting air through the fire-doors, these must be left slightly open, after charging with fresh coal. By a due observance of the three last directions, the formation of black smoke with north country coal may be prevented. The cinders, as they fall through the spaces between the fire-bars, are to be raked forward in the ash-pits, and at every fresh charge a portion of them is to be thrown upon the fires after the green coal, so that nothing is removed from the stoke-hole but clinkers and ashes. The spaces between the fire-bars are at all times to be kept clear of clinkers and ashes, so that the air may have free access to the burning fuel. When the coals cake on the bars, the poker must be gently used to raise and open them for the admission of air to the mass of the burning fuel.

Patent fuels.

Some of the "patent fuels" have a very high evaporative power, but they are all, more or less, difficult to manage in the furnace, and should never be used where the stokers are unaccustomed to their peculiarities. They are very valuable in special cases, from the compactness with which they may be stowed.

Marine engines.

We shall now advert to a few particulars having reference to the general construction and management of the Marine Engines of steam-vessels. The first valve through which the steam passes after leaving the boiler is the *throttle-valve*, by means of which the flow of steam to the engines is regulated or shut off entirely by hand. In the event of a ship pitching very much in a heavy sea, it is often necessary to station a man at the throttle-valve to shut off the steam from the engine whenever it begins to "race," or fly off at a high velocity, according as the resistance is removed by the propeller becoming raised out of the water. Both paddle and screw engines are subject to this dangerous action, but particularly the latter, on account of the screw being, from its position in the ship, more exposed to sudden variations of "dip" or immersion. To mitigate this (in some measure), the contrivance called a "governor" has been successfully applied in many cases of screw-steamers, whose consumption of fuel in bad weather has been thereby much diminished, as well as the working of the machinery rendered more regular. Indeed, the commander of a screw-steamer has often found it practicable, after this little instrument had been fitted to his machinery, to keep his vessel head to wind in such weather as would have formerly necessitated his laying to.

Marine governor.

Description of Silver's governor.

The annexed figure (23) represents the best, and indeed almost the only, species of marine governor that has yet been applied. It is called "Silver's momentum-wheel governor," constructed by Messrs J. Hamilton and Company of Glasgow, who have purchased the patent. "It consists of a momentum-wheel A, fixed on the boss of a pinion B, which works loosely on the spindle C, and gears into the two-toothed sectors DD. These two sectors, being supported on a crosshead E, made fast to and carried with the spindle C, work in opposite directions on the pinion B; and as they are linked by the rods FF to the sliding collar G, which receives and works the forked lever H, communi-

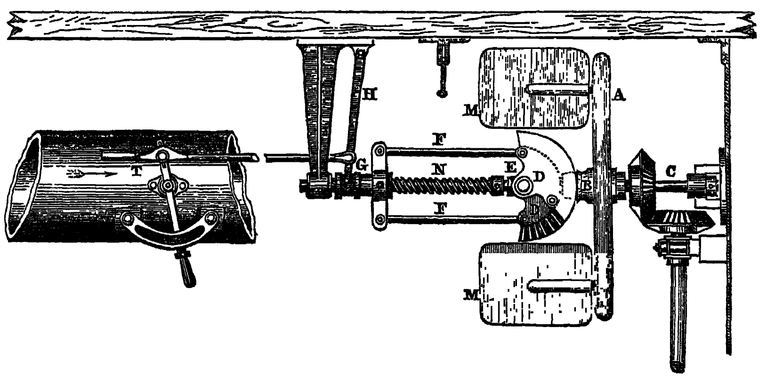

Fig. 23.
Silver's Marine Engine Governor.

cate motion to the throttle-valve T. MM are vanes, and N is a spiral spring, both of which are adjustable."

"The action of the above instrument is as follows:—When the spindle of the governor is turned by the engine to which it is attached, the two toothed sectors, which are carried on the fixed crosshead, being geared into the pinion on the momentum-wheel, have the tendency to turn round on this pinion; but as they are linked to the sliding collar, they necessarily pull inwards this collar, and so compress the spiral spring, and this spring reacting on the collar, and consequently on the toothed sectors, serves to turn round the momentum-wheel, while the vanes on the momentum-wheel balance the action of this spring by the resistance the atmosphere offers to their progress through it. As the leverage action of the toothed sectors upon the momentum-

wheel pinion increases (as the spring becomes distended, and *vice versâ*), it will be seen that the reaction of the spring in propelling the momentum-wheel will at all times be uniform, and as much only is required as will carry round the momentum-wheel with its vanes at its proper speed, and overcome the friction of working the throttle-valve and throttle-valve connections. When the momentum-wheel is in motion, it will rotate with the engine to which it is attached at a velocity proportioned to that at which it is fixed by the connecting gear; and while the engine, from the usual causes, may attempt to vary this velocity, it cannot affect the momentum-wheel, but leaves it free to act upon the sliding collar, and consequently upon the throttle-valve—at one time closing the throttle-valve by its action in resisting any increase of velocity, and at another time opening the throttle-valve by its action in resisting any decrease of velocity on the part of the engine. A momentum-wheel of 2 feet 8 inches in diameter, and 2 inches breadth of periphery, running at a speed of 180 revolutions per minute, is found to be sufficient to work with promptness and ease the largest throttle-valve."

The same engineers have also introduced, for this purpose, an ingenious modification of the ordinary Watt's centrifugal governor, called "Silver's four-ball governor," in which the action of a spiral-spring is substituted for that of gravity, and the whole apparatus (like the preceding one) is balanced, so as to remain undisturbed in its action by the pitching or rolling of the vessel.

Jensen's marine governor.

It is evident that the action of all such governors is so far imperfect, that they do not shut off the steam before the speed of the engine has begun to be sensibly affected by the very evil it is desired to remedy, and it has been therefore attempted (by Mr Jensen of Copenhagen) to construct a marine governor, which may make use of the *cause* of the evil as the remedy against it; or, in other words, to employ the irregular immersion of the vessel as the means of regulating the engines, in preference to letting the engines regulate themselves. This he effects in a very simple and ingenious manner, by employing two small cylinders, which communicate with the sea below their pistons, whose motion is then transmitted, by rods and bell-cranks, to the throttle-valves of the engines. These cylinders are placed inside the vessel (one on each side), and as near as possible to the position occupied by the propeller. As the sea has free admission under the pistons, the latter are subjected to a varying pressure of water, nearly corresponding with that to which the propeller itself is exposed. This varying pressure (modified by the action of a spiral spring) is therefore communicated immediately to the throttle-valves through the cranked rods, and thus shuts off or admits the steam before the engines have felt the variation in the load about to be transmitted to them from the propeller.

Expansion-valve.

The steam, after passing the throttle-valve, next enters the *expansion-valve*, where it is cut off at any desired portion of the stroke, by the action of an eccentric, or cam, on the main shaft. Such an arrangement is shown in Plate XXIX. The valve usually employed for this purpose is the "equilibrium" or "double-beat" valve, as shown in the annexed engraving. This kind of valve has the advantage of being opened and shut with great facility, since, from its construction, the pressure of the steam has no tendency to jam it against its seat, the objection to which all single flat valves are subject. It is also apparent that a slight rise of this valve gives a large opening for the steam to pass. In the engraving, the valves *a a* are made of *brass*, and the valve-box, and the spindles connecting the valves, are of *iron*. In this instance the valves are purposely connected by iron spindles, in order that the linear expansion of the sides of the box containing the valves, and of the spindle connecting them, may be equal in amount, and therefore have no tendency to raise the upper valve off its seat, which would certainly ensue were the valves connected by a brass spindle, in consequence of the greater expansion of that metal by heat. This arrangement of the metals will be seen to be of special importance when superheated steam is used, and the temperature thereby increased.

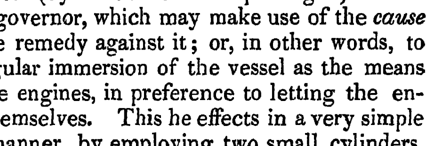

Fig 24.

Slide-valves.

Having passed the expansion-valves, the steam now enters the jacket of the cylinder *slide-valves*. These are usually so constructed and arranged as to fulfil the following conditions for the admission and exclusion of the steam, independently of the action of the expansion-valves:—1*st*, The steam is shut off a little before the end of the stroke, by the valve prematurely closing the steam-port aperture. The use of this is to check the velocity of the piston, by causing it to finish the stroke by the expansion of the enclosed steam only. This is effected by giving "lap" to the valve. 2*d*, The eduction-port, or the passage to the condenser, is closed a little before the end of the stroke, which is called *cushioning* the piston, because it then completes the stroke against an elastic *cushion* of vapour shut up between it and the top or bottom of the cylinder. 3*d*, The port is opened for the admission of steam to the cylinder a very little before the piston begins the return-stroke, in order that the steam may have filled the passages and the "clearance" of the piston, and have acquired its full pressure, by the time that the crank shall have turned the centre. This is effected by giving what is called "lead" to the valve. 4*th*, The communication with the condenser is opened a little before the end of the stroke, so as to have a vacuum ready made in the cylinder so soon as the return stroke begins. In this way each operation which takes place in the cylinder is slightly *anticipated* by the mode of setting the valves. In the case of screw-engines especially (which run at a high velocity), it is of the greatest importance that the steam-passages and valves should be of ample size, and those valves only should be used which give a large opening for the steam, with a short "travel" of the valve.

Condenser.

As the nature and limits of this article preclude a minute description of the details of the marine engine (which indeed are very similar to those of the stationary condensing engine, already given in the article STEAM-ENGINE), we will not attempt this, but at once follow the steam from the cylinder into the *condenser*. In this magical little chamber the whole of those perplexing processes we have been considering are at once reversed, and all the labour and expense incurred in generating the steam in the boilers (themselves about twenty times larger than the condenser), are, as it were, instantly annihilated. The condensation of the steam is usually effected by the dispersion of a jet of cold sea-water amongst it, which is the most effectual means yet known for producing that instantaneous condensation, upon which the efficacy of the process is entirely dependent.

Surface-condensers.

Many attempts have been made, as we have before stated, to condense the steam by contact with cold metallic surfaces without the use of the water-jet, but they have all, more or less, failed, from the condensation not being sufficiently sudden. The plan known as "Hall's Condensers" is, indeed, partially successful; but, owing probably to their weight, bulk, complexity, and expense, they are very little used, although it is now twenty years since their first introduction. In most surface-condensers the steam is passed through a great many small copper pipes, contained in a cistern of cold water, through which a current from the sea is made to flow by means of a force-pump. In such an arrangement, the loss of water arising from

Steam Navigation.

leakage, or from blowing-off at the valves, is compensated to the boiler by employing a small apparatus to distil sea-water, by the aid of which the boilers are kept constantly supplied with fresh water. A close connection exists between the temperature of the condenser and the vacuum, the latter being of course more complete as the temperature is reduced. There is a limit, however, beyond which any further reduction of temperature, by injecting more sea-water, is attended by a loss of power. It is found in practice, that a temperature of from 95° to 105° (depending upon the pressure of the steam), is the most economical, with which a vacuum of from $27\frac{1}{2}$ to 26 inches of mercury is obtained when the weather barometer stands at $29\frac{1}{2}$ inches, the standard of this country. It is a curious fact, and contrary to what might at first sight have been anticipated, that a better vacuum, and a lower temperature of the condenser, is obtained with superheated steam, than with common steam, being probably owing to the more perfect condensation of the steam, when not mixed with particles of hot water held in mechanical suspension. This fact appears also to indicate, that the extra doze of heat contained in the superheated steam has been all previously and usefully expended in the cylinder (by supplying the expanding steam with latent heat), and that no portion of it survives to enter the condenser. Whatever the cause may be, the result is, that considerably less injection-water is required when superheated steam is used, much to the surprise of the engineer in charge.

Best vacuum for the condenser.

Superheated steam condenses freely.

Contents of the condenser.

According to Dr Ure's experiments, uncondensed watery vapour at a temperature of 100° balances 1·86 inch of mercury; at 110°, 2·45 inches; at 120°, 3·3 inches; at 130°, 4·366 inches; at 140°, 5·77 inches; and at 150°, 7·53 inches of mercury, or exerts a pressure of $3\frac{1}{4}$ pounds per square inch. In addition to the uncondensed vapour, a considerable quantity of atmospheric air is always present in the condenser, having entered it in combination with the condensing water. The contents of the condenser, therefore, are sea-water used for condensation, condensed steam, uncondensed watery vapour, and atmospheric air. To remove these is the duty of the *air-pump.* It has a capacity of about $\frac{1}{8}$ths of that of the cylinder, and is furnished with a "bucket" and valves, which are now usually formed of a stout circular disc of vulcanized India-rubber. The air-pump draws its contents from the condenser through the *foot-valve,* and then passes them on through the *delivery-valve* and the *discharge-pipe* into the sea, a small portion of the hot water being abstracted by the feed-pumps to supply the boilers.

The air-pump.

Marine engines should be simple.

The machinery of a sea-going steamer should be as simple in design and possess as few moving parts as possible. In vessels designed for long voyages more especially, as well as in those which are intended for foreign stations, it is far preferable to dispense with those clever and ingenious contrivances for saving infinitesimal quantities of fuel which are in vogue with some manufacturing engineers of the present day, and more especially in Scotland. During a long run, as from Aden to Australia, for instance, the chances of derangement of the machinery are much increased by the mere inability to make the usual adjustments demanded by ordinary wear and tear; and it is surely wise to avoid the additional risk attending a great multiplicity of parts, the failure of any of which may cause the stoppage of the engines. When we consider that a large pair of engines may very possibly have five hundred different parts all in motion at once, and that each of these parts is making a thousand rotations, or double-oscillations, each half-hour, for twenty days consecutively, it can scarcely be wondered at that accidents should occasionally happen. But allowing that everything goes well with this complicated machinery, it is not by the use of such finical refinements of mechanism that any great saving of fuel can be effected (for this is the main point aimed at), but rather by the careful and judicious management of the boilers and engines. The fortunate selection of a good chief-engineer for the vessel will generally effect more saving in fuel than the most ingenious and expensive "modern improvements." These remarks are not intended to apply to the obvious advantages obtained by superheating the steam, large expansion, careful clothing (or jacketing) of the cylinders and steam-pipes, &c., which do not add much to the complexity of the engines.

Large bearings necessary.

The tendency of modern practice is to run the pistons of steam-engines at a much higher speed than formerly. This is more especially the case with screw-engines, whose pistons frequently run at the rate of 400 feet per minute, in place of Watt's old rule of 220 as a maximum. Although theory does not impose larger dimensions on the moving parts of a machine on this account, it is found in practice that the shafts of screw-engines running at a high velocity must be considerably increased in size to avoid accident. This arises partly from the increased momentum of the parts in motion; partly from the greater tendency of the bearings to heat from friction; and partly from the more rapid wear and tear of the brasses and sockets, by which the accurate fitting of the parts is destroyed, and these are consequently subjected to unequal jerks and strains. The simple remedy for such disorders is to enlarge the main-shafts and bearings, the latter being also made unusually long, so as to diminish the effects of friction and wear and tear.

Linings of bearings.

The iron shafts of marine engines revolve in sockets or bearings lined with brass or gun-metal. These give rise to little friction, but, as their wear is rapid, they require frequent attention to keep the lining screwed up to the neck of the shaft, and they must be renewed when much worn. In the case of screw-ships, where the bearings of the screw-shaft are not readily accessible, this used to give much trouble, until it was found out (partly by accident) that bearings lined with *lignum vitæ* instead of brass are subject to exceedingly little wear or friction. A plan has been therefore adopted of fitting these bearings with rings of *lignum vitæ* alternating with rings of gun-metal, which answers very satisfactorily.

Deterioration of shafts.

Before leaving the subject of shafts, it may be remarked that these, whether paddle or screw, appear liable to deteriorate by continued use, and finally to give way, sometimes suddenly, but oftener gradually. It is contended by some that the iron of which they are formed has a tendency to lose its toughness, and assume a crystalline texture, from long exposure to the shocks and vibrations to which all such shafts are subject. Having had very many opportunities of observing broken shafts, the author does not hold with this theory, but thinks the following explanation to be more probable. It is allowed to be a difficult operation to make large shafts perfectly sound in the centre, where the bars of iron of which they are built up are not always thoroughly welded into one homogeneous mass. These imperfections, when they exist, are of course not visible on the outside, nor do they seriously affect the strength of the shaft at first; but as the continued jarring and twisting goes on from year to year, they become more and more developed, and the shaft becomes loose in the centre, acquiring a "reedy" structure which gradually extends to the surface. A fracture then takes place, if the crack be not observed and the shaft renewed.

Lubrication of the machinery.

The efficient lubrication of the bearings and other working parts of the engine with oil or melted tallow is a material point to be attended to, both as regards the smooth working of the machinery and its preservation from injury. From want of this simple precaution the bearings get strongly heated by the friction, and may either be damaged by the consequent expansion which takes place, or else

cracked by the cold water which is usually poured on them from a hose, to cool them down again. Self-lubricating apparatus is preferable for this purpose, wherever it can be applied, as it is both more economical of oil and more certain in its operation. Although compactness in an engine is desirable within certain limits, this should never be carried to such an excess that the engineer is unable to get conveniently about his engine while it is at work, in order to lubricate the parts, and tighten brasses and packings.

Engineer's log.

Every chief engineer of a steamship should be furnished with a printed form of Engineers' Log to be filled up by the engineer in charge during each watch of four hours. It should be arranged in a manner somewhat similar to the annexed form:—

Steamer .... ENGINE-ROOM REGISTER.

Note.—Indicator-diagrams to be taken occasionally.

Steam-vessels are propelled either by paddle-wheels or screws.

Paddle-wheel;

1. Paddle-Wheels.—There are two kinds of paddle-wheels in general use in this country, namely, the common wheel, and that with feathering floats. The common paddle-wheel, notwithstanding many attempts to supersede it, still maintains a high place as a simple and efficient propelling agent; the faults which have been attributed to it being, it is believed, more apparent than real. When a steam-vessel is moored in a harbour and prevented from moving, or when first commencing motion after having been at rest, the defects of the common paddle-wheel appear to be very great. The paddle-boards, on entering the water, press obliquely down into it, tending to raise or lift the vessel up out of the water with a force which produces no useful effect. Again, when the paddle-board is leaving the water, it seems to do little more than raise or drive the water upwards in the form of back-water. It is only, therefore, in the middle of its path that the propulsion of the paddle seems to be exerted in forwarding the boat, and that only for a short time. A large part of the force of the steam-engine seems thus to be expended in raising the vessel, and in elevating the back-water, and only a small portion in carrying the ship forward.

its defects are more apparent than real.

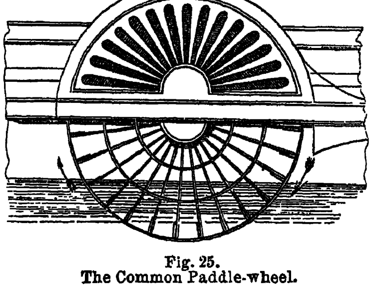

Fig. 25.
The Common Paddle-wheel.

This is the case of a vessel at rest, or not in rapid motion; but the phenomena of a paddle-wheel revolving when the vessel is in motion differ essentially from the phenomena of a wheel revolving on a vessel at rest. When it is just starting, or as yet moving very slowly, the evils here mentioned do in some degree take place; but by the motion of the vessel forwards (which is the result of the revolution of the paddles), the faults complained of are at once remedied, and the paddle-float of a common wheel in a quick vessel is virtually "feathered" as perfectly as the most practised rower could feather his oar. A little study of the geometrical conditions of a paddle moving forwards and in a circle at the same time renders this plain. The paths described by the boards are trachoidal curves, being of the family of the cycloid; and from the study of the motion actually performed by the paddle-board of the common wheel, it is seen, first, that the board is inserted into the water in an angular position resembling closely the entrance of an oar into the water; secondly, that it is then made to act horizontally on the water during a short interval; and thirdly, that it is withdrawn from the water edgeways, with an easy and graceful movement.

Its actual motion.

Feathering paddle-wheel.

When the paddle-wheel is either badly proportioned, immersed too deep in the water, or attached to a very slow boat, its action becomes much impaired or impeded. Hence much attention has been devoted to the construction of a paddle that should be more effective in these unfavourable circumstances than the common wheel. Some of the contrivances invented for this purpose have failed for want of perception of the precise motion it was necessary to give to the paddle-board; others from the complexity of the mechanism employed. In the year 1829 a patent was granted to Elijah Galloway for a paddle-wheel with movable boards, which patent was purchased by Mr William Morgan, who made some unimportant alterations in the

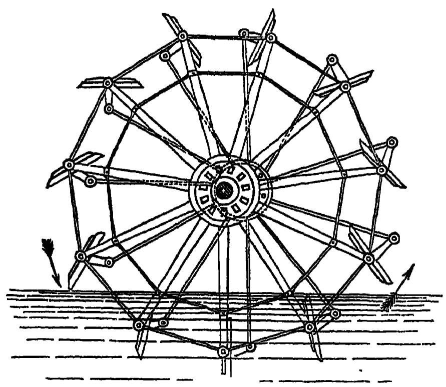

Fig. 26.
Feathering Paddle-wheel.

mechanism. This, called the feathering paddle-wheel, is represented by the above wood-engraving (fig. 26), by

Steam Navigation.

inspecting which it will be seen that a distinct feathering movement is imparted to the boards on entering and leaving the water. This movement, it will be observed, is derived from the excentric motion of the periphery of the second paddle-centre, to which are hinged the long rods that communicate the desired movement to the boards turning on pivots. Wheels made on this principle, though considerably heavier and more expensive than the common paddle-wheels, are frequently preferred for sea-going steamers subject to much variation of draught. They have been known to improve the average speed of a steamer by more than a knot an hour, and they are always accompanied with less vibration than the common paddles.

Slip of the paddle.

The "slip" of the paddle-wheel, by which is meant the excess of its velocity above that of the vessel, is usually reckoned at $\frac{1}{5}$th (or 20 per cent.) of the vessel's speed when the wheel is well proportioned, and the vessel tolerably fast. Feathering wheels have less slip.

Want of power in a steamer to start a load.

The captains of steamers are frequently both surprised and disappointed to find how powerless their vessel is to drag a stranded ship off the shore, even when the whole power of their engines is exerted for this purpose. A slight consideration of the subject will show that the requirements of such a case are very unfavourable to the proper development of the power of a steamer. We will suppose a vessel fitted with a pair of paddle-wheel engines of 500 horse-power collectively. The diameter of each cylinder will then be, say, 80 inches, and the stroke 6 feet. The length of the crank will therefore be 3 feet, driving a paddle-wheel of, we will suppose, 28 feet effective diameter, reckoned at one-third of the depth of the boards from their extreme edge. When the piston of each engine alternately arrives at the top or bottom of its stroke, that engine is then powerless, and the whole of the work devolves upon the other engine, which is then at half-stroke, with the crank nearly at right angles to the thrust, and therefore in the most advantageous position for transferring the power. By bringing the pistons of both engines to $\frac{3}{4}$ stroke, we obviously improve upon this, for now both engines are assisting to turn the shaft, though acting at a reduced leverage in the proportion of 3 feet to 2·15 feet nearly. By calculating the pressure upon the two pistons, we find the statical power exerted by the engines (the one *pushing* and the other *pulling*); but as the thrust thus found is transmitted by a lever of the second order, the short arm of which is the crank, and the long arm the radius of the paddle-wheel, it is necessarily reduced in the inverse ratio which these bear to each other, or as 14 : 2·15. The calculation would then be as follows:—

Explanation.

$$\overset{\text{Sq. in.}}{5026\cdot5}\ (\text{area of cyl.}) \times \overset{\text{lb.}}{22} \left\{ \begin{array}{l} \text{supposed effective press.} \\ \text{per sq. inch of piston..} \end{array} \right\} \times 2\ (\text{for both cylinders}) = 221\cdot166\ \text{lb.} = 98\cdot75\ \text{tons total pressure on pistons.}$$

Then as 14 : 2·15 : : 98·75 : 15·16 tons.

This being further reduced by 20 or 25 per cent. for the friction of the machinery, working the air-pumps, &c., leaves scarcely eleven tons of thrust available for starting a weight, or dragging a stranded vessel off the shore, by a steamer of 500 nominal horse-power.

A similar calculation made for screw-engines shows a like result.

Definition of a screw.

2. *Screw-Propeller.*—A screw as used for propelling vessels may be defined as a metal plate wound, edgeways, round a cylinder or spindle, as shown in the accompanying sketch (fig. 27 *a*), which represents one full turn of the common screw.

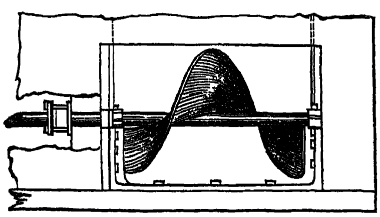

Fig. 27 *a*.

This would be a single-threaded screw, but it is evident that two, three, or more threads, if kept uniformly parallel to each other, may in the same way be wound round the spindle without interfering with each other. We should thus have a two-threaded or a three-threaded screw, the former being chiefly used for propelling in the navy, and the latter in the merchant service. The whole length of one complete turn of the screw, measured in a straight line along the spindle, is called the PITCH of the screw. In the preceding engraving, therefore, the pitch is measured by the length of the spindle (fig. 27 *a*), since the thread makes one complete turn upon it. It is also apparent, that if this screw were turned once round in a piece of soft wood (in the same manner as a carpenter's screw), it would advance through the wood the exact distance between the cut ends of the thread, which (we have seen) is the pitch. Hence, by the pitch of a screw, we understand always its linear progression for one revolution, and the speed of the screw is measured by multiplying the pitch into the number of revolutions. If the screw were working in a solid, the speed thus found would give its actual linear advance; but as it revolves in water, which is a yielding medium, the water gives way to some extent, and the screw does not advance the full amount of its pitch, this deficiency in its progress being called the SLIP of the screw.

Pitch of the screw.

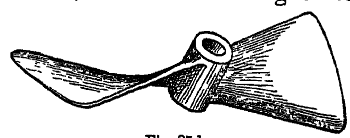

Fig. 27 *b*.

Slip of the screw.

Form of the screw-propeller.

Now, if the screw represented by fig. 27 *a* be cut into several portions by planes passing across it at right angles to the axis, each of these sections would have the appearance of the vane of a windmill. If the screw were two-threaded, the vanes or "blades," as they are called, would be exactly opposite each other, as shown in fig. 27 *b*, or as in the annexed sketch, fig 28 *b*, which represents a two-bladed screw as used in propelling. The

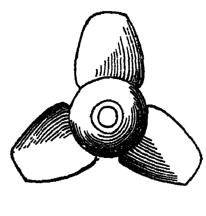

Fig. 28 *a*.

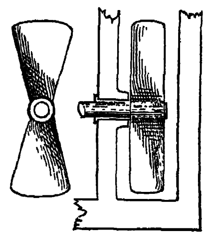

Fig. 28 *b*.

screw here represented is about one-sixth part only of the whole length, or *pitch*, of the full turn of the screw shown by fig. 27 *a*, this small fraction of the pitch being found sufficient to absorb the whole power of the engines, so that any greater length of screw would only be hurtful by causing unnecessary friction, as well as by increasing the size of the aperture in which it works. By the LENGTH of the screw, therefore, is meant the fraction of the pitch employed, measured along the axis of the screw. By the DIAMETER of the screw is meant the diameter of the circle described by the extremities of the blades during their revolution.

Action of the screw in propelling.

The effect produced in propelling the ship will be best understood by supposing the screw represented by fig. 27 *a*, to be revolving rapidly in a trough full of water. It would then send the water away from it with great force; but as action and reaction are equal, it would be itself, at the same time, urged in the opposite direction with exactly the same degree of force. If we suppose it, then, to be fixed in a ship, the ship will be pushed *forward* with the same force that is exerted by the screw in pushing *back* against the water. If the screw is made to revolve in the opposite direction, the converse of this takes place, and the ship is then pushed backwards by the reaction of the screw.

Different forms of screws.

The screw-propeller has been subjected by would-be inventors to an endless variety of form; but these have generally shown themselves more or less inefficient according as they may have departed from the principle of the true screw. The first patent of any interest connected with this subject is that of Mr B. Woodcroft, taken out in 1832, for an "increasing pitch" screw-propeller. His specification describes "A spiral worm-blade or screw coiled round a shaft or cylinder of any convenient length and diameter, in such form that the angle of inclination which the worm makes with the axis of the cylinder continually increases, and the pitch or distance between the coils or revolutions of the spiral continually increases throughout the whole length of the shaft or cylinder upon which the spiral is formed." Mr Woodcroft's idea, that the after-part of the screw would thus be made to act with increased efficiency upon the water which had been previously acted upon by the foremost part, is undoubtedly correct in principle, and had a full turn of the thread been found necessary for propelling (as was at first thought), this plan would probably have been found practically advantageous; but when the length of the screw was cut down by Lowe to one-sixth part of the pitch, very little scope was afforded for Mr Woodcroft's refinement, and it has proved to be really of little or no value.

Woodcroft's propeller.

Smith's screw.

Mr F. P. Smith's patent was secured in 1836 for "a sort of screw or worm made to revolve rapidly under water in a recess or open space formed in that part of the after-part of the vessel commonly called the dead rising or deadwood of the run." Mr Smith's original drawings showed a screw with two whole turns of the thread, which was afterwards altered in 1839 to one whole turn.

Lowe's screw-blades.

Mr James Lowe obtained a patent in 1838 for a screw-propeller formed of "curved blades, each a portion of a curve, which, if continued, would form a screw." The drawings attached to his specification show a shaft with one blade, a shaft with two blades, and a shaft with four blades. The screw-propeller now generally used (see fig. 27 *b*, and fig. 28 *b*), may be considered as a combination of Smith's screw and Lowe's blades, its present form having been in a great measure determined by the series of experiments with the Rattler in 1844. (See page 660.)

Griffith's propeller.

Griffith's screw-propeller, first patented in 1849, is probably the best modification of the common screw which has yet been produced. Its principal feature consists in the employment of a large sphere occupying the central portion of the screw. The second peculiarity of Griffith's screw consists in the peculiar form of the blades, which, unlike those of the common screw, are larger towards the centre, and tapering towards the extremities. The extremities of the blades are curved from the front or propelling side towards the vessel, which causes the screw to take a greater hold of the water, and drive it towards the inner or central portion, which, in Griffith's screw, is the most effective part.

Description.

This propeller is represented in its simplest form by the wood-engraving (fig. 28 *a*), and as recently improved by the annexed engraving (fig. 29.) It will be seen that this propeller consists of three main parts, viz., the boss which is keyed on to the screw-shaft in the usual manner; and the two blades, which have turned shanks fitting into bored recesses in the boss. Each blade is retained in its position by a key, which is adjusted into its place after the blade has been inserted and turned in its socket about ninety degrees, or until the arrow marked on the flange points to the pitch which it is desired the screw shall have, of which several have been previously measured, and marked upon the screw.

When Griffith's screw was first introduced, it was expected that great advantages would result from an arrangement in its construction (which it shared with Maudslay's feathering screw), by which the pitch or angle of the blades could with facility either be increased, diminished, or "feathered" during the voyage, to suit the varying exigencies of a steam-vessel at sea. Experience, however, has proved that the risk of derangement incident to the machinery requisite for this purpose is too great to admit of practical success, and also that the advantages to be obtained by such an arrangement are far less than was supposed. The use of screws to feather at sea has, therefore, been very generally abandoned.

Feathering-screws not successful.

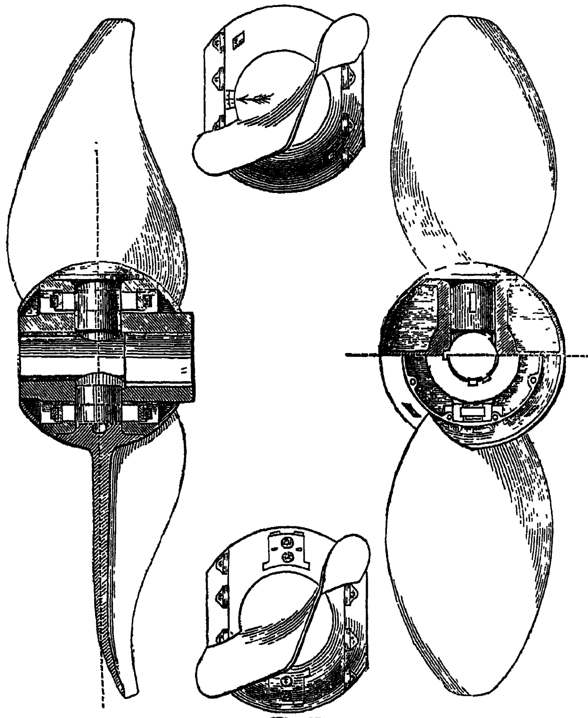

Fig. 29.
Griffith's Improved Patent Screw-propeller.

Advantages of Griffith's screw.

It will be observed, by looking at the engraving, that the blades of Griffith's screw are quite distinct from the boss, into which they are inserted and keyed in such a manner that their angle or pitch may be altered and fixed before the voyage, though not at sea. The use of this arrangement is, that the engineer may find out *experimentally* the particular pitch of his screw which is most suitable to the engines and ship, experience having shown how very difficult a thing it is to hit upon the right pitch by previous calculation alone. Another advantage resulting from this arrangement is, that when a blade is accidentally broken, it can be replaced without having to remove the centre part, which in Griffith's form of screw is tolerably safe from injury. It is unnecessary, therefore, to carry a spare screw, but only a couple of blades. When the ship is placed under canvass alone, the screw is brought into a position with the blades vertical, in a line with the stern-post, when little resistance is offered to the water. Although Griffith's screw cannot be said to have shown any very decided superiority in speed over a common screw of the best form, it is certainly not inferior in this respect, while it is attended with less vibration, is less affected by a rough sea, and is more manageable under canvass from offering less resistance to the water, and less obstruction to the free action of the rudder.

Common screw.

When the common screw is employed in merchant-steamers, a three-bladed screw is usually preferred, since this causes less vibration, and gives a steadier motion in a rough sea than the two-bladed screw.

Resistance to sailing.

The resistance which such a screw occasions to the vessel, when sailing under canvass alone, is very serious, in addition to the difficulty experienced in steering; and it is found in practice, that but little advantage is gained by disconnecting the screw from the engines, and letting it revolve in its bear-

Steam Navigation.

ings, in preference to *dragging* it through the water. Hence, in the case of steamships which depend much upon their canvass, one of three remedies must be adopted: namely, the screw must either be hoisted bodily out of the water; it must be feathered; or, thirdly, such a form must be employed (as Griffith's two-bladed screw, for instance), which will not interfere much with the sailing and steering of the ship, when the blades are placed vertical, and the screw left down in its place.

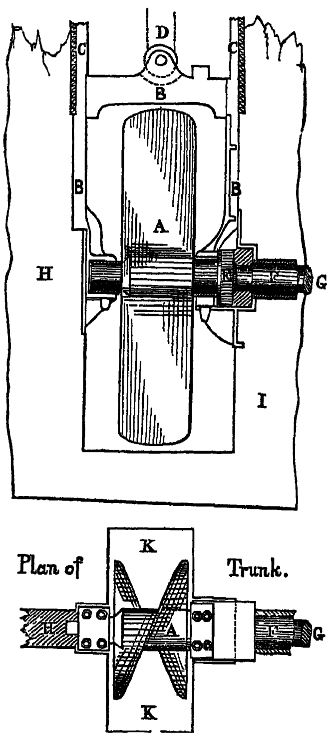

Fig. 30.

Hoisting screw.

The *hoisting* screw has been adopted generally for war-steamers, which are supposed to make great use of their sails, and which have a larger number of men available for quickly hoisting and lowering it. The annexed engraving shows the manner in which this is effected in the royal navy.

Description.

A is the screw (of gun-metal); B is the hoisting-frame (also of gun-metal) which lifts the screw, with its bearings, bodily out of the stern-frame of the ship; C is a gun-metal rack, to hold the hoisting-frame at any portion of its ascent; D is the chain and pulley used in hoisting; E is a clutch upon the screw-shaft, to enable the screw to be disconnected, and rise when brought into a vertical position; F is the gun-metal lining of the screw-shaft, which passes water-tight through the inner stern-post I; G is the iron screw-shaft; H is the outer stern-post; K is the "trunk" through which the screw is raised to the main-deck, when the blades are brought vertical.

Having now seen what are the principal forms of screw-propellers in general use in this country, let us briefly examine some of the qualities inherent in the screw itself.

Functions of the pitch of a screw.

1. *Pitch.* The question between the relative valves of fine and coarsely pitched screws still remains, in a great measure, undecided. In fact, our experience hitherto has only tended to show, that nothing but actual trial of different pitches can satisfactorily establish the best pitch of screw for any particular vessel. The points to be considered in reference to this inquiry are so numerous and complicated in their bearings upon each other, that they utterly defy previous calculation of their effects; some vessels giving the best results with coarsely-pitched screws running at a low speed, while other vessels, not very dissimilar, attain their highest velocity with a finely-pitched screw running fast. It is generally acknowledged, however, that a coarsely-pitched screw is the best for a vessel with fine after-lines, and a finely-pitched screw for vessels with full sterns. The form of the after-lines has undoubtedly a very great influence on the most advantageous pitch of screw for that particular ship, depending on the amount of "back-water" in which the screw works, and the velocity with which it follows the ship. It is by no means an uncommon thing for one vessel to gain a knot an hour by an alteration of the pitch; while in the case of another vessel, perhaps, no improvement is effected by a similar alteration.

Steam Navigation.

Diameter.

2. *Diameter.* This is made simply as great as the draught of water will admit. In sea-going steamers the top of the screw should be submerged about 18 inches or 2 feet at the average trim, to allow for the undulations of the sea.

Area and length.

3. *Area and Length.* By the area of the screw is generally understood the plane projection of the resisting surface of the blades. In the experiments made with the Dwarf, it was found that the speed of the vessel remained almost a constant quantity, although the length of her screw was successively diminished from 2 feet 6 inches to 1 foot, the *area* corresponding to each of these lengths being respectively 22·2 and 8·96 square feet. The slight improvement which did take place in the speed of the boat attended the diminished area. It seems at first sight extraordinary that so great a variation in the resisting surface should cause so little disturbance either in the speed of the engines or of the vessel, thus showing plainly how small a segment of the whole pitch is required to absorb all the power which the reaction of the water is capable of imparting, any extra length of screw beyond this point only retarding by friction. The Rattler's experiments were in the same way commenced with a screw 5 feet 9 inches long, which was gradually shortened until it reached its point of maximum effect at 15 inches only. It is now a common practice to make the length of the screw $\frac{1}{6}$th of the pitch.

Slip.

4. *Slip.* The apparent slip of the screw depends upon a great variety of circumstances. It is modified by the diameter and by the speed, being generally found to diminish as these increase. Thus, the diameter of the Rattler's screw, during her experiments, was 10 feet, and her average slip 15 per cent.; while the Dwarf and Fairy, with screws of 5 or 6 feet diameter, show an average slip of about 35 per cent. The form of the after-lines of the vessel has a very notable effect on the apparent slip of the screw, which must not be regarded as a measure of the efficiency with which the propeller is acting. On the contrary, many vessels whose lines are most unfavourable for speed show an exceedingly small slip of the propeller; and in some instances of this kind there is not only *no slip* apparent, but the screw has actually what is called *negative slip*, which implies that the vessel is going faster than the rate at which the screw which propels it would advance if working in a solid.

Negative slip.

This curious and paradoxical result is due to the current which all ships, more or less, but especially those with full sterns, carry in their wake; and since the screw acts in this current, the *apparent* slip will be positive or negative in proportion as the *real* slip, or the velocity of the current, may preponderate; but in every case the screw must have some slip relatively to the water in which it acts. Suppose, for instance, that a badly formed ship has a current of water following in its wake, and closing in upon the screw at a velocity of 4 miles an hour, while the *real* slip of the screw is but 3 miles an hour, the result will be that the screw will show an apparent negative slip of 1 mile an hour. It must not be supposed that in such a case the power of the engines is economically applied, for, in fact, much power is uselessly consumed in dragging this current of water after the ship. The same apparent diminution of slip is always found when the vessel is advancing with a tide or current. Anomalies of this kind most frequently occur in auxiliary screw-steamers, where the vessel, after attaining a high velocity by sails alone, still continues to receive a propelling thrust from the screw, even after the speed of the latter *appears* to be less than that of the vessel.

Trials of screws in the Rattler.

In order to give the reader some perception of what really are the conditions of the screw most conducive to speed in the vessel, I have selected the trials of twelve different screws made in the same vessel, the Rattler, arranging them in the order of their relative efficiency, beginning with the lowest.

1. With a four-threaded Woodcroft's increasing pitch screw, 9 feet diameter, 1 foot 7 inches long, and the pitch varying from 11 feet to 11 feet 6 inches (mean 11·275), the speed of the vessel was 8·159 knots; the engines making 24·15 revolutions per minute, and the screw 96—slip, 23·5 per cent.

2. With a three-threaded common screw, 9 feet diameter, 3 feet long and 11 feet pitch, the speed of the vessel was 8·23 knots; the engines making 24·2 revolutions, and the screw 94·3—slip 19·66 per cent.

3. With Sunderland's propeller, 8 feet in diameter, the speed of the ship was 8·38 knots; the engines making 17·49 revolutions, and the screw-shaft 69 97.

4. With the same screw as No. 2, reduced in length to 1 foot $7\frac{1}{2}$ inches, the speed of the vessel was 8·57 knots; the engines making 24·8 revolutions, and the screw 98·4—slip, 19·7 per cent.

5. With the same screw as No. 1, but with two of the blades cut off, the vessel's speed advanced to 8·63 knots; the engines making 27·07 revolutions, and the screw 107·5—slip, 25·97 per cent.

6. With a two-threaded common screw, 10 feet diameter, 3 feet long, and 11 feet pitch, the speed of the vessel was 8·958 knots; the engines making 24 revolutions, and the screw 95—slip, 13·8 per cent.

7. With a four-threaded common screw, 9 feet diameter, 1 foot 7 inches long, and 11 feet pitch, the speed of the vessel was 9·18 knots; the engines making 26·3 revolutions, and the screw 104·4—slip, 27·7 per cent.

8. With a two-threaded common screw, 9 feet diameter, 3 feet long, and 11 feet pitch, the speed of the vessel was 9·25 knots; the engines making 26·8 revolutions, and the screw 106—slip, 19·5 per cent.

9. With the same screw as No. 6, shortened to 2 feet, the vessel's speed increased to 9·448 knots; the engines making 25·5 revolutions, and the screw 107—slip, 13·5 per cent.

10. With the same screw as No. 6 further reduced in length to 1 foot 6 inches, the speed of the vessel was 9·811 knots; the engines making 27·92 revolutions, and the screw 110·7—slip, 18·3 per cent.

11. With the same screw as No. 2 further reduced in length to 1 foot 2 inches, the speed of the vessel was 9·88 knots; the engines making 27·39 revolutions, and the screw 108·4—slip, 15·97 per cent.

12. With the same screw as No. 6 further reduced in length to 1 foot 3 inches, the speed of the vessel increased to 10·74 knots; the engines making 26·19 revolutions, and the screw 103·97—slip, 10·42 per cent.

Trials of screws in the Doris.

A very interesting series of experiments has been recently made with the screw-frigate Doris, to determine the most suitable form of screw-propeller for our steam-vessels of war. The following is a resumé of the principal results arrived at, the first five trials having been made with the common or admiralty screw, and the last three with Griffith's propeller. The engines of the Doris (by Messrs J. Penn and Son) are of 800 nominal horse-power. The draught of water while under trial was kept constant at about 19 ft. 6 in. forward and 21 ft. 9 in. aft—exact mean, 20 ft. 6 in.; giving an immersed midship-section of 7421 square feet. Pressure of steam in boilers, 20 lbs.; indicated horse-power, about 3000. The first trial with the admiralty screw was with a diameter of 18 feet, the vessel's speed being 11·823 knots. On the second trial, with the diameter increased to 20 feet, the speed realized was 11·826 knots, with a great increase of vibration; steering imperfect. On the third trial, the "leading" corner of each blade was cut off, and in this form the common screw attained its greatest speed, giving a result of 12·032 knots, with 50 revolutions of engines per minute, and 2384 indicated horse-power; vibration reduced, and steering good. On the fourth trial, both the corners of each blade were cut off, so as to assimilate the blades to Griffith's form, when, with a greater number of revolutions, the speed fell off to 12·012 knots. In the fifth trial, with the "following" corner of each blade cut off, but the screw restored to its perfect form in every other respect, a result of 11·815 knots was obtained. The common screw was then removed, and the next trial was made with Griffith's propeller, 20 feet diameter and 32 feet pitch; this gave a result of 11·981 knots, there being scarcely any vibration, and the ship steering well. The second trial, with the same Griffith's propeller, having the blades set at 26 ft. 6 in. pitch, gave a speed of 12·269 knots, being the highest of the series; steering perfect, and no vibration perceptible; indicated horse-power, 3091. The third trial of Griffith's 20-feet screw, with the blades set at a medium pitch of 30 feet, gave 12·158 knots.

Results of Doris's trials.

Several important points connected with the screw-propeller seem to have been proved by these trials—1*st*, That the leading edge of the screw is the part that mostly affects the steering of the ship, and also causes the greater part of the vibration; 2*d*, That increased diameter of the screw is better than increased pitch for reducing the speed of the engines, but it considerably increases the vibration with the common screw; whereas with Griffith's it did not produce that effect, in consequence of its chief propelling surface being towards the centre. The common screw, when its blades are cut to the form of Griffith's, is not so effective as when the centre sphere is applied to them. The power required to obtain the same speed was very much the same for both screws.

The annexed sketch is interesting from the peculiar markings shown upon the surface of the screw, which is that of the steamer Crœsus. This vessel had on one occasion got under way while the paint on her screw was still wet, and on being docked soon afterwards the paint was found streaked by the water, as here shown.

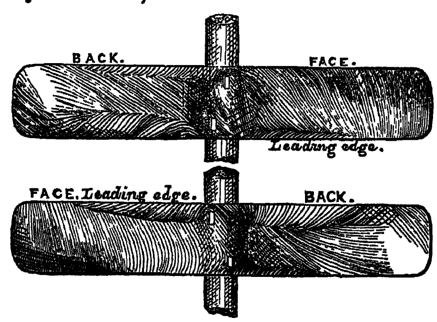

Fig. 31.

Official explanation of the Table of "Results of Trials made in her Majesty's Screw-ships."

"The numbers in the last two figure-columns of the table show approximately the relative excellence, in respect of speed, of the forms of the various vessels, conjointly with the relative efficiency of the propeller, as adapted to each of them.

"The formulæ by which the calculations are made are founded on the assumption that the resistance of a vessel varies as the square of her velocity, and, therefore, that the power required to produce that velocity varies as the cube, and that the usual effect of the engine—that is, the effect which remains after deducting the power absorbed in overcoming friction, working air-pumps, &c.—bears a constant ratio to the power developed in the cylinder, known by the term 'Indicated horse-power.' The resistance is, in the first of these columns, assumed to vary, *cæteris paribus*, as the area of the midship-section, and in the last column as the square of the cube-root of the displacement.

Steam Navigation.

"None of these assumptions, however, more especially the last two, are absolutely correct, but probably they are not so far from the truth as to render useless and uninteresting a comparison, of which they are the basis, made between the performances of any two screw-vessels; while between two vessels which do not materially differ in engines and displacement, or in the area of their midship-sections, such a comparison is not only highly interesting, but it may prove of great value in pointing out the forms of vessels and proportion of propellers which ought to be adopted. In some striking cases it is scarcely necessary to make any other comparison than that of speed. For example, as may be seen in the table printed in 1850, the Teazer, after her form had been improved, went above a knot an hour faster with 40-horse engines than she had previously gone with engines of 100 horse-power. Again, these engines of 100 horse, when transferred to the Rifleman—a vessel approaching to double the tonnage—drove her, after her form had been altered, as fast as she was previously driven by engines of double the power, and nearly two knots faster than the same engines drove the smaller vessel before the alteration of her after-body.—Admiralty, August 1856."

Ruthven's water-jet propeller.

The only other mode of steam-propulsion which has been attended with any considerable success is that known as Ruthven's water-jet system, in which the propelling power is derived from the reaction, or recoil, of two jets of water projected, at a high velocity, from nozzles at the ship's side. The first experimental vessel on this principle was built by Messrs. Ruthven, of Edinburgh, in 1843, and was tried on the Firth of Forth, when it attained a speed of from 6½ to 7 miles an hour. This was an iron-boat, 40 feet long.

The Enterprise.

More recently, in 1853, the Enterprise was constructed on Ruthven's principle, for deep-sea fishing, a preference being given to the jet propeller in this case, from its being less likely to interfere with the fishing-nets than the screw or the paddles. The dimensions of the Enterprise are as follow:—length of deck, 95 feet; length on the water-line, 87 feet; breadth of beam, 16 feet; depth, 8 feet; draught at load-line, 4 feet; burthen, 100 tons. The propelling power is derived from two pairs of horizontal oscillating cylinders, each 12 inches in diameter, and 24 inches stroke (condensing), working a vertical shaft. There is one cylindrical boiler, 6 feet in diameter, and 5 feet long, with two fire-tubes running through it, each 22 inches diameter, and 105 return flue-tubes, each 5 feet long, and 2 inches internal diameter. The propeller consists of a fan-wheel, or centrifugal pump, 7 feet in diameter, with curved blades, keyed on the lower end of the vertical crank-shaft; this revolves horizontally in a water-tight casing into which the water from the sea flows (along a covered passage), through crescent-shaped openings in the bottom of the hull. The water is expelled laterally, from the fan-wheel, in two continuous streams, through curved pipes with nozzles, 10 inches in diameter, protruding from the sides of the hull. The nozzles turn in collars fixed to the ship's side, so that they can be pointed a-stern or a-head, as required, for forward or backward motion, or downwards, when the vessel is to remain at rest. These changes can be made rapidly and easily from the deck, since the nozzles alone require to be operated upon, while the engine continues to work at full speed. Again, by setting the nozzles in opposite directions, one pointing a-head and the other a-stern, the vessel can be turned on the spot, swinging on her beam without the aid of the rudder; and she could thus be steered by the nozzles in case of the rudder being lost or disabled, the manœuvring of the vessel being entirely in the hands of the officers on deck. The vessel progressed very smoothly, without tremulous motion.

In a trial trip with the Enterprise on the 16th of January 1854, from Granton to Kirkcaldy, in the Firth of Forth, and back, a distance of 10½ miles each way, the speeds obtained were 9·69 statute miles per hour going, and 9 miles per hour returning, giving an average of 9·35 miles per hour—the engine making 50 revolutions per minute. On another occasion, she is stated to have made a considerably higher speed, the engine making 65 revolutions per minute. The draught of the vessel, during the trial, was 3 feet 2 inches; and the immersed midship-section, 40·5 square feet. The indicated horse-power of the engine was not known, no indicator-diagrams having been taken. In such an arrangement, much power is necessarily lost in communicating to the water which enters the propeller a velocity equal to that of the ship, besides a considerable loss from friction, eddies, &c.; but upon the whole, the power of the engine seems to be applied to considerable advantage.

Advantages of the water-jet propeller.

Even allowing that the speed attained does not equal that from paddles or screw, the jet-propeller possesses other undoubted advantages which recommend it for special cases, as for instance, in the Government floating-batteries and steam-rams, where the screw and the rudder are particularly liable to be fouled by wreck and cordage. It would also be preferable to the screw in cases of river-steamers of very light draught, where the paddle might not be applicable. Several of the large floating fire-engines on the Thames have been fitted with this propeller, the water being ejected by the powerful steam-pumps with which these vessels are fitted. The speed, however, has in these cases not proved satisfactory. A steamer, called the Albert, propelled on this principle, was placed on the Rhine, as a passenger-boat, a few years since, but did not attain a speed proportional to her power or consumption of fuel.

Paddle and screw compared.

It is frequently asked, Whether is the paddle-wheel or the screw the most efficient propeller? This question may now be safely answered, by asserting, that when both are in their best trim, and both are equally well proportioned to the engines and vessel, they are, as nearly as possible, equally efficient. It follows, therefore, that the preference for one or the other, in any particular case, depends entirely upon the class of vessel and the nature of her service. The objections to the paddle, as compared with the screw, may be thus briefly stated, namely, the unequal immersion of the wheels, according as the vessel swims light or deep; the obstruction to the *sailing* of the ship caused by the resistance of the paddle-boxes to the wind; and the dragging of the paddle-boards through the water when the engine power is not used, and the wheels are not disconnected; and, in the case of steam-vessels of war, the exposure of the wheels and machinery to an enemy's shot. The *advantages* of the paddles, on the other hand, are, that they are not so much affected by the pitching motion of the ship, when steaming head to wind, as the screw is; that they do not require such a speed of engine (or else gearing); and that, from the disposition of the weights in respect to the centre of gravity of displacement, the movements of the vessel are easier than those of a screw-steamer, a matter of considerable interest to the *passengers* at least. With regard to the screw, its efficiency is but little impaired by variations of trim in the ship, but it is most injuriously affected by the pitching motion. Its advantages in facilitating the sailing of the ship are self-evident, and have been already alluded to. In fine, the superiority of the screw for sea-going steamers appears to amount to this, that it retains its efficacy as a propelling agent under a greater variety of conditions of sea, weather, and trim, than the paddles, and that it admits of more use being made of the sails and a greater display of seamanship in the navigation of the vessel. Under proper management, therefore, it appears to be more economical of steam-power than the paddle-wheels; and this, it may be remarked, is the actual experience of the Peninsular and Oriental Company, whose steam fleet is composed of vessels on both principles.

Having thus briefly considered, firstly, the engine-power of the steamship, and secondly, the immediate propelling agents employed to produce locomotion, it will now be necessary to view her as a completed whole, and to ex-

amine some of the general properties and qualifications inherent in, or demanded by, this complicated structure, as well as the relations they severally bear to each other. The construction of the steamer's hull will be found amply detailed in the article Ship-Building, so this need not be here adverted to.

Resistances offered to a steamer.

When a steamer is once set in motion, the motion is, of course, continued by her momentum, and she would then evidently continue to advance at a uniform speed, without any more force being applied to her, were it not for the opposition of external causes. These external forces which she encounters, and which are constantly at work to destroy her momentum, and bring her to a state of rest, are the resistance of the water to her hull, and the resistance of the air to her upper works and rigging; the *impetus* of the waves and the winds being exerted sometimes in her favour, and at other times against her. The power of the steam-machinery is, therefore, applied to counteract these retarding forces, and to maintain a certain amount of progressive motion in the ship, depending upon the resistance on the one hand, and the power of the engines on the other.

The resistance offered by the water to the passage of the hull must be divided into two parts; firstly, that due to the dividing and displacing of the water, to make room for the hull of the ship to pass through (which is analogous to scooping out a long trough or canal, of the full breadth of the ship); and, secondly, the resistance arising from the friction of the water upon the sides and bottom of the vessel. Of these resistances, the first is by much the more serious, although the second must not be overlooked. The resistance offered to the passage of the hull depends mainly upon the area of the immersed midship-section of the ship, (or its greatest cross-section), but also very materially upon the form of the vessel's lines under the water. There is considerable discrepancy of opinion as to the relative value of these two functions of the ship; one naval constructor relying for speed upon a small immersed midship-section, while another holds that fine lines for dividing and closing the water are still more essential. The lines of a ship undoubtedly exert a great influence upon her speed, as has been shown experimentally in numerous instances. In the case of the Government dispatch-boat, Flying Fish, (already referred to at page 660), this vessel, of 1050 tons displacement, attained a speed of only 11·73 knots, with 1166 indicated horse-power. That performance did not equal the expectations of the Admiralty authorities; and without making any variation in the other parts of the vessel, they added, not a *new* bow, but an elongated bow, 18 feet in length, in advance of the original one, to divide the water more freely. The result was, that with the same draught of water, the velocity of the vessel increased from 11·73 knots to 12·55 knots an hour.

Direct resistance.

Influence of form.

Mr J. Scott Russell, in the course of a discussion on this subject at the Institution of Civil Engineers,[1] has given some very interesting results of experiments, all tending to show that the shape of the vessel has a very decided influence upon her speed, irrespective of her engine-power. He relates that he had, on one occasion, the control of four timber ships of the same dimensions, the same displacement, and the same horse-power; but each had different lines, being constructed by different ship-builders. The engines were all alike, being made by the same firm. The result was that, upon a run of 16 miles, their several speeds were $12\frac{1}{2}$, 12, under 11, and between 10 and 11 miles an hour. In another instance, a steamer, constructed to go both ways, but built with one end finer than the other as an experiment, went fully a knot faster one way than the other, although the midship-section and the horse-power were necessarily identical at all times. A third case was the following:—Two vessels were built of the respective lengths of 190 feet and 186 feet, their breadths being equal. The engines were the same in each, the cylinders being 48 inches diameter and 4 feet 6 inches in stroke, making 39 revolutions per minute. The speed attained by the first vessel, however, was 15·03 knots, while that of the second was but 11·32 knots. The difference in the two vessels consisted mainly in the shape, the other and minor elements being much in favour of the slower vessel. For instance, the faster vessel had 124 feet of midship-section, whilst the slower vessel had but 71 feet of midship-section to drag through the water. The faster vessel drew 6 feet 8 inches of water, whilst the slower vessel drew only 2 feet 10 inches. The difference in length was only 4 feet, yet a radical difference in shape thus reduced the velocity, with equal power, from 15 knots to 11 knots per hour.

Colonel Beaufoy's experiments determined the resistance of the water to a ship with a square head only, and it has since been found that a semicircular or round head offers two-thirds of the resistance derived from his formula $\left(R = aw\frac{v^2}{2g}\right)$, and an elliptical head considerably less.[2] By making the bow still finer, the resistance had been gradually reduced to one-sixth, and one-eighth, of that given by the formula; and Mr Scott Russell believes that the engine-power required to drive a large vessel through the water has now, in some cases, been reduced as low as one-twelfth. We learn from the same authority (the highest, indeed, which it is possible to adduce on this subject), that with a vessel of proper form, measuring about 1500 tons, the resistance of a ship can be reduced to 50 lb. per square foot of immersed midship-section, while steaming at the rate of 10 knots an hour. This is the direct resistance of the water upon the hull, and Mr Scott Russell asserts that he has thus been enabled to calculate confidently, to within a quarter of a knot, the amount of steam-power necessary to propel a given ship at a given speed, basing the calculation upon his own peculiar form of "wave-line," there being necessarily a shape for every speed. For instance, when a speed of 10 knots an hour was desired, he provided engine-power for 50 lb. per square foot of immersed midship-section (exclusive of the resistance of the machinery, which brought it up to 65 lb. per square foot), for a vessel of about 1500 tons, built on the "wave-line" construction. These figures, 50 lb. and 65 lb., are *gross* resistances, and include friction of skin.

Frictional resistance.

With regard to the absorption of power by the friction of the skin, it is seen by every day's experience how much a vessel will fall off in speed by the fouling of her bottom. This often amounts to a loss of one-fifth of her original speed, the engine-power exerted remaining the same, so that, under these circumstances, double the power would be required to attain the same speed as before. The total immersed surface of the Rattler's hull has been calculated at 7000 square feet, and according to Beaufoy's experiments on the friction of immersed surfaces, the resistance thus arising would be eight-tenths of a pound per square foot for a speed of 10 knots an hour, and nearly 1 lb. per square foot at 11 knots. At the speed and friction first named, the power absorbed would be equivalent to nearly 170 I.H.P., the total I.H.P. of the engines amounting to 428 H.P. only. In the case of the Himalaya, an immersed surface of about 18,000 square feet is exposed, the friction from which, at a velocity of 13 knots an hour,

[1] See *Transactions of Institute of Civil Engineers*, Session 1856–57.

[2] In the formula in the above sentence a represents the midship-section in square feet, v the velocity of the vessel in linear feet per second, g the accelerating force of gravity $= 32\frac{1}{6}$ and w the weight of a cubic foot of sea water at $64\frac{1}{3}$ lb. avoirdupois.

would absorb about 650 I.H.P., supposing the bottom to be perfectly clean.

Effect of increased length.

The consideration of frictional resistance, of course, places a limit to increase of length in a steamer, although many instances have occurred in which the vessel has gone as fast, or very nearly as fast, with the same engines, and on the same draught of water, after some 30 or 40 feet have been added in midships. The Candia is a remarkable instance of this, as will be seen by the following comparison of her speed when originally built, and after she was lengthened in midships by $33\frac{1}{2}$ feet, her load displacement being thereby increased about 470 tons:—

Date of trial.	Draught of water.	Length.	Displacement.	Weight on board.	Revls. of engines.	Pressure of steam.	Indicated H.P.	Pitch of screw.	Number of blades.	Speed of vessel.
	Ft.	Ft.	Tons	Tons	No.	lb.	H.P.	Ft.		Knots.
May 31, 1854...	18·6	281	2·520	650	$36\frac{1}{2}$	22	1672	20	2	12·651
Aug. 12, 1857..	19·0	314·6	3 090	1000	33	20	1462	21	3	12·443

Although in this instance, from some unexplained cause (owing possibly to improved trim, or circumstances of wind and sea), it would appear from the trial trips that a considerable increase of length has been obtained without any corresponding absorption of power, there must necessarily be a limit where further extension of length is more than neutralized by increased frictional resistance.

Law of resistance.

It is universally admitted that the gross resistances (direct and frictional) to which a vessel is subject increase as the square of the velocity, and therefore, as a necessary consequence, the power expended in producing this velocity varies as the cube of the velocity. For instance, if the resistance to one square foot of midship-section propelled through the water at 5 miles an hour be 5 lb., then the resistance at 10 miles an hour would be four times 5, or 20 lb. But the latter resistance has acted over double the space, so that the result must be again doubled for the measure of the power expended; and hence the power developed in one hour must necessarily and unavoidably be as the cube of the velocity. This rule cannot be expected to hold strictly good in all steamers alike, looking to the great diversity of form and displacement which exists, but in the great majority of cases it is fully borne out in practice. Thus, in H.M. screw-steamer Desperate, the following relation between power and speed was found to obtain:—

Relation of power to velocity.

	Indicated Horse-Power.	Knots.	Coal per I.H.P. p. hour.
			lbs.
With 4 boilers and 4 cylinders	805·89	9·15	4·61
With 3 boilers and 4 cylinders, working expansively	579·32	8·25	5·13
With 2 boilers and 4 cylinders, do. ...	363·87	7·35	5·58
With 1 boiler and 2 cylinders, do. ...	169·32	5·98	5·89

The Retribution, paddle-wheel steamer, had a speed of 10·4 knots with 1092 I.H.P., and a speed of ·6·22 knots with 226 I.H.P. The Onyx, with 2 boilers and 533 I.H.P., realized a speed of 13·16 knots, whilst with one boiler and 158 I.H.P. the speed was 8·6 knots. The Minx, with 234 I.H.P., made 9·14 knots, and with 31·6 I.H.P. 4·51 knots. These, and many other instances, are all in accordance with the rule, that the power and consumption of fuel vary as the cube of the velocity.

Practical examples.

The practical value of this rule will be made apparent by the following examples:—

1. If it be wished to find the speed corresponding to a diminished consumption of fuel for any particular steam-vessel, the calculation will be effected thus:—The vessel, we will suppose, has engines which propel her at the rate of 12 knots, with a consumption of 35 tons of coal per diem, and we wish to find the speed corresponding to a consumption of 25 tons per diem; then—

$$35 : 25 :: 12^3 : V^3 \text{ (cube of required velocity).}$$

When reduced, $7 : 5 :: 1728 : V^3$

As an equation, $5 \times 1728 = 7\,V^3$;

or, $\dfrac{8640}{7} = V^3$.

And $\sqrt[3]{1234} = V^3$ 10·726 knots $= V$, the required velocity.

It is thus seen, that by reducing the consumption of fuel by 10 tons per diem, we lose in this instance about $1\frac{1}{4}$ knot per hour.

2. If it be wished to increase the speed of the vessel, on the other hand, from 9 to 11 knots, and we desire to know the increased consumption attending the increase of speed, this will be in the proportion of 9^3 to 11^3, or as the numbers 729 : 1331, or as 1 : 1·825. All we have to do, therefore, is to multiply the present consumption by this latter number.

3. If a certain steamer consumes, say 220 tons of coal, during a run of 1600 miles, performed at the average speed of 11 knots per hour, and we wish to find her probable consumption of coal for a longer voyage of 2400 miles, at a reduced speed of 9 miles, the calculation will then be as follows:—

$$220 \text{ tons coal} : C \text{ (required consumption)} :: 11^2 \text{ knots} \times 1600 : 9^2 \text{ knots} \times 2400 \text{ miles,}$$

Then $C \times 121 \times 1600 = 220 \times 81 \times 2400$;

or, $C \times 193{,}600 = 42{,}768{,}000$.

Reduced to $C = \dfrac{427{,}680}{1936} = 220{\cdot}9$ tons, required consumption.

It is thus seen that the consumption of fuel is almost exactly equal in these two cases, showing that the same vessel would steam 1600 miles at 11 knots, or 2400 miles at 9 knots, with the same quantity of coals.

4. Supposing that we have a steamer with stowage-room for only 460 tons of coal, which she has nearly expended during a trip of 1800 miles, while steaming at the speed of 11·5 knots an hour, and we wish to place her upon another station, where she must run 2500 miles without coaling, it is required to find at what reduced speed she must steam so as not to run short of coals?

$$\underset{\text{tons.}}{460} \times \underset{\text{knots.}}{11{\cdot}5^2} \times \underset{\text{knots.}}{1800} = \underset{\text{tons.}}{460} \times \underset{\text{knots.}}{2500} \times V^2 \text{ required velocity;}$$

or, $460 \times 132{\cdot}25 \times 1800 = 460 \times 2500 \times V^2$;

reduced to $109{\cdot}503 = 1150\,V^2$;

or, $V^2 = \dfrac{109503}{1150} = 95{\cdot}04$.

Therefore, $V = \sqrt{95{\cdot}04} = 9{\cdot}75$ knots, required velocity.

We thus find that the same vessel which ran 1800 miles at a speed of 11·5 knots, and with a consumption of 460 tons of coal, must reduce her speed to $9\frac{3}{4}$ knots, to enable her to run 2500 miles with the same consumption.

Efficiency of a steamer.

The preceding examples all show that an increase of speed is obtained only by the expenditure of a very great increase of power. Hence, to draw even the most superficial comparison between the efficiency of different steam-vessels, their speeds must first be reduced to a common standard, and the relation must then be found between the consumption of fuel at the standard speed, and the size or tonnage of the vessel, the *maximum* speed of each being treated as a separate question. The value of the term *efficiency* also varies so much for different classes of vessels, that steamers of the same class only can be justly compared together. The number of tons displacement that 100 gross or indicated horse-power will propel, at the rate of 10 knots an hour, has been proposed as a standard of comparison between different steamers.

Modes of comparison.

A vessel, for instance, is known to have a speed of 12 knots an hour, the engines exerting 1620 indicated horse-power, at a displacement of 2240 tons.

Then, as 12 knots : 10 knots :: $\sqrt[3]{1620 \text{ H.P.}}$: $\sqrt[3]{\text{Ind. H.P. required}}$;

or, 1728 : 1000 :: 1620 : 937·5;

and 937·5 : 2240 :: 100 : 238·9 = tons displacement propelled by 100 I.H.P., at 10 knots an hour.

By making similar calculations for other vessels, their relative efficiency may be, to a certain extent, compared one with the other. It is found, in practice, however, that the form of the vessel influences the ratio existing, theoretically, between the power exerted and the resulting speed.

Thus, in the Flying Fish, before she was altered, an increase of only 1·68 knots in the speed of the ship was obtained by doubling the indicated horse-power; but after a fine bow was fitted, she gained 2·452 knots by doubling the power, the latter increase of speed being just proportional to the cube of the extra power exerted.

Formulæ for determining steamship performances.

A formula frequently employed in comparing the relative merits of vessels is $\frac{V^3 D^{\frac{2}{3}}}{I.H.P.}$, which is thus expressed in words:—The cube of the speed in knots, multiplied by the square of the cube-root of the displacement, and divided by the indicated horse-power. The resultant number is called the co-efficient of dynamic duty for that particular steamer, and forms a criterion of the cost at which she performs her work, the higher the co-efficient the greater being the economy. In a steamer of good average performance, the co-efficient, as calculated by this rule, should lie between 250 and 320, or thereabouts.

As the preceding formula does not take note of the area of immersed midship-section, the following is also useful as a means of comparison: $\frac{V^3 \times \left\{\text{midship-section.}\right.}{I.H.P.}$

The two formulæ next to be given are used indiscriminately for estimating the probable speed of a steamer, viz.—

No. 1.—$V^3 = \frac{\sqrt{H.P. \times C,}}{D^{\frac{2}{3}}}$; or, when expressed in words, the cube of the velocity equals the square-root of the nominal horse-power, multiplied by the diameter of the cylinder in inches, divided by the square of the cube-root of the displacement.

$$\text{No. 2.—}V^2 = \frac{\frac{2}{3}\,I.H.P. \times 100}{\text{mid. sect.}}$$

The speed of the Candia, when measured by the first of these rules, is 11·38 knots, and by the second, 11·28 knots; while her actual speed, under the same conditions of displacement, &c., is 11·93 knots. In the same way the speed of the Pera, by the first rule, is 11·22; by the second, 11·28; and actual, 12·55 knots. The actual speed, in both of these cases, is therefore in excess of that calculated by the formulæ.

Proportion of horse-power to tonnage.

In proportioning the horse-power of a steamer, the fact must be borne in mind that the effective power of the engines increases in a higher ratio than simply as the tonnage, since the resistance varies as the square of the cube root of the tonnage. Thus, if a vessel of 1200 tons and 400 horse-power have a speed of 12 knots, a similarly constructed vessel of 1650 tons and 550 horse-power (with the same proportion of power to tonnage), ought to have a considerably higher speed, since the square of the cube root of 1200 being 112·78, and the square of the cube root of 1650 being 139·47, the proportion will then be 112·78 : 400 : : 139·47 : 494·6 horse-power, instead of 550 horse-power.

The proportion of horse-power to tonnage recommended for different classes of ocean steamships may be stated as follows:—For full-powered passenger paddle-steamers of from 500 to 1200 tons (builders' O.M.), 1 horse-power to 3 tons; for ditto, of from 1200 to 3000 tons, 1 horse-power to 4 tons; for full-powered passenger screw-steamers of from 500 to 1200 tons, 1 horse-power to 4 tons; for ditto, of from 1200 to 3000 tons, 1 horse-power to 5 tons; for auxiliary screw-steamers, 1 horse-power to 6, 7, or 8 tons, according to size.

It must not be supposed that a steamer can, or ever will be constructed by the sole aid of "formulæ," which are themselves, for the most part, empirical. They serve, however, to assist in estimating the value and tendency of the several proportions and attributes of the structure, a wide margin being left for the exercise of practical sagacity and experience on the part of the constructor.

Main elements of steamship economy.

To sum up, in a few words, the main elements upon which economy in steam navigation seems to depend, these are—a fine form, a moderate speed, considerable magnitude, a clean bottom, and a high ratio of length to breadth; to which may be added, effective engines, and a properly proportioned propeller. Again, after the naval constructor and engineer have each done their best, much still remains for the skill of the commander and officers of the ship.

Proportions of length, breadth, and depth.

With regard to the relative proportions of the hull, our fastest and most successful ocean merchant-steamers of the present day have their length and breadth as 7, 7·5, or even 8 to 1 for iron screw-steamers, wooden hulls being generally confined to 6·5 and 7 times the beam. The proportion of depth varies very much, but this should never exceed eight-tenths of the breadth, and is better limited to six-tenths. A very deep steamer is always unweatherly and unmanageable, and often dangerous. The proportions in actual use will be seen by inspecting the tables of steamers in the royal navy, and the table of merchant-steamers, at pages 669, 670, 671.

Management of a steamer at sea.

With reference to the management of steamers at sea, a full-powered passenger-steamer is generally so tied to time that she cannot afford to disuse any portion of her steam-power, contenting herself with expanding more or less in the cylinders, according as the wind and sea are propitious or otherwise. Every opportunity of a fair wind, however, should be eagerly seized for hoisting sail, which, in the case of a screw-steamer especially, affords a great addition to the power of the engines. Steam-vessels of war, on the other hand, are expressly designed to sail well, in addition to their steaming powers; and in estimating the performance of a Government steamer, we should rather look to the direct distance run by the combined action of steam and sails, at a moderate but uninterrupted speed, and with a small consumption of fuel, than to the attainment of a high velocity, which is seldom wanted in war-steamers. In steaming against a strong head wind, with a paddle-wheel steamer of moderate steam-power, it is found preferable to keep the vessel in a direct course as long as possible; but, so soon as her head begins to fall off for want of good steerage way, the fore and aft sails should be set, and the vessel tacked, the engines being kept working. In the screw-steamer, on the other hand, there is no economy in keeping a direct course against a head wind and sea, after her speed is reduced to three or four knots an hour, since the engines keep up their usual number of revolutions, and the steam is mostly wasted in slip, or during the "racing" of the machinery. In such a case, therefore, the ship's course should be altered, and the sails set to assist the screw, so soon as the speed falls to this amount. In paddle-wheel engines, the waste of steam is not so great while going head to wind, since the revolutions decrease with the speed of the vessel. When a vessel is steaming against an opposing stream or tide, it is found that her engine-power is most economically applied when she goes half as fast again as the velocity of the stream. Notwithstanding the many undoubted improvements which have been recently introduced in the application of the screw propeller, and the extended experience we have now had of its operation in different classes of ships, and under every variety of trial, the position which it holds in the merchant service, either as an antagonist to the paddle-wheel in full-powered steamers, or as an auxiliary to the sails in sailing ships, is still far from being well defined.

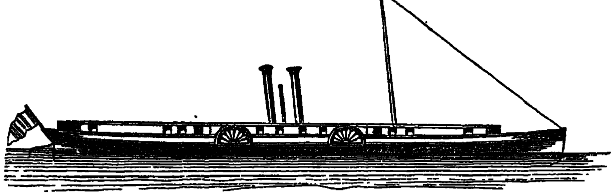

Fig. 32.
Paddle-steamer for the rivers of India.

Steam Navigation.

Before bringing this article to a close, it is proposed to give a few examples of steam-vessels which have either proved unusually successful, and may, therefore, stand as *types* of their class, or have some peculiarity of structure which seems to point them out for special notice.

1. DUKE OF WELLINGTON, 131 guns, steamship of the line, is 240 feet 6 inches long between perpendiculars, and 60 feet broad. Tonnage, 3826, builders' O.M. Has two horizontal, geared, screw-engines. Diameter of cylinders, 94½ inches, and 4 feet 6 inches stroke. Nominal H.P., 780; indicated do., 2500. Machinery by Robert Napier & Sons, of Glasgow. Has 4 tubular boilers, each containing 5 furnaces of the following dimensions, viz.—7 feet 4 inches long + 2 feet 9½ inches wide; the total space occupied by the machinery being 70 feet in length. The diameter of the screw shaft next the engines is 12½ inches. The screw itself is double threaded, 18 feet diameter, 16 feet 3 inches pitch, and 3 feet 4 inches long. The driving-wheel of screw-gearing is 10 feet 6 inches diameter, working into a pinion (with wooden cogs), 4 feet 6 inches diameter, and 4 feet 5 inches broad. The speed of the vessel at her trial trip was 10·2 knots.

2. MERSEY, 40 guns, screw steam-frigate, is 300 feet long between perpendiculars, and 52 feet beam. Tonnage, 3726; nominal H.P., 1000; indicated H.P., 4000. Makers of the machinery, J. Penn and Son. Pressure of steam, 20 lb.; mean number of revolutions of engines (direct), 55¼. Screw, diameter, 20 feet; pitch, 29 feet; immersion at trial, 6 inches; revolutions of screw, 55¼. Draught of water of ship, forward, 20 feet 8 inches; aft, 22 feet 7 inches. Coals on board, 850 tons; consumption of fuel at full speed, about 140 tons per day of 24 hours. Number of furnaces, 32; length of stoke-hole, 68 feet 10 inches; breadth of ditto, 10 feet; temperature of ditto, 100° Fahr. The tops of the boilers are 4 feet under the water-line; fitted with three auxiliary engines, two of which supply the boilers, and the third acts as a steam fire-engine. Weight of shot fired by one broadside, 1652 lb. Speed at trial, 13 29 knots.

3. RATTLER, screw-sloop, 179 feet 6 inches long between perpendiculars; 32 feet 8½ inches beam; 888 tons builders' O.M.; 13 feet 6 inches mean draught of water at trial; area of immersed midship-section, 330 square feet; displacement at trial, 1078 tons; nominal H.P., 200; ditto, indicated, 436; diameter of cylinders, four of 40⅛ inches each; length of stroke, 4 feet. Revolutions during trial, 27. Diameter of screw, 10 feet; pitch, 11 feet; length, 1 foot 3 inches; multiple of gearing, 4 : 1; revolutions of screw per minute, 107·9; slip per cent., 17·67. Description of engines, vertical geared. Makers of the machinery, Maudslay, Sons, and Field. Maximum speed of the vessel at trial, 10 knots.

4. GROWLER, screw gun-boat. Length between perpendiculars, 100 feet; breadth, 22 feet; draught of water, mean, 6 feet 10½ inches; immersed midship-section at this draught, 130 square feet; horse-power—nominal, 60; indicated, 200; high pressure engines working direct, with 2 cylinders, each 15½ inches in diameter, and 18 inches stroke. Makers of the machinery, Maudslay, Sons, and Field. Pressure of steam, 50 to 60 lb.; weight of engines, 8 tons 14 cwt. Boilers, 3 in number, are cylindrical, with internal tubes. Length of boilers, 15 feet 4 inches × 4 feet diameter, with one furnace in each, 2 feet 2 inches broad × 4 feet 6 inches long. Each boiler contains 82 iron tubes, 2 inches in diameter and 8 feet long. Total grate-bar surface in the three boilers, 29·25 square feet; weight of the three boilers complete, 13 tons 1 cwt.; weight of water in the three boilers, 9 tons. Screw, two-threaded, 6 feet diameter; 8 feet pitch; 16 inches long; weight, 840 lb. Total weight of the machinery with spare gear, 32½ tons. Coals carried in bunkers, 28 tons. Speed at above immersion, 8·38 knots; speed of engines and screw, 154 revolutions per minute; slip, 31 per cent.

5. WARRIOR, iron-cased steam-frigate, is built of iron; extreme length, 380 feet; breadth, 58 feet; depth, 41 feet 6 inches; tonnage, 6177. Weight of hull, about 5700 tons; fitted with engines of 1250 nominal horse-power, weighing 950 tons. Builders of the ship, the Thames Iron Co.; makers of the machinery, J. Penn & Son. She will carry 950 tons of coal, and the weight of armament, masts, stores, &c., will amount to about 1200 tons. The total weight at sea will thus be about 9000 tons. Sheathed with wrought-iron armour-plates 4½ inches thick from 5 feet below the water-line to the level of the upper deck for 220 feet of the broadside, each plate being 15 feet long by 4 feet broad. Behind the iron armour-plates there is a thickness of 24 inches of teak, protecting all the fighting portion of the vessel. The bow and stern are not thus sheathed, being merely plated with thick iron plates in the usual way, and crossed by several water-tight bulkheads. Armament will consist of Armstrong guns, each capable of throwing a 100 lb. shot a distance of 5 miles. The total cost of each frigate will be about L.320,000. Estimated speed, 14 knots an hour.

6. VICTORIA AND ALBERT, H.M. steam-yacht, is built of timber, and has the following dimensions:—Length between the perpendiculars, 200 feet 1 inch; breadth of beam, 33 feet; depth of hold, 23 feet 9 inches; burthen in tons, builders' O.M. 2343; horse-power, noninal, 600; horse-power, indicated, at trial 2980. Propelled by paddle-wheels. Has oscillating engines by J. Penn and Son, with two cylinders, each 88 inches in diameter and 7 feet stroke, the total weight of her machinery being 401⅓ tons. Her draught of water when complete for sea, with stores and coals on board, is 15 feet forward and 15 feet 9 inches aft. Revolutions of engines at this draught, 22; displacement at medium load-draught, 2120 tons. Has four tubular boilers, containing in all 3024 brass tubes, each 6 feet 5 inches long by 2½ inches external diameter. The boilers have altogether, 24 furnaces, each 7 feet long by 3 feet wide, fired from two stoke-holes. The pressure of steam on the safety-valves is 20 lb. The steam is superheated; has two funnels, each 5 feet 6 inches diameter, and 40 feet 3 inches high from top of boiler. The coal-boxes contain 410 tons of coal. The paddle-wheels are feathering, 29 feet extreme diameter, 14 boards to each wheel, each board 11 feet 6 inches by 4 feet 2 inches. The wheels can be disconnected by a friction-disc and break. Speed at trial trip, 17·022 knots.

7. FAIRY, H.M.'s screw steam-yacht, is built of iron, and has the following dimensions:—Length between the perpendiculars, 144 feet 8 inches; breadth extreme, 21 feet 1½ inches; mean draught of water at trial, 4 feet 10 inches; area of immersed midship-section, 71·5 square feet; mean displacement at trial, 168 tons. Tonnage, builder's O.M., 312; nominal horse-power, 128; indicated horse-power, 364. Builders, Mare & Co.; machinery by J. Penn & Son. Diameter of screw, 5 feet 4 inches; pitch, 8 feet; length, 1 foot. Revolutions of screw at trial, 258 per minute; slip of the screw, 34 per cent. Has two vertical, oscillating, geared engines, the cylinders 42 inches diameter, and 3 feet stroke, making 51½ revolutions per minute. Speed of the vessel at trial, 13·324 knots.

8. HIMALAYA, steam troop-ship, propelled by the screw, is built of iron, and has the following dimensions:—Length between the perpendiculars, 341 feet; breadth, extreme, 46 feet 4 inches; depth of hold, 35 feet; tonnage, 3560; horse-power, nominal, 700. Has horizontal direct engines, with cylinders 84⅜ inches diameter, and 3 feet 6 inches stroke, making 59 revolutions per minute. Boilers on Lamb and Summer's sheet-flue principle. Pressure of steam, 14 lb. She can stow 1000 tons of coal; her daily consumption, at full speed, being 70¾ tons. Fitted with the common 3-bladed screw, 18 feet diameter, by 28 feet pitch, making 59 revolutions per minute. Speed at trial, 13·9 knots. This steamer has proved eminently successful, having made the trip from England to Alexandria, on several occasions, at an average speed of 12 knots an hour; and with a favourable breeze, she has been known to run 16 knots within the hour.

9. TROOP RIVER-STEAMERS for India. These are now being built for Government of the following proportions:—Length on the water-line, 350 feet; length over all, 375 feet; breadth, 46 feet. Built of steel-plates, weighing about 5 lb. per superficial foot, with the exception of the keel-strakes, which are 7 lb., and the girder-strakes 15 lb. per square foot. They are flat-bottomed, to draw only 2 feet of water, with machinery, fuel, stores, and 800 troops on board. The hulls are estimated to weigh only 370 tons. They are to be propelled by paddle-wheel engines of 200 horse-power. They will be steered by two large patent steering-blades. The hull is stiffened by two iron girders, rising above the deck, and running for 300 feet of the length, from which vertical and diagonal trusses are carried. They will be sent to India in parts, after being put together and tried in this country. Estimated speed, 12 miles an hour.

10. GREAT EASTERN, of iron. Length between the perpendiculars, 680 feet; length on deck, 691 feet; breadth, extreme, 83 feet; depth of side, 58 feet; draught of water, from 20 to 30 feet. Gross tonnage, 22,500. Nominal horse-power, 2600. Builder, J. Scott Russell. Her screw-engines of 1600 horse-power, by James Watt and Company; and paddle-engines of 1000 horse-power, by J. Scott Russell. The screw-engines are horizontal direct, with 4 cylinders, each 84 inches diameter, by 4 feet stroke, making 45 strokes per minute; with tubular boilers, carrying 25 lb. pressure. The screw is of the common construction, with 4 blades, 24 feet diameter, with a pitch of 44 feet. The paddle-wheel engines are oscillating, with 4 cylinders, each 74 inches diameter, by 14 feet stroke. Boilers, tubular, 25 lb. pressure. Paddle-wheels are of the common construction, 50 feet diameter, 13 feet length of floats, and 3 feet depth. Total coals carried, 10,000 tons. Speed about 15 knots. Her ship-draught is shown in the plates illustrating article SHIP-BUILDING.

11. PERSIA, transatlantic mail-steamship, of iron, has the following dimensions:—Length between the perpendiculars, 360 feet; breadth of beam, 45 feet; depth of hold, 29 feet 8 inches. Medium load-draught of water, 21·5 feet. Displacement at this draught,

Steam Navigation.

5285 tons. Area of immersed midship-section, 818 square feet. Tonnage, builders' O.M., 3586. Builders of vessel and makers of the machinery, Robert Napier and Sons. The bottom plates of the hull are $\frac{15}{16}$ inch thick, tapering to $\frac{3}{4}$ inch at the load water-line, and above this $\frac{11}{16}$ inch, except round the gunwale, where they are $\frac{7}{8}$ inch. The hull is divided into 7 water-tight compartments, and has a double iron bottom for a considerable portion of her length. The launching weight of the iron hull was 2200 tons, her displacement with machinery, coals, and stores on board being about 5400 tons, on a draught of 23 feet. Accommodation is provided for 250 passengers (besides a crew of 150 persons), and stowage room is found for 1200 tons measurement goods. Coals carried are 1400 tons. The engines are on the side-lever construction, with 2 cylinders, each $100\frac{1}{2}$ inches diameter, and 10 feet stroke, 850 nominal horse-power, and about 3000 indicated horse-power. Diameter of paddle-shaft, $23\frac{1}{4}$ inches. There are 8 tubular boilers, containing, in all, 40 furnaces, each 7 feet long by 2 feet 9 inches wide. Total length occupied by the machinery is 107 feet 6 inches. The paddle-wheels are of the common construction, 38 feet 6 inches diameter to extremity of boards, which are 10 feet 8 inches long, 2 feet 1 inch broad, on 28 arms. On the occasion of the Persia's trial trip from Glasgow to Liverpool, she ran 175 knots in 10 hours 43 minutes; thus accomplishing an average speed of 16 knots, or nearly 19 British statute miles an hour.

12. PERA, Alexandria mail screw-steamship, is of iron, and has the following dimensions:—Length between the perpendiculars, 303 feet 7 inches; breadth extreme, 42 feet 3 inches; depth of hold, 27 feet 2 inches; gross tonnage, 2613; nominal horse-power, 450; indicated horse-power, 1500. Builders of the vessel, Mare and Company; makers of the machinery, Messrs Rennie. She has vertical trunk-engines, geared, with 2 cylinders each $70\frac{1}{2}$ inches diameter (trunk 30 inches diameter), and 4 feet length of stroke. Strokes of engine per minute, $29\frac{1}{2}$. There are four sheet-flue boilers; pressure of steam 16 lb., superheated. 700 tons of coal are carried in boxes; coals burned per day of 24 hours, 44 tons (in place of 56 before superheating apparatus was fitted). Screw propeller has 3 blades, is 15 feet 6 inches diameter, 21 feet pitch, making 60 revolutions per minute. Speed at trial trip, 12·5 knots. The Pera has made some very remarkable passages. Thus, in the month of July 1859, she ran from Southampton to Gibraltar, 1000 miles, in 3 days 21 hours (being at the rate $10\frac{3}{4}$ knots per hour); thence to Malta, another 1000 miles, in 3 days 12 hours (11·9 knots per hour); and from Malta to Alexandria, 1000 miles, in 2 days 19 hours (14·92 knots per hour). The Pera's lines are shown in the plates of article SHIP-BUILDING.

13. LEINSTER, ULSTER, MUNSTER, CONNAUGHT, new Holyhead mail-packets, are of iron, and propelled by paddle-wheels. They have the following dimensions:—Length extreme, 350 feet; breadth, 35 feet; depth, 20 feet; draught of water, 12 to 13 feet; tonnage, 2000; nominal horse-power, 700; indicated horse-power (estimated), 3500. Average speed contracted for, 20 miles an hour. The engines are oscillating, and the paddle-wheels have feathering floats. Three of the vessels are built by Messrs Laird, and one by Messrs Samuda; and the machinery is by Messrs Ravenhill, Salkeld, and Company, and Messrs James Watt and Company. They will be rigged very lightly, for fore and aft sails only, their great engine-power making them independent of the wind. They have 9 water-tight bulkheads, extending to the upper deck, one of which divides the engine and boiler rooms; this latter bulkhead constituting an important element of safety and strength, which might be advantageously introduced into iron steamers much more frequently than it is. The cabins are 9 feet 6 inches high; the principal saloon being 60 feet long.

14. BREMEN, screw-clipper steamship, is built of iron, and has the following dimensions:—Length between the perpendiculars, 318 feet; breadth of beam, 40 feet; depth of hold, 26 feet; mean draught of water at trial, 18 feet 6 inches. Displacement at this draught, 3440 tons. Area of immersed midship-section, 606 square feet. Rate of displacement at load draught, 25 tons per square inch. Builders of the ship and makers of the machinery, Messrs Caird and Company. The engines of the Bremen consist of two direct-acting inverted cylinders, each 90 inches diameter and 3 feet 6 inches stroke. Nominal horse-power, 500; indicated horse-power at trial, 1624. Speed at trial trip, 13·15 knots per hour. The average performance at sea, between Bremen and New York, with a mean displacement of 2950 tons, was found to be 11·05 knots, the engines showing a mean indicated horse-power of 1045. The superiority shown by the Bremen is believed to be principally due to her fine form of body, and judicious proportions. Her ship-draught will be found amongst the plates illustrating the article SHIP-BUILDING.

15. WINDSOR CASTLE, Clyde river-steamer, propelled by paddle-wheels, is built of steel-plates, and has the following dimensions:—Length, 190 feet; breadth, 20 feet; depth, 7 feet 6 inches; tonnage, gross, 190; register, 93. Mean draught at trial, 3 feet 1 inch. Immersed midship-section at this draught, 52 square feet. Average number of revolutions, 43. Nominal horse-power, 115. Indicated horse-power at trial, 620. Pressure of steam in the boilers, 40 lb. Builders of the vessel and makers of the machinery, Messrs Caird and Company. The cylinders are placed diagonally; they are 40 inches in diameter and 5 feet stroke, cutting off steam after 12 inches. The steam is supplied by an upright tubular boiler, and is superheated in the funnel to a temperature of 375° Fahr. before entering the cylinders. The boilers have 76 square feet of fire-grate surface, and 1526 square feet of total heating surface, consuming about 20 cwt. of coal per hour. The paddle-wheels are feathering, 15 feet diameter, each having 10 boards 8 feet long by 2 feet 3 inches broad. Speed at trial trip, 17·083 knots, or 19·679 British statute miles an hour. In this steamer *weight* is economized in every possible way, and only 10 tons of coal are carried.

16. TACHTALIA, river-steamer for shallow navigation, is built of iron, and has the following dimensions:—Length, 150 feet; breadth, 20 feet; draught of water, with machinery and passengers on board, $12\frac{1}{2}$ inches. Builders of the vessel and makers of the machinery, Messrs J. and A. Blyth. She is propelled by 4 condensing engines, of the collective power of 40 horses, acting through 4 paddle-wheels, each 6 feet in diameter and 6 feet wide; the forward engines making 87 revolutions and the after engines 96 revolutions per minute, and the speed through still water being about 11 miles per hour. The hull is formed of very thin plates, stiffened by frequent transverse bulkheads, and webs of plate surrounding the vessel internally. By employing 2 pairs of paddle-wheels, each pair driven by a distinct pair of steam-engines, not only are the weights of the machinery, water, and coals diffused over the vessel, but the propelling power is also widely distributed over the structure. The use of 4 paddle-wheels in place of 2 greatly improves the steering of the vessel, always a matter of much difficulty with boats of shallow draught running on swift rivers. Lightness of machinery in this vessel is promoted by the substitution of gun-metal for cast-iron in the condensers, &c., and of cast-steel and wrought-iron for the framing of the engines. The boilers are constructed of Lowmoor plates throughout, without angle-irons, to save weight. Vessels of this class are well adapted for the rivers of India. A representation of the Tachtalia is given at page 664.

17. SCREW-STEAMER for the rivers of INDIA, built of iron. Length, 70 feet; breadth, 7 feet 6 inches; depth, 3 feet 6 inches; draught of water, 2 feet. Boat and machinery constructed by Messrs G. Rennie and Sons. Propelled by two screws, one on each quarter (see annexed wood engraving, fig. 33); diameter of the

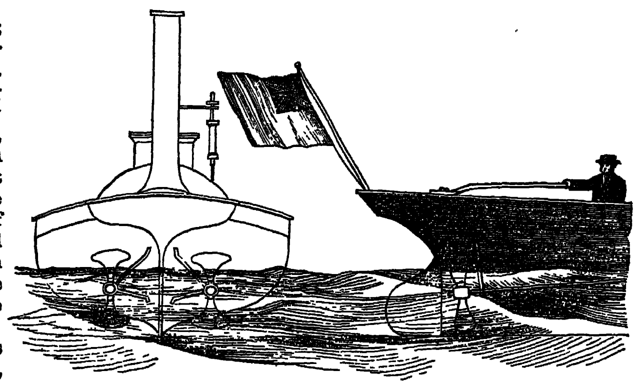

Fig. 33.

Screw-steamer for the rivers of India.

screws, 2 feet 2 inches; pitch, 4 feet. Driven by a pair of disc engines, acting direct. Speed of the engines and screws, 260 revolutions per minute. Speed of the boat, 10 knots per hour. Weight of the boat, 3 tons 8 cwt.; weight of the machinery, 3 tons. Consumption of coal, per hour, 100 lb. Power of traction, at slow speed, 250 tons. Cost of trackage, $\frac{1}{4}$ of 1d. per ton per mile.

18. AMERICAN STEAMBOATS (by a correspondent of *The Engineer*).—"Going aboard at a late hour in the evening, the scene which presented itself to our eyes was novel in the highest degree. Painted a pure white, as nearly all American river-steamboats are (for the anthracite coal burned under their boilers makes no smoke whatever), the enormous mass of the vessel rose like a giant iceberg above the water. Hurrying over the broad gangway, we found ourselves in a crowd of nearly 700 passengers, more than one-third of whom were ladies. We were upon the main-deck, although under a lofty ceiling, over which was a grand saloon of

palatial proportions and magnificence. Looking aft, a broad entrance, flanked with gilded columns and luxurious drapery, opened to the ladies' saloon—a *sanctum sanctorum* not to be profaned by the footsteps of a bachelor, although steamboat etiquette was not so strict, nor steamboat regulations so inflexible, as to forbid the momentary presence there of gentlemen accompanying their wives, or other fair charges, to be intrusted to the care of the stewardess. On either side of this entrance were broad staircases descending to an immense lower cabin, along the sides of which were more than 400 berths. The supper tables were then set out with a degree of splendour for which an English traveller would be altogether unprepared. Nearly amidships, on the main-deck, a grand staircase, sweeping both to the right and left, conducted to the great saloon, or state-room hall, nearly 300 feet in length, several yards in width, and having an upper gallery, with a second story of state-rooms—a lofty arched ceiling, glazed with ground and coloured glass, and supported by richly-carved columns, covering the whole. In its construction this steamboat (the New World) is totally unlike anything ever seen in British waters. It is of enormous size. Originally 376 feet long, it was afterwards lengthened to 468 feet over all. With a breadth of beam of 50 feet, the main-deck is extended by means of platforms, or "guards," projecting over the water to the full width across the paddle-boxes, 85 feet, being thus wider than the main-deck of the Great Eastern. Yet the vessel, which is flat bottomed, with bilges nearly or quite square, draws only 5½ feet of water, the whole displacement being about 2500 tons, and the immersed mid-section 275 square feet. All American boats have wooden hulls, and how to stiffen such a vast and shallow craft, flat-bottomed as Noah's Ark? There are no tubular cells, no 'double skins,' nor is there a hundredweight of boiler-plate, excepting in the boilers themselves, in the whole structure. As if to increase the strain, the boilers, weighing, with water, 75 tons each, are placed upon the "guards" outside the hull, and of course several feet above the load-line. To make the whole as rigid as a tubular girder, two enormous arched trusses, placed one over each side of the hull, extend over nearly 350 feet of the length of the boat. These great bows, like the arches of a bow-string bridge, are connected to king-posts and queen-posts, and strapped and fastened, so that the whole is as stiff as a man-of-war. Then there are four or five large king-posts, or masts, stepped upon the keel, and carrying the weight of the projecting 'guards' by long diagonal tension rods. These masts carry no spars, booms, or rigging of any kind, all of which would be so much top hamper, worse than useless, at a speed of 20 miles an hour. These posts, like nearly all the rest of the wood-work, are painted a dazzling white, and surmounted by gilded balls. The lines of the hull are very sharp, and at twenty-two statute miles an hour, a speed not unfrequently attained, there is only a thin spurt of water breaking into spray to mark the keen entrance of the cutwater."

We subjoin a list of those parts which are considered most necessary to be carried as SPARE GEAR for sea-going PADDLE-WHEEL ENGINES of a large class:—

100 bolts and nuts for paddle-wheels; 50 bolts and nuts for paddle-floats; 6 paddle-floats; 2 sets of gearing for paddle-floats (feathering-wheels); 1 connecting-rod for ditto, ditto; 1 driving-arm for ditto, ditto; 4 large pins and 2 small for brackets, ditto; 2 radius boss pins for ditto, ditto; 2 bushes for ditto, ditto; 8 brass washers for gearing, ditto; 4 bolts and nuts for radius-boss, ditto; 4 segments of paddle-centres; 4 arms for paddle-wheels; 18 iron washer-plates; 2 brass linings for outer-bearings; 120 brushes for boiler-tubes; 36 stoking-irons; 60 scrapers, circular and forked; 1 set of stocks, taps, and dies, from ¼ in 1¼ inch; 1 air-pump rod and nut; 1 cylinder-cover, bush, and gland; 1 piston and rod; 1 piston rod cap, complete; 2 complete sets of all India-rubber valves; ½ set of fire-bars; 1 set of bearing-bars for one furnace; boiler-plate, about 6 or 8 cwt.; 60 boiler-tubes; 300 ferrules for boiler-tubes; 8 handles for boiler-tube brushes; 24 drifts (short and long) for tubing; 12 mandrils for ditto; 1 crank-pin for engine; 1 eccentric-band, complete; 1 feed-pump rod, complete; 1 bilge-pump rod; 1 gross iron washers of various sizes; 120 bolts and nuts; 8 glass guage-tubes for boilers; 2 glass tubes for barometers.

The following is a list of SPARE GEAR for SCREW-ENGINES of a large class:—

1 Cylinder-cover, complete; 1 connecting-rod; 1 centre-bonnet, for cylinder; 1 air-pump rod; 1 piston and rod, complete; 1 feed-pump rod; 1 bilge-pump rod; 1 slide-rod, complete; 1 eccentric strap, complete; 1 spiral-spring, for escape-valve; 1 cross head; 1 guide-block and brass (if so made), complete; 1 cap for thrust-block, fitted with white metal; 2 screws for thrust-block; soft metal bearings, various; 2 complete sets of India-rubber valves; 1 wrench for piston-rod nuts; 1 set of taps and dies, complete; 50 bolts, assorted (iron and metal); 80 bolts and nuts (assorted); 40 spanners, various; ½ set of fire-bars; 60 fire-irons, assorted; 110 scrapers (50 circular and 60 forked); 3 bearing-bars; 100 boiler-tubes; 300 ferrules for boiler-tubes; 40 drifts and mandrils for boiler-tubes; 200 tube-brushes, and 4 handles; 140 washers for boiler-tubes; 3 boiler-plates; 16 glass gauge-tubes, and 60 India-rubber rings.

* Paddles.

DESCRIPTION OF THE PLATES.

PLATE XXIX. represents the usual type of the side-lever marine-engine. The principal parts are—A the cylinder, B the valve-chest, C the condenser, D the hot well, E the air-pump, F the feed and bilge pumps, GG the great lever, G′ its main gudgeon, H the cylinder side-rods, I the cross-head, K the piston-rod, LL the parallel motion, M the air-pump cross-head, N the air-pump side-rods, O the air-pump piston-rod, P the connecting-rod cross-tail links, Q the cross-tail, R the connecting-rod, S the crank, U the eccentric pulley or cam, *u u u* the eccentric-rod, V the valve-shaft, WW the valve-lever and counterbalance lever.

The apparatus for working the valves expansively is distinctly shown. On the crank-axle, T, is placed a series of cams *t t t*, which act upon the roller of the expansion-valve tumbler. Y *y y y* are the expansion-valve connecting-rods and levers. Z is the valve-chest, and the valve is of the kind called equilibrium-valves, or crown-valves.

PLATES XXX., XXXI., and XXXII. represent a pair of direct screw-engines of 500 horse-power (nominal), as constructed by Messrs Ravenhill, Salkeld, and Company, for various ships in the royal navy. The following vessels have been fitted with machinery on this plan, viz.—the Waterloo and Nelson, 98 guns, 500 H.P.; the Undaunted, Glasgow, and Newcastle, 50-gun frigates, and 600 H.P.; the Narcissus, 50 guns, and the Jason, 21 guns, each of 400 H.P. These engines have given much satisfaction, being at once compact, and at the same time easy of access to all the working parts.

The following are the principal dimensions of the 500-horse screw-engines:—

Diameter of the cylinders (two)	71 inches.
Length of stroke	3 feet.
Revolutions of engines and screw-shaft, per min.	50
Pressure of steam in the boilers per sq. inch	20 lb.
Diameter of the screw	18 feet.
Pitch of do. mean	20 feet.
Description of screw	Griffith's.
Mean draught of the ship (H.M.S. Nelson)	24 ft. 9½ in.
Speed at the measured mile	10 9 knots.
Indicated horse-power	2150 horses.

The various parts of the engines will be recognised by reference to the following letters:—AA are the cylinders; B the piston-rods, of which there are two to each cylinder; C the connecting-rods, working between the guiding surfaces DD, and giving motion to the main cranks EE; F is the screw-shaft; G, the thrust-block, on which the thrust of the screw is taken; H the coupling for disconnecting the shaft; I a worm-wheel for turning the engines by hand; K the steam-pipe from the boilers; L the throttle-valve; M the expansion-valves; N the cylinder slide-valves; O the exhaust-passages; P the condenser; Q the air-pump-rods, which work direct from the piston, passing steam-tight through the cylinder covers like small piston-rods. The air-pumps themselves cannot be seen, being concealed by the condenser. R the discharge-pipes; S the feed and bilge plunger pumps; T eccentrics and gear for working the slide-valves.

Plates XXXIII. and XXXIV. represent the engines and boilers of the screw-steamship Thunder, which are possessed of several interesting peculiarities and appliances for economizing fuel and steam. The vessel (built by Messrs Lungley of London) is of iron, 240 feet long, 30 feet beam, 22 feet 6 inches deep, and 1062 tons B.O.M. Her draught of water is 13 feet 8 inches aft, and 10 feet 8 inches forward. The engines are constructed by Messrs Dudgeon, of Millwall, London, and have the following dimensions:—

Diameter of cylinders (two)	55 inches.
Length of stroke	36 „
Revolutions of engines and screw per min.	58
Diameter of screw	15 feet.
Pitch of screw	29½ „
Nominal horse-power	210 horses.
Indicated horse-power with full steam ..... 950 to 1000	„
Do., with expansion when cutting off after ¼th ... 696	
Speed, with an immersed midship-section of 342 square feet and displacement of 1175 tons, the engines making 54 revolutions per minute, and cutting off steam after ¼th of the stroke	14 knots.
Maximum speed at trial with full power	15 „

The cylinders of these engines are inverted, and are fixed directly over the crank-shaft. They have separate expansion-slides, and double-port steam-slides. The exhaust is carried round the cylinders by broad belts (see O, Plate XXXIII.), into the condenser P, the belts thus acting as steam-jackets to the cylinders to preserve their temperature. The condensers themselves form part of the framing on which the cylinders stand. The shaft is forged with solid cranks, and the thrust of the screw is taken by the long collared bearing at C, which is supported independently of the engine framing. The pressure of steam in the boilers is 19 lb., the steam being cut off in the cylinders (when working most expansively) after one-fourth of the stroke.

The letters of reference, previously given, indicate the same portions of the machinery for this and all the remaining plates.

The boilers are tubular, two in number, with four furnaces, and are fired from each end. Each boiler has 360 tubes, 3¼ inches external diameter, and 7 feet long. The boilers are fitted with superheating apparatus (A), on Mr Beardmore's plan; each consists of two steam-chambers, placed one on each side of the chimney, connected by 172 tubes in each, each tube being 2 inches in diameter. The lower end of the chimney is expanded so as to encase the tubes, through which all the steam from the boilers passes on its way to the cylinders. These boilers generate steam with much facility. The advantage of having two funnels in this case is, that the draught thus becomes more direct, and therefore sharper than it would be with one large funnel. The temperature of the superheated steam is about 320°.

These engines have exhibited a very remarkable economy of fuel, the consumption, under favourable circumstances, not exceeding 1½ lb. per I.H.P. per hour; and when the vessel was deeply laden, this did not exceed from 2 to 2½ lb. during a ten days' voyage at sea. The Thunder ran from Plymouth to St Vincent in 9 days, 14 hours, the chief engineer writing thus from the latter place:—"We have run 285 miles during the last 24 hours; and our average speed has been throughout the voyage 11 knots per hour, on a consumption of 15 tons of coals per 24 hours. Pressure of steam 10 lb.; 44 revolutions per minute. Temperature of steam in superheaters, 310°." This is equal to a consumption of about 12 cwt. of coal per hour while steaming at the rate of 11 knots, which, for a displacement of 2000 tons, is an extraordinary result. Whilst on her trial trip her displacement was only half the above, when, under the most favourable circumstances, she went at the rate of 14 knots on a consumption of 8 cwt. per hour.

Plates XXXV. and XXXVI. represent a pair of "combined-cylinder" paddle-wheel engines of 320 horse-power collectively (nominal), as constructed by Messrs Randolph, Elder, and Company, of Glasgow, in the steamships Callao, Lima, and Bogotâ.

These vessels are 245 feet long, 36 feet broad, and 23 feet deep, and are designed with lines favourable for speed. Their tonnage is 1650 tons; draught of water, 11 feet forward, 12 feet aft; fitted with feathering wheels 25 feet 2 inches diameter.

The cylinders are four in number, viz., two of 52 inches diameter, and two of 90 inches diameter, and 5 feet stroke. It will be observed that they lie diagonally to each other. During the trial trips the engines made from 23 to 26 revolutions per minute, and indicated from 1000 to 1300 horse-power, the pressure of steam being 26 lb., and the speed of the ships from 12½ to 13 knots per hour. The boilers are tubular, and superheat the steam in the steam-chests by contact with the up-takes only, these being purposely divided and prolonged with this view. The cylinders are further provided with "jackets" kept well supplied with hot steam, to guard against condensation within the cylinders.

These engines have also been attended with a remarkable economy of fuel. The Bogotâ lately ran from Glasgow to St Vincent, a distance of 2470 nautical miles, in 9 days 21 hours, on a consumption of 232 tons of coal, thus giving an average speed of 10·42 knots, on a consumption of 19 cwt. per hour. The average I.H.P. being 950, this gives an average of 2¼ lb. of coal per I.H.P. per hour.

Plate XXXVII. represents a pair of combined-cylinder engines of the same description as shown in the preceding plates, and by the same makers, but designed for driving the screw-propeller. These, it will be observed, are geared engines, driving the screw-shaft by means of internal gearing.

The nature and presumed advantages of "combined-cylinder" engines have been already explained. It may be here repeated, however, that the steam is first admitted into the small cylinder for about one-third of the stroke; and after expanding during the remainder of the stroke in the small cylinder, it enters the large one, and completes its work there by further expanding to the end of its stroke.

Plate XXXVIII. is a section of inboard works of the paddle-steamer Delta, carrying the Indian mails from Southampton to Alexandria. (R. M—Y.)

Steel || Steele, Sir Richard.

STEEL. See CUTLERY and IRON.

STEEL-YARD. See WEIGHING-MACHINES.

STEELE, SIR RICHARD, was born at Dublin in the year 1671. One branch of the family was possessed of a considerable estate in the county of Wexford. His father, a counsellor-at-law in Dublin, was private secretary to James duke of Ormond; but he was of English extraction; and his son, while very young, being carried to London, he put him to school at the Charter-House, whence he was removed to Merton College in Oxford. He left the university without taking any degree, in the full resolution to enter the army. This step was highly displeasing to his friends; but the ardour of his passion for a military life rendered him deaf to any other proposal. Not being able to procure a better station, he entered as a private gentleman in the Horse Guards, notwithstanding he thus lost the succession to his Irish estate. However, as he had a flow of good-nature, a generous openness and frankness of spirit, and a sparkling vivacity of wit, these qualities rendered him the delight of the soldiery, and procured him an ensign's commission in the guards. In the meantime, as he had made choice of a profession which set him free from all the ordinary restraints of youth, he spared not to indulge his inclinations in the wildest excesses. Yet his gaieties and revels did not pass without some cool hours of reflection; it was in these that he drew up his little treatise entitled *The Christian Hero*, with a design, if we may believe himself, to be a check upon his passions. For this purpose it had lain for some time by him, when he printed it in 1701, with a dedication to Lord Cutts, who had not only appointed him his private secretary, but procured for him a company in Lord Lucas's regiment of fusiliers.

During the same year he brought out his comedy, called *The Funeral, or Grief à la Mode*. This play procured him the notice of King William, who resolved to give him some essential marks of his favour; and though, upon that prince's death, his hopes were disappointed, yet, in the beginning of Queen Anne's reign, he was appointed to the profitable place of gazetteer. This post he owed to the friendship of Lord Halifax and the Earl of Sunderland, to whom he had been recommended by his schoolfellow Mr Addison. That gentleman also lent him a helping hand in promoting the comedy called *The Tender Husband*, which was acted in 1704 with great success. But his next play, *The Lying Lover*, had a very different fate. Upon this rebuff from the stage, he turned the same humorous current into another channel; and early in the year 1709, he began to publish the *Tatler*, in concert with Dr Swift. His reputation was perfectly established by this work; and, during the course of it, he was made a commissioner of the stamp-duties in 1710. Upon the change of the ministry the same year, he joined the Duke of Marlborough, who had several years entertained a friendship for him; and upon his Grace's dismission from all employments in 1711, Mr Steele addressed a letter of thanks to him for the services which he had rendered to his country. As, however, he still continued to hold his place in the stamp-office under the new administration, he wisely declined the discussion of political subjects; and, adhering more closely to Addison, he dropped the *Tatler*, and afterwards, by the assistance chiefly of that steady friend, he carried on the same plan, much improved, under the title of the *Spectator*. The success of this paper was equal to that of the former; and before the close of it, he was thus encouraged to proceed upon the same design in the character of the *Guardian*. This was begun in the beginning of 1713, and was laid down in the ensuing October. But in the course of the year his thoughts took a stronger turn to politics: he engaged with great warmth against the ministry; and being determined to prosecute his views by procuring a seat in the House of Commons, he immediately removed all the obstacles that stood in his way. For that purpose he took care to prevent a forcible dismission from his post in the stamp-office, by a timely resignation of it to the Earl of Oxford; and at the same time gave up a pension which had hitherto been paid to him by the Queen as a servant to the late Prince George of Denmark. He now wrote the famous paper in the *Guardian* upon the demolition of Dunkirk. It was published August 7, 1713; and the parliament being dissolved next day, the same journal was soon followed by several other warm political tracts against the administration. Upon the meeting of the new parliament, Steele having been returned a member for the borough of Stockbridge in Hampshire, took his seat accordingly in the House of Commons; but was expelled in the course of a few days, for writing a paper called the "Englishman," and another entitled the "Crisis." Presently after his expulsion, he published proposals for writing the history of the Duke of Marlborough. At the same time he also wrote the *Spinster;* and in opposition to the *Examiner*, he set up a paper called the *Reader*, and continued publishing several other papers and tracts in the same spirit till the death of the queen. As a reward for these services, he was immediately taken into favour by her successor to the throne, King George I.; was appointed surveyor of the royal stables at Hampton Court, and governor of the royal company of comedians, was put into the commission of the peace for the county of Middlesex, and in 1715 received the honour of knighthood. In the first parliament of that king, he was chosen member for Boroughbridge in Yorkshire: and, after the suppression of the rebellion in the north, was appointed one of the commissioners of the forfeited estates in Scotland. In 1718, he buried his second wife, who had brought him a handsome fortune with a good estate in Wales; but neither this, nor the ample addition lately made to his income, was sufficient to answer his demands. The thoughtless vivacity of his spirit often reduced him to little shifts of wit for its support; and he was constantly engaged in speculative projects that generally ended in failure.

The following year he opposed the remarkable peerage bill in the House of Commons; and, during the course of this opposition to the court, his license for acting plays was revoked, and his patent rendered ineffectual at the instance of the Lord Chamberlain. He did his utmost to prevent so great a loss; and finding every direct avenue of approach to his royal master effectually barred against him by his powerful adversary, he had recourse to the method of applying to the public, in hopes that his complaints would reach the ears of his sovereign, though in an indirect course, by that channel. In this spirit he formed the plan of a periodical paper, to be published twice a-week, under the title of the *Theatre;* the first number of which appeared on the 2d of January 1719-20. In the meantime, the misfortune of being out of favour at court, like other misfortunes, drew after it a train of more. During the course of this paper, in which he had assumed the feigned name of *Sir John Edgar*, he was outrageously attacked by Dennis, the notorious critic, in a very abusive pamphlet, entitled *The Character and Conduct of Sir John Edgar.* To this insult he made a humorous reply in the *Theatre.*

While he was struggling with all his might to save himself from ruin, he found time to turn his pen against the mischievous South Sea scheme, which had nearly brought the nation to ruin in 1720; and the next year he was restored to his office and authority in the play-house in Drury Lane. Of this it was not long before he made an additional advantage, by bringing his celebrated comedy called the *Conscious Lovers* upon that stage, where it was acted with prodigious success; so that the receipt there must have been very considerable, besides the profits accruing by the sale of the copy, and a purse of L.500 given to him by the

Steen.

king, to whom he dedicated it. Yet notwithstanding these ample supplies, about the year following, being reduced to the utmost extremity, he sold his share in the play-house; and soon after commenced a lawsuit with the managers, which, in 1726, was decided against him. Having now again, for the last time, brought himself by the most heedless profusion into a desperate condition, he was rendered altogether incapable of retrieving the loss, by being seized with a paralytic disorder, which greatly impaired his understanding. In these unhappy circumstances, he retired to his seat at Llangunnor near Caermarthen in Wales, where he died on the 1st of September 1729, and, according to his own desire, was privately interred in the church of Caermarthen. Among his papers were found the manuscripts of two plays, one called *The Gentleman*, founded upon the *Eunuch* of Terence, and the other entitled *The School of Action*, both nearly finished.

Sir Richard was a man of undissembled and extensive benevolence, a friend to the friendless, and, as far as his circumstances would permit, the father of every orphan. His works are chaste and manly. He was a stranger to the most distant appearance of envy or malevolence; never jealous of any man's growing reputation; and so far from arrogating any praise to himself from his conjunction with Addison, that he was the first who desired him to distinguish his papers. His great fault was want of economy; and it has been said of him, he was certainly the most agreeable and the most innocent rake that ever trode the rounds of dissipation.

Thackeray, in his *Lectures on the English Humorists*, 1858, winds up his remarks on Steele in these words—"We are living in the nineteenth century, and poor Dick Steele stumbled and got up again; and got into jail and out again; and sinned and repented; and loved and suffered; and lived and died scores of years ago. Peace be with him! Let us think gently of one who was so gentle; let us speak kindly of one whose own breast exuberated with human kindness."

STEEN, Jan, a celebrated Dutch painter, was born in Leyden in 1636. His father, who was a brewer, observing his son's predilections for art, had him apprenticed to one Knupfer, a German artist of note. He subsequently received lessons from Van Goyen, and the hand of his daughter Margaret in marriage. Steen soon rose into considerable reputation as a painter, but his tastes unfortunately were much too expensive for the income of a prosperous young artist. He spent too much of his time in taverns, and was a great patron of brawls. While the drinking-shops fattened, poor Jan Steen got much out at elbows, and threw down his pencil in despair. What could man do more than he had done, and see what had come of it? His relations assisted him to set up a public-house, which met with great success, but Jan Steen drank as hard as ever. He resumed his pencil, and plied it with great success. More than 300 paintings came from his hand, and he is known to have painted with great care. His pieces represent merry-makings, sick-rooms, and scenes of debauchery; schools, alchemists' laboratories, and card parties; taverns, tabâgies, and prodigality; gluttony, wine-bibbing, and wretchedness; all delineated with such exceeding truthfulness and power that one could pardon the satirist even though the moral were wanting. In his drawing he is correct: in his colouring, rich and transparent; and he displays a delicacy of execution equal to Metzen. He sometimes attempted historical subjects, but he was much too great a humorist to succeed in them. He lived and died a spendthrift. After his decease, which occurred in 1689, his works rose rapidly in value, and they are now sold at exceedingly high prices. Fine specimens of this master are to be seen in the collections of the Duke of Wellington, Sir Robert Peel, Lord Ashburton, Her Majesty, the Earl of Ellesmere, Mr Hope, Mr Lonsdale, the Earl of Carlisle, and others. The galleries at the Hague, Amsterdam, and St Petersburg contain also many excellent specimens of his painting.

Steevens || Steffani.

STEEVENS, George, was born at Stepney, in the county of Middlesex, in 1736. His father, who was a London merchant, and a director of the East India Company, placed his son at a school in Kingston-upon-Thames, where he had Gibbon, the future historian, as his companion. Steevens was subsequently placed on the foundation at Eton, and afterwards became a scholar of King's College, Cambridge, in 1754. His first publication was a four-volume edition of *Twenty of the Plays of Shakespeare, being the whole number printed in quarto during his lifetime*, 1766. On the whole, this reprint was exceedingly faithful; and in several instances of doubtful meaning, the various readings of other editions of the great dramatist were added in the foot-notes. The reputation which Steevens gained by this edition of Shakspeare, for minute, accurate, verbal acquaintance with early English literature, brought him into contact with Johnson and his literary acquaintances, and led to his association with the great lexicographer in the edition of Shakspeare which appeared in 1773 with their joint names. In 1778 Malone had rendered some assistance to Johnson and Steevens in the second edition of the works of Shakspeare, and in 1780 he published by way of Supplement an edition of the doubtful plays and poems of the poet. For this act Steevens, who fancied his vanity was hurt in the most vital part, resolved to be avenged of Malone, and accordingly set to work with an open contempt for all the Malones and their plodding diligence, to give to the English public a new Shakspearean metre, purged alike of "useless and supernumerary syllables, and an occasional supply of such as might fortuitously have been omitted." So great was his zeal in this new project which he had undertaken, that for eighteen months he went every morning before day-break from his house in Hampstead to his printers in London to correct the proof-sheets. This work was completed in 15 volumes in 1793. His experiment, strange to say, met with great success, and except Malone's edition of 1821, no popular issue of the works of Shakspeare attempted anything different till that of Knight appeared in 1838. Steevens, whose ample means put him beyond the necessity of literary labour, published very little else beyond his editions of Shakspeare. He assisted Nichols in his *Biographical Anecdotes of Hogarth*, and Isaac Reid in his *Biographia Dramatica*, and occasionally ventilated his acute and sarcastic mind in the pages of the *St James's Chronicle* and the *Critical Review*. In those journals he made the bitterest attacks on many literary characters to whom, when stripped of the guise of anonymity, he was all smiles, and bows, and courtesy. Whether or not this conduct can be freed from the charge of malignity, and be set down to the less guilty one of mere mischief, as Johnson asserted to Topham Beauclerk, it is at least certain, that if such doings could gratify his sense of power, the soul was a very mean one that could be touched by such base appliances. Among his numerous dirty tricks was his setting up Amner and Collins as literary scape-goats on whom he might father some of his more objectionable annotations, and ascribed a fierce attack on Capell to his less decided and more timid rival, Malone. Steevens died at Hampstead in 1800.

STEFFANI, Agostino, commonly known under the name of the Abbate Steffani, a celebrated composer of vocal music, was born in 1655, at the small town of Castelfranco, in the Venetian States. The fine quality of his voice obtained for him early employment in some of the churches of Venice. There, a German nobleman hearing him sing, was so delighted with the youth's musical talent, that he offered to take him to Munich and provide for him. Steffani accompanied his German patron to Munich, where he was placed under the famous Roman composer Giuseppe Ercole Ber-

nabei, then chapel-master in the service of the Bavarian court. From that master, one of a celebrated musical family, Steffani rapidly acquired skill in writing for voices; an art in which the Roman school was greatly distinguished. Having early entered into holy orders, he was, in due time, made abbot of Lipsing, and apostolic prothonotary; and, finally, Bishop of Spiga in Spanish America. These appointments he owed partly to his musical talents, partly to his diplomatic services. Besides composing several masses for the Elector of Bavaria's chapel, and motets for three voices and figured bass, he wrote the music of eleven operas, of which *Servio Tullio* was reckoned the finest. This opera induced the Elector of Brunswick to offer the place of chapel-master to Steffani, which he accepted. His new patron became afterwards Elector of Hanover. Steffani composed also sonatas for two violins, viola, and figured bass (*basso continuo*). In 1698 he published a small work in Italian, on *The Certainty of the Principles of Music, and its estimation among the Ancients.* His earliest publication was a collection of Psalms for eight voices, with a figured organ-bass. These appeared in 1674, when Steffani was only nineteen years old, and are masterly compositions. Padre Martini published one of them in the second part of his *Saggio di Contrappunto*, pp. 311–315. Padre Martini (ibid.) writes in the highest terms of the Abate Steffani's compositions, and particularly mentions his duets for two voices, soprano and contralto, with figured bass, printed in 1683: "Held," says Martini, "in great esteem by all professors of music, and in which are wonderfully displayed his deep knowledge, his great practical skill, and especially in double counterpoint of all kinds." These celebrated duets seem to have been studied as models by Clari, the author of charming works of the same kind, as well as of trios for three voices with figured bass. Handel gained much by studying the compositions of Steffani, Clari, and Scarlatti. In 1710, Steffani left his places of chapel-master and music-director at Hanover; pointing out Handel as his successor. After a long absence from Italy, he returned thither in 1729, and passed the winter at Rome in the society of Cardinal Ottoboni, that great patron of musical talent. Returning to Hanover, he was soon afterwards obliged to go to Frankfort, where he fell sick, and died in a few days, in the year 1730, aged seventy-five. Unfortunately, many of his works, composed for the court of Brunswick and Hanover, are now unknown. Among these were several oratorios, of which even the titles are forgotten. Might not some of these valuable manuscripts be even now recovered by careful research? (G. F. G.)

STEFFENS, HEINRICH, an eminent thinker of the last half-century, was born at Stavanger in Norway on the 2d of May 1773. Passing to Helsingör and Copenhagen, he entered the university of the latter city in 1790, and received a travelling prize four years afterwards. He resided successively at Bergen, Hamburg, Kiel, and Jena, and while in the latter town he became an enthusiast in the new philosophy which Schelling was then engaged in elaborating. Having been created adjunct professor of philosophy to the University of Jena, he then repaired to Freiberg, where he wrote his *Geognostisch-Geologischen Aufsätze*, which did not appear till 1810, and he elaborated his *Handbuch der Oryktognosie*, 1811–19. Returning to Denmark in 1802, he delivered a course of able lectures, but finding himself more at home in the lecture-halls of Germany, he accepted an invitation in 1804 from the University of Halle, where he became professor, and published his *Grundzüge der Philosophischen Naturwissenschaft* in 1806. During the succeeding years he took a very active share in the political struggles in which Prussia was then engaged with France. In 1813 he was made professor of physics and natural history at Breslau, and in 1831 he removed to a similar chair at Berlin, where he remained till his death in 1845.

As illustrations of the labours of Steffens in behalf of Schelling's philosophy, we may point to his *Anthropologie*, published in 1822, and to his *Polemische Blättern zur Beförderung der Speculativen Physik*, 1825–35. Besides occasional essays on subjects more immediately connected with the university, he likewise engaged in the religious controversies of the time, and wrote on the Pietistic side with much more than the average amount of thought and originality. He subsequently engaged in a series of novels, which, while portraying with much lively interest the deep religious feeling of his sect, and displaying very correct delineations of picturesque scenery, nevertheless are tainted by too much egotism and display of the feelings and opinions of the writer. During the last five years of his life he was engaged on an autobiography *Was ich erlebte*, which was subsequently published in 10 vols. Schelling wrote a preface to the posthumous works of Steffens.

STEIN, HEINRICH FRIEDRICH KARL, BARON VON, a distinguished Prussian statesman, was born at Nassau on the 15th of October 1757. He was sprung from a very old and noble family of Germany, who were in possession of large estates and of wide influence in the Prussian empire. He studied successfully at Göttingen, at Wetzlar, and at Vienna, and in 1779 he entered the Prussian service as a director of mines. On the death of Frederick the Great in 1786, Stein visited England, and spent much of his time and attention in inquiring into the social and political condition of the country. He was much impressed, it is said, by the spectacle of popular institutions and of popular freedom which everywhere met his eye. Stein returned to Prussia a wiser man than he left it, resumed his business in connection with the mines, and married the Countess of Wallmoden-Gimborn, by whom he inherited large property. He was subsequently appointed commissioner, director, president, and supreme president successively of the Westphalian Chambers of Wesel, Hamm, and Minden, and in this capacity he originated and executed numerous improvements in agriculture, roads, and general social economy.

Stein had not yet sufficient scope for the magnificent administrative schemes which were simmering in his brain. He had been appointed, in 1804, minister of indirect taxation, commerce, and the public debt, and he had set vigorously to work to introduce various reforms, when the misunderstandings between Napoleon and Frederic William III. brought his work to a stand-still. Stein, who from the first took a thoroughly patriotic view of the question, had to yield up his office in 1807. When he reappeared, the kingdom was shorn of much of its territory. Having been solicited to his side by his desponding master, Frederick William III., he developed his plan for the restoration of Prussia to a high place in the councils of Europe. "What the state loses," says Stein, "in *extensive* greatness, it must make up by *intensive* strength." He proposed to reorganize the entire administrative system of Prussia. He would lay his hand upon the people, as upon the real strength of the nation, and by emancipating them from the burdens to which they had been so long subjected, would destroy in a great measure the antiquated system of villeinage and of class distinctions under which so many of them had groaned for centuries. He proposed, also, to adopt a new scheme of militia service throughout the kingdom of Prussia. As a man of genius, with a strong will to guide his movements, generally overmasters other minds, as if by storm, so Stein in this instance got the ear of the king, and succeeded in apparently convincing him that the new scheme which he had just laid before him would materially improve his country and set Prussia in the front rank of nations. Stein's "system" accordingly got set on foot as warily as possibly, for Napoleon had no difficulty in seeing far over his own immediate horizon, and its operation was attended with the best

Stein-Am-Anger || Stenography.

results. The sleepless Napoleon had heard, however, of the doings of "one Stein" on the other side of the Rhine, and in November 1808 he was obliged to resign and take refuge in Austria. The military and municipal parts of his system were left to another to execute, and he began to concoct and bring forth the *Tugend-bund* or "Moral Union," a society which had in view the ultimate liberation of the entire German people. After spending some time in Russia, he accompanied the allies to Paris in 1814, and drew up his opinions on the re-organization of Germany. His enlarged views of free institutions, of popular election, and so forth, did not meet the taste of the Congress, and on Napoleon's fall, the weak king of Prussia, who had in his extreme need given in his adherence to the system of Stein, now that the enemy was chained to a lonely island of the sea, thought fit to bid good-bye to him and his system, and took refuge in the hereditary arms of absolutism. Baron Von Stein's name, however, shall live for ever among all who reverence free institutions, free representations, and free governments throughout the world. He received the Order of the Prussian Eagle in 1816, he had a place at the Congress of Aix-la-Chapelle in 1818, he was made a member of the Prussian Council of State in 1827, and he published the same year a critical review of Bourienne's *Life of Napoleon*, in some portions of which his own conduct had been commented on. The Baron died on the 29th of June 1831, leaving a name for statesmanlike qualities such as many in Germany will not willingly let die.

STEIN-AM-ANGER, a town of Hungary, in the government of Eisenburg, on the river Güns, and 12 miles E.S.E. of the town of that name. It has a splendid cathedral, three convents, an episcopal palace, philosophical seminary, gymnasium and other schools, and a museum of antiquities. Stein-am-Anger occupies the site of the ancient Roman colony Sabaria. Pop. 4300.

STELVIO, a celebrated pass across the Alps where they separate the Tyrol from Lombardy. It leads from Bormio in Italy to Glurns in the Tyrol, and the carriage-road by this pass, which was opened in 1824, is the loftiest in Europe, being at its highest point 9100 feet above the sea.

STENDAL, a town of the Prussian monarchy, capital of the Altmark in Saxony, in a fertile valley on the Uchte, near the left bank of the Elbe, 35 miles N. of Magdeburg. It is walled and entered by five gates; and it contains, among other buildings, a fine cathedral of the fifteenth century, four other Protestant churches, a Roman Catholic church, with numerous towers, a gymnasium, and an orphan hospital. Woollen cloth is manufactured here; and there is an active trade in linen. Stendal was at one time the residence of the margraves of Brandenburg. Winckelmann the antiquary was born here. Pop. 7484.

Roman shorthand.

STENOGRAPHY. The invention of the stenographic or swift mode of writing, by signs, employed by the Roman notarii in the time of the Cæsars, has been assigned by various authors to different persons. Diogenes Laërtius has been made to say that Xenophon first took down the sayings of Socrates in notes; but the original text may mean, that he merely noted down the sayings of Socrates. The Latins, however, claimed for themselves the invention of the Roman Notes. Ennius, about 150 B.C., is said to have invented 1100 common notes, or abbreviations; called common, because intended for general use. Plutarch rejects Ennius, and is in favour of Cicero. Eusebius gives the merit of the invention to Tyro, a freedman of Cicero's; and Seneca ingenuously attributes the invention and the cultivation of this species of writing to freedmen and slaves (as Tyro, Persennius, Aquila), whose performances were, according to the usage of the times, attributed to their patrons.

Tyro's notes.

These notes are constructed on the principle of extreme abbreviation of the letters of the Roman alphabet; for, though every letter of the alphabet is employed, very few words, comparatively, are written in full. Indeed, the characters are so ill adapted for joining, that hundreds of examples are found wherein, apparently to preserve the writing horizontal, the shape, slope, and size of the letters are variously modified, and the letters themselves either disconnected or written across each other. The Roman shorthand alphabet, with a specimen of Tyro's "Notes," written in it, is given in Pitman's *History of Shorthand*, in the *Phonotypic Journal* for 1847.

In this first system of shorthand of which we have any account, all the principles of stenography, as at present practised, were acknowledged; namely, the adoption of simpler forms than the common letters of the alphabet; making each letter the representative of some common word; leaving out such letters as could be spared, particularly the vowels, in order to save time; and sometimes joining or intersecting the initial letters of several words, so as to express them by one series of forms, and, if possible, without removing the hand from the paper or tablet. All that the authors of modern systems have gained in brevity over the ancients has been effected by the adoption of a simpler alphabet. The letters of Tyro's (or perhaps Cicero's) system of shorthand, were made by abridging the Roman alphabet; some of them were, therefore, necessarily complex. Modern stenographers have preferred a new alphabet, made of the simplest geometrical forms; and by sometimes classing under one sign two sounds that are nearly related to each other (as *f* and *v*, *s* and *z*), a right line and a curve in various positions, with the occasional addition of a small circle or hook at the commencement, have supplied a sufficient variety of signs for the letters of the alphabet.

Cato's speech on the Catilinian conspiracy taken down in shorthand.

By Tyro's system, according to Plutarch, was preserved the oration of Cato relative to the Catilinian conspiracy. In his life of Cato the younger, he remarks, "This, it is said, is the only oration of Cato's that is extant. Cicero had selected a number of the swiftest writers, whom he had taught the art of abbreviating words by characters, and had placed them in different parts of the senate-house. Before his consulate they had no shorthand writers." Soon after this, shorthand came into general repute among the Romans, and was patronised and practised by the emperors themselves. Augustus and Titus were proficients in it, and some of the authors of that age allude to the art in their works. Ovid, in speaking of Julius Cæsar, who wrote to his friends in shorthand, says, "By these marks, secrets are borne by land and by sea." Some passages in the Latin writers, that have been supposed to refer to shorthand, appear to refer to writing in cipher.

Early English systems

To England belongs the honour of having revived in modern times the useful art of shorthand writing, no original system having been published on the continent that can be compared with the popular English stenographies of the seventeenth and eighteenth centuries.

Summary of the history of English stenography.

There are four principal periods in the improvement and dissemination of the art since the revival of learning in the fifteenth century. The *first* period extends from the publication of the first alphabetic system by John Willis, in 1602, to the publicatian of the matured system of Mason, in 1682. During this period the system most used was that invented by Rich, afterwards practised, amended, and republished by Dr Doddridge. (Before Willis's shorthand alphabet appeared, Timothy Bright, in the reign of Elizabeth, 1588, produced a system of arbitrary shorthand characters that represented *words*. This, as far as is known, was the first treatise on the art in modern times.) The *second* period extends from 1682 to the appearance of Taylor's system in 1786, and during this time Mason's system enjoyed the greatest share of the public favour. It was republished by Thomas Gurney, in 1751, and is practised

by his descendants, as reporters to the government, to the present day. The *third* period reaches from 1786 to 1837, the date of the publication of Pitman's *Phonography*, or Phonetic shorthand. During this period Taylor's system was perhaps used more than any other; but many persons wrote the systems invented by Byrom (1767), Mavor (1789), and Lewis (1815). The *fourth* period reaches from 1837 to the present time. In these twenty-three years the practice of *Phonetic* shorthand has extended to almost every town and every large village in Great Britain and Ireland, and in the United States. This system we now proceed to explain, premising that it is as legible as ordinary writing, and may be written in from one-fourth to one-eighth of the time required for longhand, according to the skill of the writer, and his employment of the principles of abbreviation furnished in the system.

Explanation of terms. Phonetics (from φωνη, *phōnē*, voice), the things relating to the voice: the science which treats of the different sounds of the human voice, and their modifications. The style of spelling in accordance with this science is named Phonetic; the common style being called Romanic, because it is formed from an alphabet derived from that which was used by the Romans.

Phonography (from *phōnē*, voice, and γραφη, *graphē*, writing), the art of representing spoken sounds by written signs; also the style of writing in accordance with this art.

Phonotypy (from *phōnē*, voice, and τυπος, *tūpos*, type), the art of representing sounds by printed characters or types; also the style of printing in accordance with this art.

Phonogram (from γραμμα, *gramma*, letter), a written letter, or mark, indicating a certain sound, or modification of sound; as, — *k*, · *ah*.

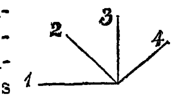
Logogram (from λογος, *logos*, word), a word-letter; a phonogram, that, for the sake of brevity, represents a word; as | *t*, which represents *it*.

Grammalogue, a letter-word; a word represented by a logogram; as *it*, represented by | *t*.

Phraseogram, a combination of shorthand letters representing a phrase or sentence.

Alphabet of nature. Phonography is based upon an analysis of the English spoken language. Its consonants and vowels are arranged so as to show, as far as possible, their mutual relations. In the consonants, *k* stands first, next *g*; the rest follow in perfectly natural order, first the mute or explosive letters, proceeding from the throat to the lips; then the semi-vocals, or continuants, in the same order; and lastly the liquids and nasals. Scarcely more than half the consonants are *essentially different*; the articulations in the pairs *k* and *g*, *t* and *d*, *f* and *v*, &c., are precisely the same, but the sound is, so to speak, light in the first, and heavy in the second letter of each pair. The consonants in each pair are represented by strokes in the same position, and of the same shape, but that chosen for the second is written *thick*, instead of *thin*. (See the shorthand signs for *k*, *g*; *t*, *d*; *f*, *v*, &c., in Plate XXXIX.) Thus, not only is the memory not burdened with a multitude of signs, but the mind perceives that a *thin stroke* corresponds with a *light articulation*, and a *thick stroke* with a *heavy articulation*. *K*, *t*, *p*, *sh*, *s*, *th*(*in*), *f*, are called light, or sharp consonants, and *sh*, *s*, *th*(*in*), *f*, are further denominated whispered, or breathed consonants; while *g*, *d*, *b*, *zh*, *z*, *th*(*en*), *v*, are heavy, flat, spoken, or murmured consonants. The distinction is, that in the flat letters (*g*, *d*, *b*, &c.) a vocal murmur is added to the action of the organs by which the sharp letters (*k*, *t*, *p*, &c.) are produced. The light sounds are also called *surds*, while all the other letters (including *ng*, *n*, *m*, *l*, *r*, *y*, *w*, and the vowels), are called *sonants*. *Ch* and *j* are double consonants, formed by the union of *t*, *sh*, and *d*, *zh*, as may be heard in fe*tch*, *ch*eap, e*dg*e, *j*em. They are placed next to the first elements *t*, *d*, which enter into their composition. The vowels are arranged naturally in two series, the first guttural and the second labial. Each series commences with the most open sound. The *short* vowels are represented by *light* dots and strokes, and their corresponding *long* sounds by *heavy* ones. After a few weeks' practice in writing phonography, the heavy strokes and dots are made without any perceptible effort; they are traced by the pen with as much facility as their corresponding heavy sounds are produced by the organs of speech.

Consonants. With one exception (*ch* and the upward *r*, as below), every right-line and curve employed in phonography is written in the direction of one of the lines in the annexed diagram, all straight lines and curves in direction 2 and the curves in direction 4 being inclined midway between a perpendicular and horizontal line. (For illustrations of single shorthand letters, see Plate XXXIX.; and for illustrations of joined characters, and the application of the various rules for writing, see Plate XL.)



Perpendicular and sloping letters are written from top to bottom, and horizontal letters from left to right. L, when standing alone, is written upward, and *sh* downward: *l* and *sh*, joined to other consonants, may be written either upward or downward, as may be convenient.

All the consonants in a word should be written without lifting the pen, the second letter beginning where the first ends, and so on. When a straight consonant is repeated, no break should be made between the two strokes; thus, —— *kk*. When a curved consonant is repeated, the curve should not be written larger, but doubled; thus, ⌣⌣ *nn*. Single consonants, and combinations of consonants that contain not more than one descending stroke, rest upon the line. When two descending letters are joined, the first should be made down to the line, and the second below.

As the straight line in direction 4, in the above diagram, may be written either up or down, it is made to represent two letters, namely, *ch* when written downward, and *r* when written upward; this additional sign being given to *r* for convenience and speed in writing. To diminish the risk of *ch* and *r* being mistaken for each other, / *ch* is made to slope 60 degrees from the horizontal, and ⁄ *r* when standing alone, 30. This line naturally takes these slopes when struck by the hand downward and upward respectively.

On account of their frequent occurrence, *s* and *z* are furnished with an additional character, particularly convenient for joining; thus o *s* or *z*. When the *s* circle is joined to straight letters, it is written on the upper side of *k*, and on the corresponding side of the other letters. When joined to curved letters, it is written inside the curve. When it occurs between two straight consonants, it is written on the outside angle. When it is joined to *l* only, the *l* is written upward; and when it is joined to *sh* only, the *sh* is written downward.

Vowels. There are six simple long vowels in the English language, namely,

	1.	2.	3.	4.	5.	6.
	ah,	*eh* (*a*),	*ee*;	*aw*,	*oh*,	*oo*;
as in	*a*lms,	*a*le,	*ee*l;	*a*ll,	*o*pe,	f*oo*d.

There are also six short vowels, of the same or similar quality, or tone, heard in the words

1.	2.	3.	4.	5.	6.
pat,	*pet*,	*pit*;	*not*,	*nut*,	*foot*.

The long and short sounds of Nos. 4 and 6 are identical in quality; Nos. 2 and 3 are nearly so; the long and short sounds of the pair No. 1 differ considerably in the south of Great Britain, but not much in Scotland: the greatest amount of difference exists in the pair No. 5.

The first three vowels are represented by a dot, and the last three by a short stroke or dash, written at a right angle with the consonant. The dot (for 1, 2, 3), and the dash

(for 4, 5, 6), are made heavy for the long vowels, and light for the short ones. When a vowel is placed on the left-hand side of a perpendicular or sloping consonant, it is read *before* the consonant; and when placed on the right-hand side, it is read *after* the consonant. A vowel placed above a horizontal letter, is read *before* the consonant, and when written under, is read *after* the consonant. This, it may be observed, is the way in which we read all European languages; namely, from left to right, and from top to bottom. The vowels are written at the side of the consonant, in three places,—at the beginning, middle, and end; the beginning of the consonant, whether written upward or downward, being the place of the first vowel-sign *ah*. The letter *l*, for instance, when written downward, has its vowels' places reckoned downward; and when written upward, the vowels are reckoned from the bottom upward.

Vowels placed at the beginning of a consonant (*ah* and *aw*, for example), are called *first-place vowels;* vowels written in the middle are called *second-place vowels;* and those written at the end are called *third-place vowels.*

The vowel points and strokes must be written at a little distance from the consonants to which they are placed. If allowed to touch, except in a few cases, they would occasion mistakes. The short vowels should not be called—No. 1, "short *eh;*" No. 2, "short *ee;*" No. 3, "short *i* (*eye*)," &c.; but—No. 1, "short *ah;*" No. 2, "short *eh;*" No. 3, "short *ee*," &c. It will be found more convenient when speaking of these short vowels to affix the letter *t* to each, and call them severally *at, et, it, ot, ut, ŏŏt.*

Diphthongs.

The double vowels heard in the words *ice, owl, ay, boy,* are represented by small angular marks.

I and *ow* are close diphthongs, accented on the second element; and *ai* (yes), *oi*, are open diphthongs, accented on the first element. Each is pronounced as one syllable. The shorthand signs for *i, ow, oi,* may be written in ANY place: *ai* is written in the FIRST place.

Letters Y and W.

The letters *y* and *w* are unlike any other consonants. They are, in fact, *consonants made from vowels; y* being a modification of *ee*, and *w* a modification of *oo;* as may be heard in pronouncing

yah, yeh, yih (or *yee*)*; yaw, yoh, yuh* (or *yoo*).
wah, weh, wih (or *wee*)*; waw, woh, wuh* (or *woo*).

It has been found expedient to represent these letters *in connection with the succeeding vowel,* by a *single sign,* having a vowel character; thus, ∪ ∩ ⊂ ⊃ These signs, like those for the simple vowels, are written by the side of consonants, in three places, heavy for long vowels, and light for short ones. When joined to consonants, they express *y* or *w* alone.

By prefixing *w* to the diphthong *ī*, the treble sound *wī* is heard, as in *twice.* It is represented by a small right angle, which may be written in ANY position.

The shorthand signs for the diphthongs, and double and treble letters of the *y* and *w* series, are always written in the same direction; that is, they do not accommodate themselves to the consonant to which they may be written, as do the signs for the simple vowels *aw, o, oo.*

Y and *w* are also furnished with full-sized consonantal forms, which are used like other consonants; thus,

yea, Yeo, use; way, away.

They give greater distinctness than the small curved double letters, in the writing of words which contain no other consonant than *y* or *w:* they are also serviceable when either of these letters is followed by *s.*

Letter H.

The aspirate occurs in English only when preceding a vowel, or *y, w,* which are modifications of vowels. It is expressed by a small dot prefixed to the vowel sign. When it is more convenient to use a consonantal form for this letter, it is written either downward, or upward, whichever may be most convenient for joining with the preceding or following letter. The names of the letters *y, w, h,* are *yay, way, aitch.*

General rules for writing.

In consequence of the deficiencies of the English alphabet, and the unphonetic character of our orthography, the spelling of a word can seldom be taken as a guide to its pronunciation. To write any given word, therefore, phonographically, its several *sounds* must first be ascertained: the student should then write the phonographic letters which represent them. The practice of phonography and the reading of phonotypy will improve the student's pronunciation, and train his ear to discriminate differences in orthoepy.

The circle *s* is generally used in preference to the stroke *s*. In any word that contains the circle *s*, the vowel is placed and read to the stroke-consonant, and not to the circle *s*, to which no vowel can be placed or read. The circle *s*, at the beginning of a word, is always read FIRST; and at the end of a word it is always read LAST. It may be made double-sized for *ss*. When a word begins with a vowel followed by *s* or *z*, or ends with a vowel preceded by *s* or *z*, the stroke form of the letter is used. The stroke *s* is used whenever it is necessary to place a vowel to this consonant. The stroke *z* is used in *all* words that begin with the sound of *z*.

When a vowel comes *between two consonants*, it is possible to write it either after the first, or before the second. Care must be taken not to write the vowel sign in an angle between two letters; as which might be read either *kee-p* or *k-ahp*. The three following rules are of general application.

FIRST-PLACE VOWELS are written after the *first* consonant. SECOND-PLACE VOWELS are written after the *first* consonant when LONG, and before the *second* when SHORT: it is thus known whether a second-place vowel sign is intended to express a long or a short vowel, independently of the heaviness or lightness of the vowel sign. THIRD-PLACE VOWELS are written before the *second* consonant. If the second consonant is the circle *s*, the vowel must necessarily be written after the first consonant.

When the diphthongs ∨ *ī* ∧ *ow*, are written by themselves for the words *I, how,* ∨ *I* is placed ABOVE the line, and ∧ *how* ON the line. When either of these diphthongs commences a word, the first place is the most convenient: in other cases they are both more easily written in the third place.

From the *kr* series of double consonants, a series of treble consonants is formed by making the hook into a circle; thus, *skr, str, spr.* They are used only initially. The same signs with a thick stem will represent *sgr, sdr, sbr.*

The *w* hook double letters (see Plate XXXIX., *wn, wm, wl, wr*), differ from those of the *kl, kr* series with respect to vocalization. The *kl, kr* double letters (or consonant diphthongs) are vocalized like the single consonants; that is, *a* (a dot in the first place), before *kl* is read *akl*, and *a* after *kl* is read *kla;* but with the *w* hook double letters (which are not consonant diphthongs), vowels can be written either before or after the *n, m, l, r,* represented by the stem of the letter, because *w* is represented by the hook.

N following a straight letter, is expressed by a final hook on the UNDER side of a horizontal stroke, and on the corresponding side of any other straight letter (see Plate XXXIX.); thus, *cane.* By making the hook into a circle, *s* or *z* is added; thus, *canes.* The *ns* circle is made double-sized for *nsez;* thus, *expenses.* After curves, the *n* hook is written inside the curve.

F or *v*, when following a *straight* letter, is expressed by a final hook on the UPPER side of a horizontal stroke, and on the corresponding side of any other straight letter; thus,

kf, tf, chf, pf, rf (upward);

as in *tough, cough.*

By halving any of the preceding letters, *t* or *d* is added, according as the letter is thin or thick; *t* being generally added when the letter is *thin*, and *d* when it is *thick;* thus, *bake,* *baked;* *rub,* *rubbed.* A vowel AFTER a half-sized consonant is read next to the primary single, double, or treble letter, and before the added *t* or *d;* thus, *point,* *bread.* *N, m, l,* and *r* are shortened for the addition of *t,* and these shortened strokes, when thickened, represent *nd, md, ld, rd.* *Lt,* when standing alone, is written upward; in other cases, either upward or downward: *ld* is always written downward. The practised phonographer may use a half-sized letter to represent either an added *t* or *d.* The only consonants that do not admit of being halved are *y, w, ng,* and the irregular *mp.* (All HOOKED letters are halved for the addition of *t* or *d.*)

A full-sized and a half-sized consonant, or two half-sized consonants, should not be joined unless they form an angle at the point of union; because it would sometimes be doubtful whether such combinations were meant for a single letter, or a full-sized and a half-sized letter, or two full-sized letters.

The termination *-tion* (*shon*), is expressed by a large final hook, twice as large as the *f* hook. After a curve it follows the direction of the curve. At the end of a straight letter beginning with a hook or circle, or springing from a curve, the *tion* hook, when final, is written on the OPPOSITE side, that the straightness of the letter may be preserved. In other cases, *-tion* when final, and following a straight letter, is written on the side opposite to that on which the preceding vowel is written, for convenience in vocalizing; thus, *caution,* *action.* After simple *t* or *d,* the *-tion* hook is always written on the right; thus, *addition.* The *n, f,* and *-tion* hooks may be used in the middle of a word, when it is convenient.

St is written by a small loop; as, *stock,* *fast.* This loop is used chiefly as initial or final, but it may be employed medially when the loop can be distinctly formed; as in *justify.* A loop half as long as a consonant, represents *str;* thus *strike,* *muster.* These loops may be combined with the initial *kr* and the final *kn* series of straight letters; thus, *against,* *striker.* *S* may be added to a final loop or to the large *ss* circle by continuing the stroke of the loop or circle; thus, *crusts,* *exercises.* A hook made by continuing the *s* circle to the other side of the consonant, adds *-tion (shn)* or *-sion (zhn);* thus, *possession.*

When a curved consonant is written twice its usual length, it expresses the addition of *thr* (in *father*), *tr,* or *dr;* thus, *neither.*

The prefixes in Plate XXXIX. are written near the following part of the word; but in reporting (except the dot *con*) they are joined, when it is convenient to do so, to save lifting the pen. When *con* or *com* is preceded by a consonant, either in the same word or the preceding word, *con* or *com* is understood by writing the syllable that follows, UNDER or CLOSE TO the consonant that precedes; thus, *inconstant,* *discompose,* *you will comply.* The preposition *in* may be expressed before the treble consonants, *skr, str, spr,* by a back hook; thus, *inscription,* *instruct.* Any consonant when disjoined from that which precedes it, expresses thereby the addition of *ality* or *arity,* or any other termination of similar sound; thus, *penalty,* *vulgarity.*

The learner should not attempt, at first, to bring into use all these abbreviating principles. He should be content to practise, for two or three weeks, a rather lengthened style of phonography, making much use of the simple consonants, until he feels confidence in the use of the phonographic characters, and in the principle of phonetic spelling. He may then gradually adopt the double and treble letters, and the prefixes and affixes, &c., *as he requires them;* that is, as he feels that the style he is employing is not brief enough for the manual dexterity he has acquired. In selecting one out of two or more possible forms for any word, the student must recollect that great ease in writing, and, consequently, the saving of time, is not secured by using hooked and grouped, and especially half-sized, letters, on all possible occasions; but he must learn to make a judicious selection, and employ those which are most easily written in any given case.

Grammalogues.

The single and compound letters are used in phonography to represent the most frequent words in the language. To write *the, and, that,* &c., in full, would be unnecessarily tedious; nor would these words, thus written, be more legible than when expressed by one simple and distinct character. Words so abbreviated are called *grammalogues,* or *sign-words,* and the shorthand letters that represent them are called *logograms,* or *word-signs.* The table in Plate XXXIX. is the result of numerous experiments in writing, continued through many years, for the purpose of ascertaining the most useful words to be abbreviated, and the shorthand letters by which they may be best represented. The stroke-vowels *aw, o, oo,* are used as logograms in each of these directions; thus,

all, too, two; oh, owe; awe, he; of, to; on, but; and, should.

And and *should* are written upward. *And* and *he* are represented by *dashes* instead of by their respective *dot* vowels, for the purpose of joining other words in reporting, and thus writing whole phrases without lifting the pen.

In the table of grammalogues (Plate XXXIX.), a word is occasionally printed with a hyphen; thus, *give-n;* or, with a double termination; thus, *importan$^{t}_{ce}$;* to intimate that the corresponding logograms represent both *give* and *given, important,* and *importance.* The context will show which is meant. *S* may be added to a logogram to mark the plural number or the possessive case of a noun, or the third person singular of a verb in the present tense.

In general, the positions of the grammalogues, ABOVE, ON, and THROUGH or UNDER the line, are determined by their vowels; and in the case of a word of more than one syllable, by its accented vowel. The positions of the vowels are:—1, *ah, aw, ī, oi, wī;* 2, *ā, ō;* 3, *ē, oo, ow, ū;* and the corresponding short vowels. The positions of the logograms are:—1, *above* the line; 2, *on* the line; 3, if down or up strokes, *through* the line; but if horizontal or half-length sloping, *below* it. Double-length curves take only the following positions:—PERPENDICULAR, *through* the line for ALL words; SLOPING, *on* the line for words containing first and second-place vowels, *through* the line for words containing third-place vowels; HORIZONTAL, 1, *above* the line, 2, *on* the line, 3, *under* the line.

The rules that determine the position of a grammalogue are, specifically, these four:—1. Common words are written, generally, on the line, because this position is most convenient: sometimes they are written in the first position, for the purpose of attaching other words in phraseography. 2. In the case of a word that contains several consonants, the letter chosen to represent it is written in the position which it occupies when the word is written in full. 3. In all other cases the logogram is written IN POSITION, in accordance with the vowel or accented vowel of the word which it represents. 4. But if that position is occupied by some other word, it is placed in the most convenient unoccupied position.

Stenography. In the following cases the name of the letter is the same as the sound of the word; the letter, therefore, represents the word: these may be called natural grammalogues;

\ *be*, ᵛ *I*, ˊ *awe*, ˡ *O! oh! owe*, ᵤ *ye*, ₙ *you*, ᶜ *we*.

These natural grammalogues it is not considered necessary to repeat in the list. Theoretically, *you, yōō*, or *ū*, is ₙ, but the light sign *yŏŏ* ₙ may be used in all cases. The double vowels ᶜ *wi*, ᶜ *wē*, when representing the words *with, we*, are written above the line, although they are third-place vowels, because this position is the best for attaching other words and forming phraseograms.

Outlines of words. As three letters in the phonographic alphabet (*y, s, r*) have duplicate forms, *w* three forms, *h* four forms, and two others (*sh, l*) are written either upward or downward; and as many groups of consonants may be expressed either by their alphabetical forms, or by abbreviations, it is evident that many words may be written in more than one way. For any given word the writer should choose that form which is most easily and rapidly written, and is at the same time capable of being clearly vocalized. The briefest outline to the eye is not always the most expeditious to the hand. The student will insensibly acquire a knowledge of the best forms by practice and observation.

Contractions. When *K* occurs between *ng* and *sh*, or *ng* and *t*, *P* between *m* and *t*, or *T* between *s* and another consonant, the *k, p*, or *t* may be omitted.

The downward *h*, when occurring before *m*, stroke *s, sh*, downward *r*, upward *l, nr*, &c., may be contracted to the simple tick ⁄; thus, *hm* (him).

The, the most frequent word in the English language, may be expressed by a short slanting stroke ⁄ joined to the preceding word, and generally written downward; thus, *in the*, but when more convenient, it is written upward. The first stroke of *on the* is made sloping to keep the sign distinct from ᵛ *I*. The tick *the* never BEGINS a phrase.

The connective phrase "of the," is *intimated* by writing the words between which it occurs *near to each other*, thus showing that the one is *of the* other.

A *or* AN.—*A* or *an* is joined to the preceding word by ı or -

The pupil is recommended to be sparing in his use of contractions in the first style of phonography. In the second, or reporting style, every legible contraction may be brought into use.

Phraseography. In longhand, swift writers join all the letters of a word together, and sometimes write several words without lifting the pen. So, in phonography several words may often be united. This practice, which is called phraseography, gives great assistance to the writer in following a rapid speaker. Some examples will be seen in Plate XL.

Punctuation, &c. Stops should be written in the usual way, except the period, for which a small cross is used; thus, , ; : × The hyphen is written thus, ⫽; the dash thus, ~~~; Interrogation (placed *before* the sentence); Exclamation; a smile. Accent may be shown by writing a small cross close to the vowel of the accented syllable. Emphasis is marked as in longhand, by drawing one, two, or more, lines underneath; a single line under a single word must be made wave-like, thus ~~, to distinguish it from ‿ *k*. In preparing manuscript for the press, a single line thus drawn underneath (wavy for a single word, and straight for more than one), signifies *italic;* two lines (which need not be waved) SMALL CAPITALS, and three lines LARGE CAPITALS. An initial capital is marked by two short lines under the word; thus, *The Times* newspaper, *Abel*. Figures are written as usual, or the words may be expressed in phonography. *One* and *two*, being grammalogues, are represented by their respective logograms. When the figures *one* and *six* are written by themselves, they should be formed thus, *1*, *6*, that they may not be mistaken for shorthand characters. (I. P.)

Stephanus, Byzantinus. STEPHANUS, BYZANTINUS, a learned grammarian, who flourished about the close of the fifth century. Nothing is known regarding him, even his very age has been questioned. He wrote a geographical lexicon, probably the first of its kind ever written, in which he made a great number of observations, borrowed from mythology and history, which showed the origin of cities and colonies, and of which we have little remaining but an abridgment by Hermolaus the grammarian. Even in this state, it has been found a work of no inconsiderable value. It is alphabetically arranged, and bears the inscription Περὶ Πόλεων, or *Concerning Cities*. The first edition was printed by Aldus, Venet., 1502, fol. This was followed by an edition printed by the heirs of P. Junta., Florent., 1521, fol. The text received many emendations in the edition of Xylander, Basil., 1568, fol. All these editions contain the Greek text, without any Latin version. An edition, with a translation and copious annotations, was published by Thomas de Pinedo, Amst., 1678, fol. Another edition, with a translation and a commentary, was prepared by Berkelius, and after his death was completed by J. Gronovius, Lugd. Bat., 1688, fol. Nor must we here omit the posthumous *Notæ et Castigationes* of Holstenius, Lugd. Bat., 1684, fol.

Stephanus, Robert. STEPHANUS (Fr. *Etienne* or *Estienne*, Eng. *Stephen*), *Henry*, the founder of a most remarkable and meritorious family of printers, was born at Paris in the year 1470. He began the business of a printer about the year 1503. This is the date of Boethius's treatise on arithmetic, the first book that is known to have issued from his press. A great proportion of the books which he published were Latin. They are printed in the Roman letter, and are not inelegant, though some of them abound rather too much in contractions. He died about the year 1520, and left behind him three sons, Francis, Robert, and Charles. His widow married Simeon de Colines (*Colinæus* in Latin), who thus got possession of Henry's printing-office, and continued the business till his death.

Of Francis, the eldest son, little more is known than that he carried on business along with Colinæus, and that he died at Paris in 1550.

STEPHANUS, *Robert*, the second son, was born at Paris in 1503. In his youth he made great proficiency in the Latin, Greek, and Hebrew languages, and at the age of nineteen had acquired so much knowledge that his stepfather intrusted him with the management of his press. He soon afterwards began business himself, and married Perrete, the daughter of Jodocus Badius, a printer and an author. She was a woman of learning, and understood Latin, which indeed was the necessary consequence of her situation. Her husband always entertained a number of learned men as correctors of the press. Being foreigners, and of different nations, they made use of no other language but Latin, which Perrete being accustomed to hear, was able in a short time not only to understand, but even to speak with tolerable ease.

In 1531 he published his *Thesaurus Linguæ Latinæ*, a work of great labour, and of great value. The device which he exhibited in all his books was a tree branched, with a man looking upon it, and these words *Noli altum sapere*, to which he sometimes added, *sed time*. In 1539, Francis I. made him his printer, and ordered a new set of elegant types to be founded for him. His frequent editions of the New Testament gave great offence to the doctors of the Sorbonne, who accused him of heresy for his annotations, and insisted upon the suppression of some of his books. Although Henry, the French king, in some measure protected him, the persecution of these divines ren-

dered him so unhappy, not to mention the expense and loss of time which an almost constant attendance at court unavoidably occasioned, that in 1552 he abandoned his country and settled at Geneva. Here he embraced the Protestant religion, and thus justified in some measure the suspicions of his theological enemies. It has been affirmed by several writers, that he carried along with him the royal types, and the moulds in which they were cast; but it is certain that he never afterwards made use of those types. Besides, is it possible that the author of so daring a theft could have been not only protected in Geneva, but even courted and honoured by the most eminent men of the age? Is it credible that such a crime could have been concealed for sixty years; or that Henry, the son and heir of the perpetrator, would have enjoyed the favour of the French king, if Robert Stephanus had acted such a shameful part? If he was burned in effigy at Paris, it was not for theft, but for having renounced the popish faith. After his arrival at Geneva, he published an account of the dispute between him and the Paris divines, which does as much honour to his abilities as his *Thesaurus* does to his learning. He died in 1559, after a life of the most extraordinary industry. The books of which he was the editor were not fewer that 360. Many of them were ancient classics in different languages. Several were accompanied with annotations which he collected, and all of them were corrected by the collation of manuscripts. He was so anxious to obtain perfect accuracy, that he used to expose his proofs in public, and reward those who discovered a mistake. His books consequently were very correct. It is said that his New Testament, called *O Mirificam* (because the preface begins with these words), has not a single fault. It was Robert Stephanus who first divided the New Testament into verses, during a journey between Paris and Lyon. The advantages of this improvement are fully counterbalanced by its defects. It has destroyed the unity of the books, and induced many commentators to consider every verse as a distinct and independent aphorism. By his last will his estate was left exclusively to such of his children as should settle at Geneva. He left behind him three sons, Henry, Robert, and Francis.

Stephanus, *Charles*, the third son of Henry, was, like the rest of his family, familiarly acquainted with the learned languages. This recommended him to Lazarus de Baif, who made him tutor to his son, and in 1540 carried him along with him to Germany. He studied medicine, and took his doctor's degree at Paris. He did not, however, forsake the profession of his family, but exercised it at Paris, where he became the editor of many books remarkable for neatness and elegance. He wrote above thirty treatises on different subjects, particularly on botany, anatomy, and history. Having been unsuccessful in business, he was imprisoned for debt in the Chatelet in 1561, and died there in 1564.

Stephanus, *Robert*, the son of Robert the first of that name, did not accompany his father to Geneva, but continued to profess the Romish religion, and to reside at Paris. His letter, as a printer, was remarkably beautiful. He was made king's printer, and died about 1589. His brother Francis, who was also a printer, embraced the Protestant religion, and resided at Geneva.

Stephanus, *Henry*, the eldest brother, was born at Paris in 1528. He became the most learned and most celebrated of all his family. From a very early age he gave proofs of uncommon abilities, and displayed an ardent passion for knowledge. The *Medea* of Euripides, which he saw acted while at school, first kindled his love for poetry, and inspired him with the desire of acquiring the language in which that tragedy is written. He entreated his father not to condemn him to study Latin, which he already understood from conversation, but to initiate him at once in the knowledge of Greek. His father willingly acceded to his request; and Henry applied with such vigour, that in a short time he could repeat the *Medea* by heart. He afterwards studied Greek under Danesius, who was tutor to the Dauphin, and finally heard the lectures of Tusanus and Turnebus. At an early age he became eager to understand astrology, and accordingly attended a professor of that mysterious art; but he was not long in discovering its absurdity. At the age of nineteen he began his travels, which he undertook in order to examine foreign libraries, and to become acquainted with learned men. He spent two years in Italy, and returned into France completely master of Italian, and bringing along with him copies of several scarce authors, particularly a part of Anacreon, which previously was supposed to be lost. He found his father publishing an edition of the New Testament, to which he prefixed some Greek verses. Soon after he visited England and the Netherlands, where he met with John Clement, an Englishman, to whom he was indebted for the remaining odes of *Anacreon*. During this journey he learned the Spanish language, which was very much spoken at that time in the Low Countries.

Whether Henry accompanied his father to Geneva, is uncertain: if he did, he must have returned immediately to France, for we find him soon after established at Paris, and publishing the odes of Anacreon. In 1554 he went to Rome, and thence to Naples. This journey was undertaken at the request, and in the service, of the French government. He was discovered, and would have been arrested as a spy, had he not by his address and skill in the language of the country been able to pass himself off for a native of Italy. On his return to France he assumed the title of printer to Ulric Fugger, a very rich and learned German merchant, who allowed him a considerable pension.

In 1560 he married a relation, as is generally supposed, of Henry Scrimger, a Scottish scholar and civilian, with whom he was intimately acquainted. His wife was a woman, as he himself informs us, endowed with the noblest spirit and the most amiable disposition. Her death, which happened in 1586, brought on a disease that had twice attacked him before. It was a disgust at all those pursuits which had formerly charmed him, an aversion to reading and the sight of books. It was probably occasioned by too constant and severe an application to literary pursuits. In 1572 he published, in four vols. folio, his *Thesaurus Linguæ Græcæ*, one of the greatest works, perhaps, that ever was executed by one man, if we consider the wretched materials which most ancient dictionaries could furnish, the size and perfection of the work, and the immense labour and learning which must have been employed in the compilation. In 1573, he added *Glossaria duo, e situ vetustatis eruta*. This work had been carried on at a greater expense than he could well bear. He expected to be reimbursed by the sale of the book, but he was unfortunately disappointed. Scapula, one of his own correctors, extracted from it whatever he thought would be most serviceable to students, and published it beforehand in quarto. By this act of treachery Henry was reduced to poverty.

About this time he was much beloved by Henry III. of France, who treated him so kindly, and made him such flattering promises, that he resided frequently at court. But these promises were never fulfilled, owing to the civil wars which soon after distracted France, and the unfortunate death of Henry himself. During the remainder of his life, his situation was very unsettled. We find him sometimes at Paris, sometimes at Geneva, in Germany, and even in Hungary. He died at Lyon in 1598, at the age of seventy. His temper during the latter part of his life is represented as haughty and severe, owing probably

to his disappointments. He was twice married, and by his first wife had a son and two daughters, one of whom was married to the learned Isaac Casaubon.

This most erudite printer was fond of poetry from his very infancy. It was his practice to compose verses on horseback, and even to write them, though he generally rode a very mettlesome steed. His *Thesaurus* was his great work, but he was also the author of many other treatises in the French and Latin languages. His poems are numerous. His *Apologie pour Heredote* is a very singular performance. It has been illustrated by the annotations of Duchat. The number of books which he published, though fewer than his father, was great, and they were superior in elegance to anything which the world had then seen. A great proportion of them were Greek. He was the editor, however, of many Latin and even of some oriental writings. His Greek classics are remarkably correct; and many of his editions are accompanied by most learned notes. His *Thesaurus* still maintains its reputation. An edition, with very ample editions, was recently published by Barker and Valpy; and another elaborate edition has been published at Paris.

STEPHANUS, *Paul*, the son of Henry, was born at Geneva in 1566, and continued his father's profession. He executed translations of several books, and published a considerable number of the ancient classics; but his editions possess little of his father's elegance. He died in 1627, at the age of sixty, after selling his types to one Chouet, a printer. His son Antony, the last printer of the family, abandoned the Protestant religion, and returned to France, the country of his ancestors. He received letters of naturalization in 1612, and was made printer to the king; but managing his affairs ill, he was reduced to poverty, and obliged to retire into an hospital, where he died in 1674, miserable and blind, at the age of eighty. Almeloveen *De Vitis Stephanorum*, Amst., 1683, 8vo; Maittaire, *Historia Stephanorum*, Lond., 1709, 8vo; *Biographie Universelle*, tom. xiii., p. 386; *Nouvelle Biographie Générale*, tom. xvi., 1856.

STEPHEN, SIR JAMES, long a faithful servant of the Colonial Department of the British Government, and a successful essayist, was born in London in 1789. He was educated at Trinity Hall, Cambridge, where he took his bachelor's degree in 1812. He subsequently adopted the legal profession, and was called to the bar at Lincoln's Inn. He had scarcely begun practice as a Chancery barrister when he received an appointment as counsel in the Colonial Department. He subsequently gave up his practice as a barrister, and became counsel to the Board of Trade, a situation which he soon after renounced for the assistant-under-secretaryship for the Colonies. Stephen afterwards became permanent under-secretary in the same office till 1847, when he resigned. During his long service he was, without question, one of the most efficient functionaries which the government possessed. In 1855 he published his views in a *Blue-book* regarding the reorganization of the civil service, when competitive examination was first broached as a means of determining the fitness of young men for public offices. On the whole, the opinion expressed by him of the public offices is not high. There are, however, he says, noble exceptions; and certainly the writer himself was one of the noblest. On his retiring he received the honour of knighthood, and he was appointed Regius-Professor of Modern History in the University of Cambridge in 1849. He was elevated to the latter post by reason of his extensive acquirements in history and in biography, prosecuted during the leisure hours of his official employment. He had contributed extensively to the *Edinburgh Review* on subjects pertaining to ecclesiastical history and general religious biography; and he issued in 1849 *Essays in Ecclesiastical Biography*, which have been well received by the public. He published likewise some very popular *Lectures on the History of France* in 1851; and, except an occasional lecture delivered before some popular institution, his publications close with this year. Sir James Stephen died at Coblentz on the 15th September 1859. His son, Fitzjames Stephen, who has likewise followed the law, is at present (March 1860) engaged on a Life of his father, which will appear prefixed to a new edition of his *Essays*.

STEPHEN, sovereigns of Rome, of Hungary, and of England; which see.

STEPHENSON, GEORGE, the founder of the railway system in Britain, and the principal improver, or (as some think) almost originator, of the present locomotive steam-engine. Some incidents in the life of this great mechanician having been mentioned in Professor James Forbes' *Dissertation* in vol. i., (pp. 883, &c.) of this work, and some observations having been there added on his part and share in the construction of the locomotive-engine, it will be unnecessary in this place to repeat what is previously recorded, and we shall therefore only cursorily notice the chief points in the life and mechanical triumphs of the subject of this biographical sketch.

In a poor cottage in the primitive, rough village of Wylam, eight miles west of Newcastle-on-Tyne, George Stephenson was born, on the 9th of June 1781. The various incidents connected with his humble origin and early occupations have the air of romance when contrasted with his ultimate attainments, fortune, and fame. Few tours in this country are more suggestive than one which the writer has undertaken to trace out the scenes and circumstances in which George Stephenson first lived and laboured; nor even yet has the most been made of the wonderful transition from obscurity to celebrity, from abject poverty to abundant wealth, from comparative ignorance to ample knowledge, fiom primitive simplicity to large experience, which has been exemplified in the life of the Wylam lad—the Killingworth breaksman; the bold projector and constructor of the Liverpool and Manchester Railway; and, finally, the owner and worker of Midland collieries, and the world-known engineer, the companion of men of science, and the father of a son who continued and augmented the glory that gathers round the name of Stephenson.

Taking up the biography of George Stephenson from the year 1804, he became a breaksman at Killingworth Colliery, seven miles north of Newcastle. The times were hard, taxes heavy, and his own prospects in particular rather gloomy. He was drawn for the militia, paid for a substitute, and contemplated emigration to the United States. Poverty prevented the step. He mended clocks and watches, repaired shoes, and cut out pitmen's clothes. Every spare minute was improved, and his observing eye was always vigilant. He improved the winding-engines of the colliery, and was fortunate in repairing and refitting a failing pumping-engine. His fame as an "engine-doctor" grew, and he was appointed colliery engine-wright at Killingsworth.

Railways were first employed in the northern collieries, the visitor to which may even now behold some remains of primitive attempts of this kind. The Wylam waggon-way is one of the oldest, and down to 1807 it was formed of wooden spars or rails, and passed close in front of the cottage where George Stephenson was born. In 1808 this wooden road was taken up, and supplanted by a "plateway" of cast-iron (a single line of rails), with sidings. In 1811 a locomotive-engine was ordered from Trevethick; and another in 1812, after the same pattern, was constructed at Gateshead. These ran upon the Wylam Railway, and are interesting though somewhat clumsy specimens of the earlier locomotives. It is remarkable that at this very time steam, in its other applications, had become a great industrial power,

Stephenson, George.

and was performing the work of thousands of horses. It had even then revolutionized the whole domain of human industry. It was driving mills and machinery, rolling iron, spinning cotton, grinding corn, and to some extent impelling ships over the waters; but the general adoption of the locomotive, which was to bring together towns and cities, almost to annihilate distance, and to confer upon man as much enjoyment and as many capabilities as if he had been endowed with wings, was not yet thought of, and could hardly have been conceived by the most sanguine spectator of the rude, unwieldy machines then creeping along the plateways of the northern collieries.

Stephenson made his first locomotive at Killingworth, and it was the first engine which had smooth wheels, the constructor being satisfied of sufficient adhesion between the toothless rim and an edge-rail. It was first placed upon the Killingworth Railway on July 25, 1814, but its performances were not remarkable. He constructed his second locomotive in the succeeding year, but its improvements were not great. In 1816 he constructed other engines, in which he further simplified the working parts, and amended the whole by resting the weight on four small cylinders, a plan which was afterwards abandoned for ordinary springs. These engines regularly dragged coals at Killingworth, and the writer has seen one of them at that colliery. Mr Stephenson became engineer of the Hetton Colliery Railway, which was opened in 1822, where five of his locomotives were soon at work. To meet the anticipated demand for these engines, he entered into arrangements with Mr Edward Pease in 1823, and soon afterwards erected the famous locomotive manufactory at Newcastle. The Stockton and Darlington Railway was opened for traffic in 1825, and the first engines employed on it were constructed after the Killingworth model, travelling at a speed of from six to eight miles an hour. Mr Stephenson was appointed in 1826 to survey the line for a railway between Liverpool and Manchester; and the history of this railway is to a great degree that of Mr Stephenson's advances; but when the line was completed the directors hesitated to adopt locomotives. A trial, however, was conceded, a prize of L.500 offered for the best engine, and on October 1, 1829, three engines appeared, and competed on the 6th. The Rocket was made by Stephenson. On the evening preceding the trial he added to it the blast-pipe, copied from the Sanspareil, a rival engine by Mr Hackworth. Up to that time the Rocket had only attained 15 miles an hour; but on the following day it ran at the amazing velocity (for that period) of 29 miles an hour, while the Sanspareil could only reach 22 miles. Controversy has settled that the merit of the blast-pipe is due to Mr Hackworth, whose engine, however, was disabled, and the Rocket obtained the prize.

It would be vain to attempt to condense into a few lines the several improvements which the locomotive experienced since that memorable trial, but their leading principles remain to this day, although numerous ingenious engineers have studied all its details, and have devised considerable improvements in its working parts, by which greater economy of fuel has been effected, and greater speed attained. The invention of the steam-blast has been attributed to Mr Stephenson, but those who are intimately acquainted with its history accord it to Mr Hackworth, and this has been contested against Dr Smiles, the biographer of Mr Stephenson. The summing up of those who hold this view is, that the speed of the locomotive-engine is mainly due to the application of Hackworth's blast-pipe, Booth's or Seguin's multitubular boiler, and Trevethick's high-pressure engine. It is therefore contended that George Stephenson did not contribute any very important *inventions* to the locomotive, but is entitled to a large share of the merit due to its ultimate success, inasmuch as he admirably simplified the machinery, and brought all possible mechanical skill to bear upon the accuracy and solidity of its workmanship, while as a private and public advocate of its powers and prospects (together with those of railways) he was second to none, manifesting and partly inspiring an almost unlimited faith in this great triumph of mechanical adaptation.

Mr Stephenson attained the culminating point of his fame upon the completion and success of the Liverpool and Manchester Railway. His subsequent life was one of activity as a railway engineer; but others now emerged from obscurity, and shared his triumphs, while they rather confirmed than lessened his celebrity. The article RAILWAYS details the various improvements in the system which were adopted at different times; while the history of railway progress, so far as it was contemporaneous with Mr Stephenson's life, displays not more his co-operation than his singleness of purpose and integrity of character. He discountenanced the lamentable railway mania, and stood, in the main, aloof from its trickeries and infatuations. He visited other countries as an engineer, and was greatly honoured in all such visits. Finally, he retired to Tapton, opened extensive collieries, and lived the life of a plain but wealthy country gentleman. In 1845 he took a warm interest in horticulture, built melon-houses, pineries, and vineries, and contended as eagerly with the cultivators of exotics as he formerly did with mechanicians, while his early affection for birds and animals revived. We have not referred to his improvements in the miner's lamp, mainly because they are noticed in the preliminary dissertation, already alluded to. He died 12th August 1848, aged 67. We should say his leading characteristics were sagacity, enterprise, and persistence.

Dr Smiles has written a popular life of this great man, replete with interesting details, but not, we think, always accurate in mechanical history. A "biography in brief" of Mr Stephenson may be found in the little work, *Our Coal and our Coal-pits, the People in them, and the Scenes around them* (pp. 228, &c.) Several points of interest in the history of the locomotive-engine have been discussed in technical periodicals, and might be advantageously collected into one publication. (J. R. L.)

Stephenson, Robert.

STEPHENSON, *Robert*, son of the preceding, was almost equally eminent as a mechanical engineer, and perhaps in some respects his father's superior. His father was married to his mother in 1802, and the Stephenson family then resided at Willington, near Newcastle-on-Tyne. Their son Robert was born there in 1803, in an humble cottage, where his father was often busy in making or mending shoes, cleaning clocks, or drawing rough sketches. Robert was christened in the school-house at Wallsend, and his earliest days were spent like those of the children of mechanics. His father's earnest wish was to give his son that education the want of which he himself so severely felt. When a widower, all his savings were accumulated with this object in view. He sent his child to school, and the boy picked up the elements of mechanics by frequenting, during long evenings, the library of the Literary and Philosophical Institute at Newcastle. Adding these acquirements to the lessons of the common workshop, he became expert in his department of knowledge. At Killingworth he made a sun-dial when he was thirteen years of age, and affixed it to his father's cottage-door, to the life-long gratification of the latter. This, however, was named to the writer as the father's work.

The son was apprenticed to the viewer of a colliery in the neighbourhood about 1819, and after spending two years in that occupation, he was in 1822 despatched to the University of Edinburgh for a session, during which he so far profited as to return with a prize for mathematics. He now spent a year or two in his father's locomotive manufactory at Newcastle, of which he was hereafter to become the principal. Having been sent out to report upon the gold

Stephenson, Robert.

and silver mines of Columbia and Venezuela, he passed two or three years in South America, and returned to England in 1827 or 1828, to find his father deeply engaged in preparing, and strenuously contending for, railways and locomotives. He devoted the ensuing four or five years to the improvement of locomotive-engines, which underwent great changes under his watchful superintendence. He made experiments upon the application of heat, the strength of cylindrical and other boilers, the best mode of riveting flat portions of the same, and established all his improvements upon the issue of such experiments. The Rocket and Planet engines were in a great measure the result of his researches, combined with those of his father, the Planet being the type of the present locomotive.

About this period (1830) he executed the Leicester and Swannington, Whitby and Pickering, and two other railways, and planned a large locomotive manufactory at Newton in Lancashire; but whilst these works were in progress, his father and others were engaged in the first survey of the great railway from London to Birmingham, and subsequently he himself was engaged upon it, and walked over the whole distance—it is said twenty times—in order to determine the best line. By the close of 1831 the requisite plans were deposited, preparatory to application for an act in the ensuing session of Parliament. The contest before committees was protracted and severe, and no less than L.72,868 were expended in carrying the bill from first to last through Parliament. The difficulties which the Messrs Stephenson encountered in the actual construction of this important railway are generally known. Extensive tunnellings and excavations, besides long embankments, had to be executed by the best contractors of that day, who, however, were mostly new to works of this nature, while specifications for various peculiar kinds of work had to be prepared by the engineers. Opposition from Northampton necessitated the Kilsby tunnel, which penetrated 160 feet below the surface for a length of 2400 yards. This tunnelling was let to a contractor for L.90,000, and appeared feasible, and free from great impediments; but it was found that at 200 yards from the south end a hidden water-bearing quicksand, overlaid by a thick bed of clay, extended 400 yards into the proposed tunnel. Eminent engineers despaired of success; but Mr R. Stephenson devised means by which the tunnel was ultimately completed in thirty months from the time of laying the first brick (of which 36,000,000 in all were used). During eight months no less than 1800 gallons of water per minute were raised and carried away by steam-engines from the quicksand; in all, 13 steam-engines, 1250 men, and 200 horses, were engaged in this task, and the total cost of the tunnel amounted to about L.350,000.

In the course of this line enormous sums were paid for land and compensation; in one instance, L.3000 was given for a piece of land, and L.10,000 for consequential damages, though in the end the land was greatly enhanced in value by the railway. From this and similar causes, the original estimates which Mr R. Stephenson had laid before Parliament, amounting to L.2,750,000, were so largely increased that the expenditure had equalled nearly L.5,000,000 before the railway was opened for traffic. During nearly five years had Mr Stephenson, as engineer-in-chief, borne the heavy responsibilities and anxieties of this great undertaking; and it was indeed a day on which he might well feel honourable pride, when, with a small party (of whom the writer was one), he travelled by the first locomotive that had traversed at one and the same time the entire line of 112 miles.

His fame as a railway engineer was now at its culminating point, and he was henceforward fully occupied for several years in devising and superintending the construction of other lines. Of these the principal were the Midland, Blackwall, Northern and Eastern, Norfolk and Chester, and Holyhead, not to name numerous branch lines. Abroad, too, his services were sought either as consulting or constructing engineer; and thus he took part in the system of Belgian and Italian railways, and was employed on some of the principal lines in France, Holland, Norway, Denmark, Canada, New Zealand, Egypt, and India. In connection with the English lines he gave much parliamentary evidence, and was concerned in several hotly-contested questions, such as the "battle of the gauges," as well as in numerous reports, arbitrations, and consultations.

As a railway engineer, his attention had been necessarily much directed to bridges, and several of those now standing on various lines attest the skill and taste of the engineer-in-chief and of his able assistants. He was thus led to consider the possibility of adapting malleable iron to a larger extent in bridges, and for far wider spans than had heretofore been attempted. His own article, IRON BRIDGES, contributed to this *Encyclopædia*, contains his mature views on this subject, as well as the details of the principal erections of this character, with illustrations. We shall, therefore, content ourselves here with saying, that his own skill in this department is exhibited in some of the greatest constructions in iron-bridge building now existing. Not to dwell upon the High-level Bridge at Newcastle and some others, we particularly refer to the Conway and Britannia Tubular-Bridges in North Wales. The latter is, indeed, celebrated through all countries, and is an object of wonder to foreigners. Its principle was a subject of profound study and frequent experiments by Mr Stephenson and his very able assistants. It must be mentioned that Mr Fairbairn claims the merit of being the originator of the tubular principle; but into the controversy on this question we are not called upon to enter, nor is this the place to pronounce upon the respective claims of either of these two eminent engineers. The bridge itself is a marvel of massiveness, design, and perseverance. Unsightly in some aspects, it is nevertheless grand as a whole. The weight of malleable-iron in it is no less than 9480 tons, and that of cast-iron 1988 tons. The length of the long tubes (in place) is 488 feet, 8 inches; their height above low-water (the Menai Straits) is 121 feet, 6 inches; above high-water, 100 feet; and the weight of each tube is 1803 tons. By this erection the value of the tubular principle is demonstrated, and the ability of all concerned established.

A bridge was commenced and built, under the direction of Mr Stephenson, across the St Lawrence, extending nearly two miles, and is now opened in connection with the Grand Trunk Canadian Railway. Unprecedented difficulties had to be overcome in founding the piers of this bridge in the rapid waters of the river, and it was necessary to sink the foundations below its bed, thereby reaching to a great depth, while operations could only be carried on during a period of the year. Grandeur of conception and successful execution are here combined in the most remarkable degree. In these respects, and in magnitude, it may be regarded as the engineer's greatest work in iron-bridge building.

It will be unnecessary to refer to minor labours and triumphs, but it should be recorded that in all his public works Mr Stephenson had the good fortune to be ably seconded by his subordinates, in selecting whom he displayed considerable judgment. Some of these may remain unknown, but others are in the front rank of the profession of their former chief.

In public life Mr Stephenson became further known (in 1814) as M.P. for Whitby, and as a respected speaker in the House of Commons upon his own subjects. In private life no man could be more honoured, loved, and happy. Great wealth, and numerous and attached friends, were his fortunate lot. He died 12th October 1859, aged 56 years. His remains were honoured with a public funeral and in-

Stepney || Stereoscope.

terment in Westminster Abbey, which was crowded on that occasion with a multitude of mourners distinguished by professional eminence and rank. Thus was he favoured in life and lamented in death. It is said that he once declined the honour of knighthood. No title would have added materially to his celebrity, and his fame will probably last as long as his great public works, which, after all, form his most appropriate and enduring memorials. To every railway traveller it may be said, with reference to the Stephensons, as once in relation to Wren and St Paul's Cathedral, *Si monumentum quæris circumspice.* (J. R. L.)

STEPNEY, a parish of England, and eastern suburb of London, in the borough of Tower Hamlets, lying to the east of the city, $2\frac{1}{2}$ miles E. of St Paul's. It contains numerous churches and dissenting places of worship, a grammar and other schools, a Baptist college, the London Hospital, and other charitable institutions. Many manufactures are carried on here to a considerable extent; among other establishments there are breweries, manufactories of sail-cloth, sails, tobacco-pipes, ropes, chain-cables, and steam-engines. Stepney contains the basin of the Regent's canal, which here joins the Thames. Area, 812 acres. Pop. 80,128.

STEREOSCOPE. The name *Stereoscope*, derived from the Greek words στερεός, *solid*, and σκοπεῖν, *to see*, has been given to a binocular optical instrument of modern invention, by which plane representations of figures or landscapes, or any objects whatever, as seen separately by each eye, are combined into one picture, which appear solid or in relief. Unlike other optical instruments, it cannot be used by persons who see only with one eye.

History.

As in all important inventions, the principle of the instrument, as well as its construction, has been claimed for different persons. The fundamental principle of the stereoscope is, that the pictures of any solid object, as seen by each eye, are different; that is, if an artist draws any solid object, as seen with each eye separately, the pictures will be different. Every body knows this that chooses to inquire into the matter; the right eye sees the right side of the nose only, as Gassendi said long ago, and the left eye the left side of the nose. The right eye sees only one glass of a pair of spectacles before the right eye, and the left eye sees only the other glass, which is before it; or, to state the fact more generally, the right eye sees more of the right side of all solid objects than the left eye does, and the left eye sees more of the left side of the same objects than the right eye. In vision these two pictures, the right and left eye pictures, are united into one. The second principle of the stereoscope is, that the pictures thus united, though flat or plane upon the retina, have the appearance of solidity or relief, and, therefore, two dissimilar pictures, like those on the retina, united by means of the two eyes, or by any method whatever, will also appear in relief.

The first of these principles was known to Euclid 2000 years ago, and is distinctly explained in his *Treatise on Optics*. Fifteen hundred years ago, Galen clearly proves that in viewing solid objects, with each eye and with both, we see *three different pictures*. "Standing near a column," he says, "and shutting each eye in succession, when the *right* eye is shut, some of those parts of the column which were previously seen by the *right* eye on the right side of the column, will not now be seen by the left eye; and when the *left* eye is shut, some of those parts which were formerly seen by the *left* eye on the *left* side of the column, will not now be seen by the right eye. But when we at the same time open both eyes, both these will be seen."

Baptista Porta.

Baptista Porta illustrates these views of Galen by the following figure, in which we see not only the principle of the stereoscope, but the binocular slide with the right and left eye picture united and producing solidity (fig. 1). Let A, he says, be the pupil of the right eye, B that of the left, and DC the body to be seen. When we look at the object with both eyes we see DC. But if it is seen with one eye it will be seen otherwise, for when the left eye B is shut, the body CD, on the left side, will be seen in HG; but, when the right eye is shut, the body CD will be seen in FE; whereas, when both eyes are opened at the same time, it will be seen in CD.[1]

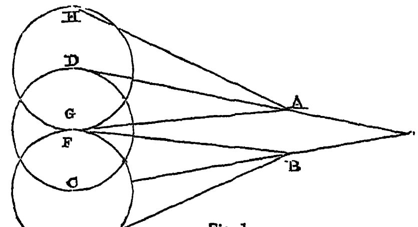


Fig. 1.

Jacopo Chimenti.

That we have here the representation of the right and left eye picture of the stereoscopic slide, and the true principle of the instrument is very obvious; but till now we had no evidence that such pictures were either executed or combined to produce relief. A gentleman who lately visited Lille, saw in the Museum Wicar two drawings by Jacopo Chimenti, placed together like AB, A being a picture of a youth sitting upon a bank and drawing with a compass, as seen by the right eye, and B, a similar drawing, as seen by the left eye. Upon looking at a point O, so as to join the drawings, the figure A rose into true relief.

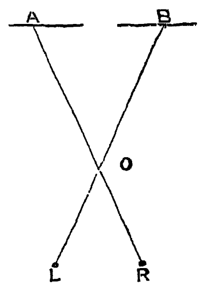

Fig. 2.

This, doubtless, is the invention of the ocular stereoscope, deduced from Baptista Porta's work. In the year 1593, when Porta's work was published in Naples, Jacopo Chimenti was in the 39th year of his age, and therefore very likely to have availed himself of the binocular theory of the Neapolitan philosopher.[2]

Leonardo da Vinci knew the same fact, and in 1613 Aguilonius, in his work on optics, wrote a whole book on the vision of solids (τά στερεά, *tu sterea*); and Dr Smith of Cambridge, Mr Harris of the Mint, and Dr Porterfield of Edinburgh, were all acquainted with the dissimilarity of the pictures as seen by each eye separately. Mr Harris, who wrote in 1775, tells us that we distinguish prominences of small parts "by the prospect we have round them;" and he adds, "By the parallax, on account of the distance betwixt our eyes, we can distinguish besides the front part of the two sides of a near object not thicker than the said distance, and this gives a visible relievo to such objects, which helps greatly to raise or detach them from the plane in which they lie. Thus, the nose on the face is the more remarkably raised by our seeing both sides of it at once." Hence it is obvious that optical writers in every age knew the two facts, that the pictures on the retina of the two eyes were dissimilar, and that by the union of these two flat dissimilar pictures we obtain the vision of solidity, the union of the two nearest similar points on the two pictures, placing that point at the shortest distance; and the union of the two most remote similar points, placing that point at the greatest distance from the eye.

In order to see objects in relief from plain representations of them, it was required only to obtain accurate

[1] *De Refractione Optices parte*, lib. v., p. 132; or lib. vi., pp. 143, 145; Neap. 1593.
[2] We have taken measures to obtain photographs of Chimenti's drawings.

Stereoscope.

pictures of them as seen by each eye, and a method of uniting these pictures. By means of photography and the binocular camera we obtain two dissimilar pictures, and by the method of Chimenti we can unite these pictures.

Elliott's ocular stereoscope.

So early as 1823 Professor Elliott of Liverpool, when a student at the logic-class in Edinburgh, was led to study the subject of binocular vision, and sometime afterwards he invented a method of uniting the two dissimilar pictures of objects as drawn by himself. He had resolved in 1834 to make the instrument, but delayed doing this till the year 1839, when he constructed an instrument for uniting two dissimilar pictures. This simple stereoscope had neither mirrors nor lenses, and consisted of a wooden box 6 inches long, at the end of which he placed two dissimilar pictures of a landscape (fig. 3) drawn by himself, as seen by each eye. These pictures were then united, and appeared in relief by converging the eyes to a point beyond the pictures. If he

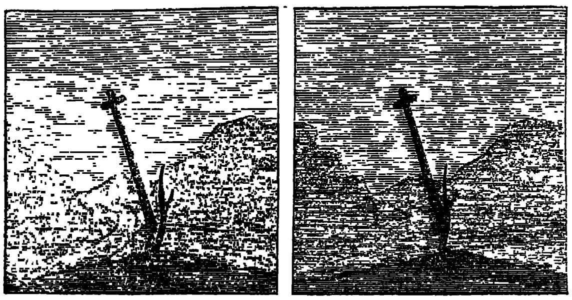

Fig. 3.

had reversed the pictures, as in fig. 3, he would have obtained the same effect by converging the optic axis to a point between the pictures and his eye. Owing to the

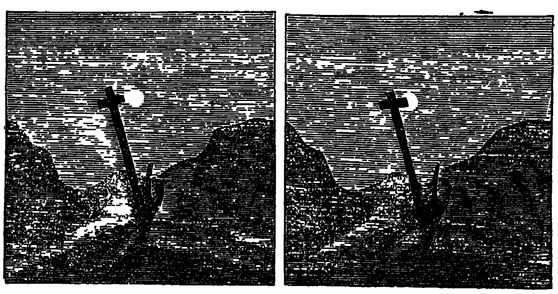

Fig. 4.

difficulty of obtaining right and left eye pictures of landscapes and figures, Professor Elliott proceeded no farther with his invention.

In 1836 Mr George Maynard, M.A., of Caius College, Cambridge, who had been previously studying the phenomena of binocular vision, published an article on the subject in a Toronto newspaper, in which he described the principles of the stereoscope, or the *Bathoscope* (from βαθος, depth, and σκοπειν, loses), as he called it.[1]

In June 1838 he communicated to the Royal Society of London an interesting paper on the physiology of vision, in which he described an instrument called a stereoscope for uniting the two dissimilar pictures of solid bodies as seen by each eye. This instrument, which is represented in fig. 5, he describes in the following manner:—

Wheatstone's reflecting stereoscope.

"AA′ are two plain mirrors about 4 inches square, inserted in frames, and so adjusted that their backs form an angle of 90° with each other; these mirrors are fixed by their common edge against an upright B or against the middle of a vertical board, cut away in such a manner as to allow the eyes to be placed before the two mirrors. C, C′, are two sliding boards, to which are attached the upright boards D, D′, which may thus be removed to different distances from the mirrors." In order to keep the two up-

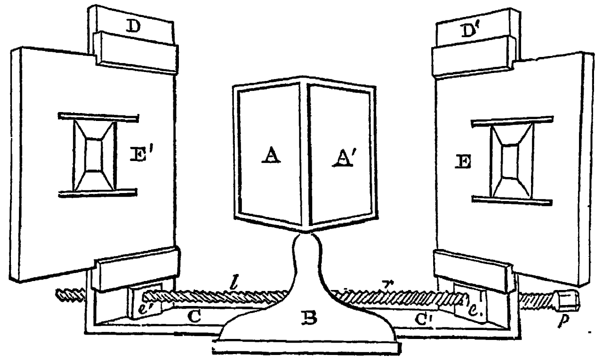

Fig. 5.

right boards at the same distance from its opposite mirror, Mr Wheatstone "employs a right and left-handed screw, *r*, *l*; the two ends of this compound screw pass through the nuts *e e′*, which are fixed to the lower parts of the upright boards D, D′, so that by turning the screw-pin *p* one way the two boards will approach, and by turning it the other, they will recede from one another; one always preserving the same distance as the other from the middle line *f*; E, E′, are pannels to which the pictures are fixed, so that their corresponding horizontal lines shall be on the same level; these pannels are capable of sliding backwards or forwards in grooves on the upright boards D, D′."

In using the apparatus "the observer must place his eyes as near as possible to the mirrors, the right eye before the right hand mirror, and the left eye before the left hand mirror, and he must move the sliding pannels E, E′, to or from him till the two reflected images coincide at the intersection of the optic axis, and form an image of the same apparent magnitude as each of the component pictures," . . . the entire effect of relief being produced by the simultaneous perception of the two monocular projections, one on each retina."

The figures to which Mr Wheatstone applied this apparatus were pairs of outline representations of objects of three dimensions, such as cubes, cones, and frustums of pyramids, like those shown at E, E′, in the figure; but though the effect produced by the apparatus was new and startling, it did not excite any general interest, and was known only to Mr Wheatstone's friends, or to one or two professors as a portion of their optical apparatus.

The lenticular stereoscope of Sir David Brewster.

Having had one of these stereoscopes constructed for him by the late celebrated optician, Andrew Ross, Sir David Brewster saw its imperfections, and its inapplicability as a general and popular instrument, and he was led to the construction of the *lenticular stereoscope*, now in universal use in every part of the world. The instrument was exhibited to the British Association at Birmingham in 1849, and a finely executed one by Mr Loudon of Dundee was exhibited by its inventor in Paris in 1850 to the Abbé Moigno. M. Duboscq devoted himself to the manufacture of the instrument, and executed for it the most beautiful daguerreotypes of living individuals, statues, and objects of all kinds. "The stereoscopes of M. Duboscq," says the Abbé Moigno, "are constructed with more elegance, and even with more perfection than the original English instrument; and while he is showing their wonderful effects to natural philosophers, and amateurs who have flocked to him in crowds, there is a spontaneous and unanimous cry of admiration."[2]

On the 30th December M. Duboscq exhibited the lenticular stereoscope to the Imperial Institute of France, and MM. Babinet, Pouillet, and Regnault were appointed a

---

[1] *On the Bathoscopical Effects of Binocular Vision, and the Principles of the Stereoscope*, p. 4, Toronto, 1856.
[2] *La Presse*, Dec. 28, 1850.

Stereoscope.

committee to examine it.[1] Although Sir David Brewster had offered the free use of his invention to opticians in Birmingham and London in 1849, yet not a single instrument was made by English artists, and it was not till a year after its introduction into France that it was publicly exhibited in England.

In the beautiful collection of optical instruments which M. Duboscq contributed to the Great Exhibition in 1851, he placed a lenticular stereoscope, with a fine set of binocular daguerreotypes. The instrument attracted the particular attention of the Queen, and before the crystal palace was closed, M. Duboscq executed one of his finest stereoscopes, which was presented to her Majesty by Sir David Brewster in the artist's name. M. Duboscq having received many orders from England, sent over a number of stereoscopes; and in a short time they were manufactured in all parts of the world, and artists dispatched into every country to take binocular pictures of its buildings, monuments, and scenery.

The lenticular stereoscope consists of two convex lenses, or two semi-lenses, or two quarter-lenses, placed 2½ inches distant, through which the observer views what is called a binocular picture, held in the hand, or placed in a box at such a distance from the lenses that it may be seen distinctly, and magnified.

In the earliest instruments two whole lenses were used, in order to save the trouble of halving them, but in this case the two outermost halves were useless, as the eyes of the observer only looked through the inner halves. But in order to make the instruments cheaper, the lenses were cut into halves, or into quarters, and each half or quarter cut into a round disc, so that a single lens could make *one* semi-lens stereoscope, or *two* quarter-lens stereoscopes.[2] These different forms of the lenses are shown in the

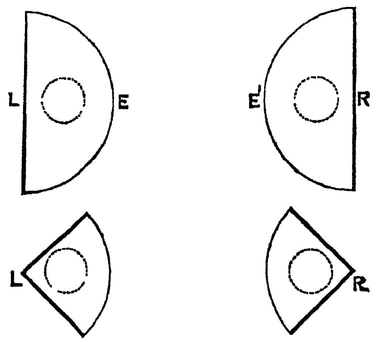

Fig. 6.

annexed diagram (fig. 6), where L is the lens opposite the left eye, and R the lens opposite the right eye, each eye looking through the part of the lens marked by a dotted circle the size of the pupil of the eye. If the eye is close to the lens it will see the object which it views as distinctly as if the lens were a foot in diameter; but as it cannot be advantageously placed close to it, the lenses are always made larger than is necessary. Beyond the size of lens which allows the pupil to see every part of the object, everything additional is superfluous. The two lenses L, R have been made so large as to meet, and sometimes the shape of a Gothic window has been given to them; but whatever be their size or shape, whether whole lenses, as they have been ignorantly made, or any other size, the eyes must look through two small circular portions equidistant from the centre, and placed at the distance of 2½ inches, as shown in the above figure.

It is hardly necessary to point out to the optical reader the peculiar advantages of semi or quarter lenses. It is impossible to give two separate lenses, L, R, the same focal length and magnifying power, however nearly we may approach to it; but two semi-lenses cut from the same lens, and the two quarter-lenses cut from the same semi-lens, have necessarily the same focal length and magnifying power.

The general form of the instrument in which these lenses are placed is shown in fig. 7. The instrument con-

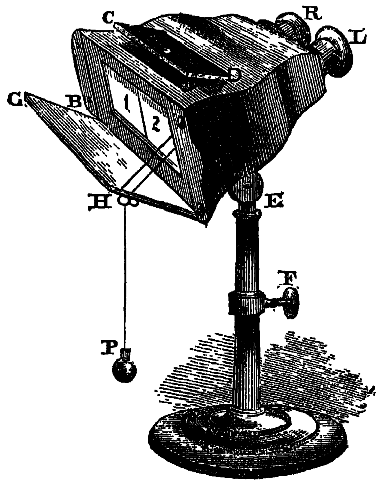

Fig. 7.

sists of a pyramidal box, or a box of any form, on the top of which are placed two eye-tubes containing the lenses R, L, which can be separated from one another in a variety of ways, to suit the distance between the eyes of the observer. They may also be drawn out so as to produce distinct vision of the picture, but they are prevented from turning round by a brass pin in the fixed tubes, which runs in a groove cut through the movable tubes. Immediately below the eye-tubes, at G, there should be a groove for the introduction of a pair of convex or concave spectacles, when necessary, or for coloured glasses, or other purposes.

If we now take a binocular slide containing two pictures of a person, or a landscape, as seen by each eye, or as drawn by the rules of perspective from two points 2½ inches distant, and put it into the horizontal opening at AB, and look into the instrument with the right eye at R and the left at L, we shall see the two pictures united into one, and having the same relief as the living person if it is a portrait, or as a scene in nature if it is a landscape; every part being no longer on a plane surface, but at its proper distance from the eye. If we shut the right eye R, and look only with the left eye L, we shall see only the picture 1, which will sink into a comparatively flat representation of the object, with only monocular relief. In like manner, by closing the left eye L, we shall see only the picture 2 comparatively flat; but when both eyes are opened the pictures 1 2, when combined, will start into all the roundness and solidity of life or nature.

The bottom of the stereoscope should be left open, so as to admit binocular pictures on glass, but in this case the open bottom must be covered either with ground glass or transparent paper, unless when the binocular slide has one of its surfaces made of ground glass. The lid CD, which is left open to throw light on opaque binocular slides like those on paper, card-board, or silver plate, must be shut when the pictures are either upon glass or transparent paper.

When the instrument is placed on a stand, as in the figure, it moves round a joint at E, and is raised or depressed by a stop-screw at F. A reflector GH is some-

[1] *Comptes Rendus*, &c., tom. xxxi., p. 897.

[2] See the article MICROSCOPE, vol. xiv., p. 770.

times added to the stereoscope for throwing different levels upon transparent pictures, and its position is regulated by a pulley P.

In order to explain why the stereoscope combines the two pictures, we shall do it most simply by desiring the reader to look at any object with his left eye through the

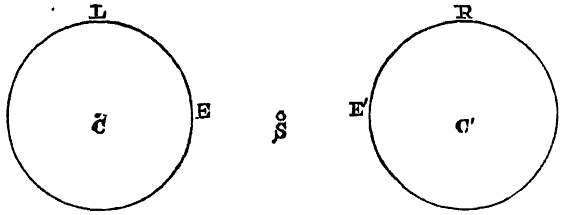

Fig. 8.

centre C of any convex lens such as L, fig. 8, so as to see it distinctly. The object will appear directly opposite C; but if, keeping the object and the eye stationary, he draws the lens gradually to the left, the object will advance towards S, just as the parts of the lens between C and E are opposite to the eye, the displacement of the object being greatest or equal to CS, when the eye looks at it through the part nearest the edge E. If the reader looks at a similar object with his right eye through the lens R, he will, in like manner, by moving it, displace the object from E′ to S. Hence it follows that if he looks with his left eye at one of the pictures of a binocular slide placed opposite the lens L, and with his right eye at the other picture placed opposite the lens R, he will see the two pictures combined in one when the left eye looks through the aperture close to E, and the right eye through the aperture close to E′. The lenses thus perform simultaneously two important functions: While they displace the pictures, they also magnify them. This is all that the stereoscope does. It simply magnifies and unites two pictures, but it does not give them binocular relief. This is done by a beautiful property of two eyes, as will be seen when we treat of the *Theory of the Stereoscope*. If the two eyes, however perfect be their vision, had not the power of converging their axes to any other distance but that of the surface of the pictures, no relief whatever would have been seen.

The lenses of stereoscopes cut out of semi-lenses, or quarter-lenses, and are placed in tubes so that the line LE or RE′ (fig. 6) is parallel to the line joining the two eyes, and they are prevented from turning round by a pin sliding in a groove, as already mentioned. Frequently, however, the pin gets out of the groove, and when the line LE or RE′, or CE, CE′, is not parallel to the line joining the eye, the picture viewed through the lenses rises above S (fig. 8), or falls below it, so that the instrument becomes useless. To prevent this the lenses have often been fixed, so that their distance cannot be altered to suit different distances in eyes, nor can they be adjusted to distinct vision by a motion of the tubes R L (fig. 7). The adjustment to distinct vision has in some instruments been obtained by making one half of the pyramidal box move within the other half; but, to avoid all these risks, whole lenses such as L, R′ (fig. 8), should be placed in tubes as at R, L (fig. 7), having neither pin nor groove, and they may be pulled out, or pushed in, or turned round without affecting the performance of the stereoscope, which is the only possible use of whole lenses. In a whole lens every radius CE (fig. 8), when it is brought opposite the eye-hole, has the same displacing power, and must always displace the picture in the same direction; that is, the two pictures must always be united at the middle point S, and will be equally magnified if the two lenses have the same focal length, which is never so certain as when semi-lenses are used.

Among the various forms which have been given to the lenticular stereoscope, those invented and manufactured by Messrs Smith, Beck, and Beck, 6 Coleman Street, London, hold a high place. These gentlemen received a medal of the first class from the jury of the Paris Universal Exhibition of 1855, for their unrivalled achromatic microscopes,[1] and if their stereoscopes had been exhibited on that occasion they would have been equally distinguished. The following is a brief description of their achromatic stereoscopes.

Smith and Beck's achromatic lenticular stereoscope

This instrument is shown in fig. 11, as taken out of its case A, and resting upon it as a stand, to which it is secured by the hooks C. It has a joint at B, and can be fixed in a vertical, horizontal, or any intermediate position by the

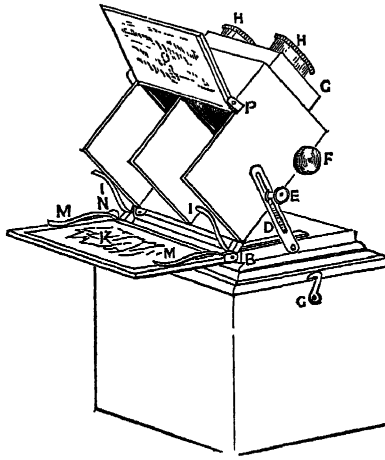

Fig. 9.

brass arm D, which is made tight by the milled head E. Two other positions, namely, when the instrument is horizontal and the person sitting, and when the person is in a standing position, may be obtained by an additional cabinet, which may be used for holding the slides.

The two semi-lenses, which, being rounded, have the appearance of whole lenses, nearly an inch in diameter, are shown at HH. They are placed in tubes, which turn round in their fittings at G, and are in their proper position when the two arrows on the brass arms HH point to one another. In order to adjust the instrument to different eyes, the part of it containing the semi-lenses is moved nearer to, or farther from the stereographs or binocular picture or slide by two milled heads F. The distance of the semi-lenses from the picture may also be increased for aged persons, by drawing them out from their fittings at G. The slides are placed outside and under the two springs I, I.

When opaque slides are used, such as daguerreotypes, or those made of card-board, light is thrown upon them by the mirror O on the inside of the door, which moves round a hinge at P.

When transparencies are used the door O is closed, and the picture illuminated by a removable reflector K, packed in the case, but which, when in use, is held by two brass arms and springs M, and is turned into different positions round the hinge B. "The silvered, or other side, is used according to circumstances; but occasionally some kind of tinted paper, or other reflecting substance, is preferable for giving a tone to the picture; but, whatever it may be, it has only to be placed above the reflector or under the springs, or in place of the reflector, if it is of a sufficiently stiff material."

In order to exhibit paper stereographs or slides, either when mounted in the ordinary way, or when they are given as illustrations in books—such as those in the *Stereoscopic*

[1] See art. MICROSCOPE, vol. xiv., pp. 779, 780

Magazine—Messrs Smith, Beck, and Beck have contrived the following ingenious form of the lenticular stereoscope.

Achromatic mirror lenticular stereoscope.

This instrument is intended to be held in the left hand by the handle A, as shown in fig. 10, the right hand being left at liberty either to shift the stereographs, or make the requisite adjustments. The semi-lenses are placed in the tubes C, C, and they are in their proper position when the arrow heads, or the brass rims D, D, point to each other. The adjustment to distinct vision is obtained by the milled head B, and a rack and pinion, and also by the motion of the tubes C, C.

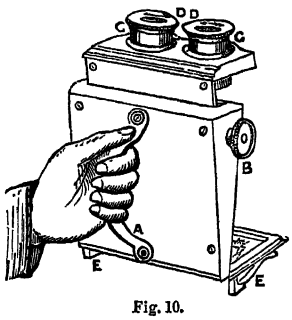

Fig. 10.

The principal feature in this form of the stereoscope is the application of a mirror EE in such a position that, when the instrument is held facing the light, the stereograph is illuminated by reflected as well as direct light, so as to obliterate the shadows of irregularities on the surface of the paper. This mirror is shown at FF, in fig. 11, which is a front view of the instrument when placed above the stereograph in a book, the springs E, E being turned up to allow the brass frame H to rest upon the back. When a separate stereograph is to be examined, the springs E, E are turned round, and the stereograph placed between them and the frame. The two pictures in the stereograph are separated by a division G, which is made of ground glass, to prevent any shadow from being formed on the picture.

In this stereoscope, as well as in the other, the tubes C, C can be turned round slightly from their proper position as determined by the arrows, in order to correct errors which occasionally exist in the stereographs, or in order to unite the pictures when seen by individuals whose eyes are imperfect.

Improvements on the reflecting stereoscope.

Various improvements have been made upon the reflecting stereoscope, for an account of some of which we must refer to Sir David Brewster's *Treatise on the Stereoscope.* The most ingenious and important of these, and one which is not described in that work, was invented by Mr Walter Hardie of Edinburgh, who has favoured us with the following description of it.

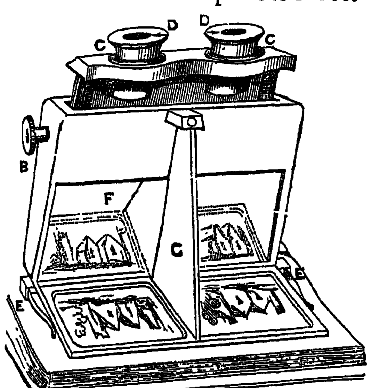

Fig. 11.

Mr Hardie's reflecting stereoscope.

In this instrument the planes of reflexion are *vertical* instead of horizontal, as in Mr Wheatstone's. The pictures are placed head to foot, and inverted towards the observer (see fig. 14). The reflectors (either silvered glass or reflecting prisms) are fixed side by side over them, and at such an inclination to each other and to the pictures that the reflected image of the upper picture in the right-hand mirror, and that of the lower picture in the left-hand mirror, are both visible in the same direction *ei*, and appear to coincide in position. When these images are viewed together, each by its appropriate eye looking into the mirror which reflects it, they are binocularly united; and if the pictures are stereoscopic, the stereoscopic illusion is produced.

The precise relative positions of the mirrors and pictures may be stated thus: the smaller angle of the *mirrors* must be equal to half the difference between that of the pictures and 180°; and the line of intersection of their surfaces must coincide with that of the two planes which are respectively perpendicular to the surfaces of the pictures at their horizons. The *pictures* being head to foot with their horizons parallel, their central perspective vanishing-points ought respectively to lie $1\frac{1}{4}$ inches (or half the width between the observer's eyes) on each side of the plane perpendicular to both picture-surfaces, and which passes through the point of contact of the inner edges of the mirrors. If the pictures are separate, by sliding one of them sideways, Mr Wheatstone's experiments in altering the inclination of the optic axes may be repeated. For ordinary use, however, it is more convenient to have both pictures on one piece of card-board, with a flexible fold or hinge between them, and with a thread stretched across from one to the other on each side, to hold them at

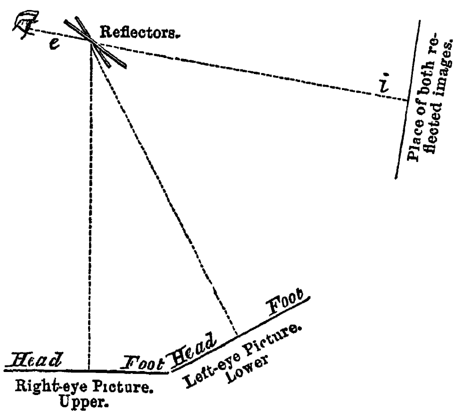

Fig. 12.
SIDE VIEW.

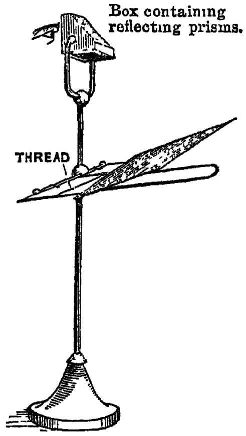

Fig. 13.

the proper angle when in use (see fig. 13, which shows the most convenient mode of constructing the instrument).

The stereoscope is adapted for pictures of any size, from that usually made for the lenticular stereoscope up to the largest that can be conveniently used in Mr Wheatstone's; and it has this advantage over the latter, that it easily allows of both pictures being equally illuminated. The distance of the pictures from the mirrors is adjusted to their size (height) by sliding the frame which carries them (upwards for the smaller pictures, or downwards for the larger ones) upon the vertical stem which supports the reflectors (see fig. 13). To facilitate this adjustment, a divided scale of inches may be marked on the upright stem; and the height on this scale, at which each particular picture requires to be placed, may be noted on the back of it. The breadth of the field of view may be further extended, so as to admit broader pictures by interposing refracting prisms (thin edges inwards) between the eyes and the reflectors. For small pictures requiring to be placed at short distances from the reflectors, lenses or lenticular prisms may be used in the same way with advantage.

Mr Claudet's stereomonoscope.

The stereomonoscope, invented by Mr Claudet, is an instrument which, as its name implies, exhibits an image *apparently* single, presenting the most complete stereoscopic illusion.

This instrument is founded on the principles of the phenomenon of relief of the image formed on the ground glass of the camera obscura, and which Mr Claudet seems to have been the first to notice and explain. Having tried to discover the cause of that phenomenon, he found that the image seen on the ground glass is not the same for both eyes; that when looking only with one eye it continually changes as we move the head, and, consequently, that the image visible for one eye is invisible for the other

Stereoscope.

The cause of this singular fact is, that the eye sees on the ground glass only the rays which are refracted by the lens in the direction of the optic axis, and that all the other rays are invisible.

This is owing to the perfect transparency of the ground glass, and to the arrangement of the molecules of its surface, by which the rays of light can—*nearly all*—pass through it without diverging from the surface, as it would be entirely the case if, instead of glass, the focussing screen was of paper or any other opaque substance, which, on account of this property of stopping the refracted rays on the surface, from which they diverge in all directions, present to both eyes at once all the different images produced by every part of the lens.

As regards the ground glass, it is evident that if each eye can see only the image produced by rays refracted in the direction of the optic axis, these rays must be those which, crossing each other on the ground glass, emerge from two opposite sides of the lens, consequently each eye having the perception of an image of different perspective, the result is perfectly stereoscopic. From the same cause, the effect is the converse of relief if we look with a pseudoscope.

The stereomonoscope is only an application of this property peculiar to the ground glass, to present to each eye only the image which is refracted in the oblique direction of the optic axis. If, instead of the natural objects, we place before the camera the two pictures of a stereoscopic slide, and have each of these images refracted by a separate lens, in such a manner that they coincide on the ground glass of the camera obscura, each eye seeing one of the two images and not the other, we have the same relief as when looking at the slide in a common stereoscope.

If, by inverting the position of the two images before the camera, we place the right picture on the left, and the left picture on the right, we have the converse of relief, or the pseudoscopic effect; but it becomes again stereoscopic by looking with a pseudoscope.

The slide must be cut in two parts, in order to be able to give them the separation by which each picture can be refracted in the oblique direction capable of bringing its image on the centre of the ground glass. The two lenses also must be able to slide in a groove, in order to adjust their position according to the separation of the two pictures, and according to the focal distance of the lenses, which of course varies as we wish to increase or diminish the size of the image on the ground glass, and it can be increased to a considerable dimension, which is one of the greatest advantages of the stereomonoscope. Nothing is more beautiful than the effect of one of these magnified pictures in perfect relief, and it can be examined by several persons at once.

The apparatus must be placed in a dark room, and the light of a window or lamp is admitted only through the openings of the pictures, if they are transparent views on glass, which are the best suited to the experiment. Views on paper, on silver plates, or positives on glass, requiring to be lighted by reflection, would necessitate a more complicated apparatus, and for this reason it is preferable to confine the stereomonoscope to the exhibition of transparent pictures, which can be easily lighted by transmitted light.

Fig. 14 represents the arrangement of the lenses A, A′, and pictures B, B′, by which the pictures coincide in one at C. Fig. 15 is a view of the whole apparatus. DD DD, is the camera, and EE EE, a sliding frame containing the pictures, by which they can be placed before the lenses at the distance required for the size of the compound image on the ground glass, which is fixed on a box sliding in the camera for the adjustment of the focal distance.

In order to understand the theory of the stereoscope, the reader must be acquainted with the phenomena and theory of binocular vision, in which we obtain single vision with two eyes, and see objects in relief, or differences in distance from flat pictures upon the retina.

Stereoscope.

Theory of the stereoscope.

1. In all stereoscopic slides or double pictures, viewed

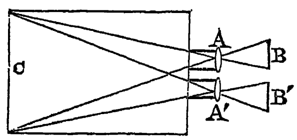

Fig. 14.

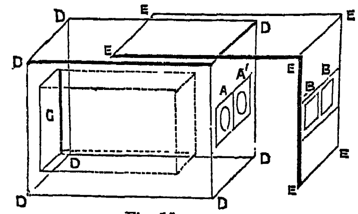

Fig. 15.

in the stereoscope, the left-hand picture, when rightly taken, which it seldom is, is a correct representation of an object as seen with the left eye, and the right-hand picture a correct representation of it as seen by the right eye; or they are correct drawings of the object as taken by the rules of perspective, from two points whose distance is 2½ inches, or that of the two eyes. These two pictures, though almost perfectly similar to one another, are essentially different; and if the one was laid upon the other, so that any one point of the one, the tip of the nose, for example, coincided with a similar point in the other, no other points in the two pictures would coincide.

2. When we look at a solid object—at a marble bust, for example—the tip of the nose, the eye, and the ear, are at different distances from the observer's eyes. When we see distinctly the tip of the nose, we see it single, and the eye and the ear are seen indistinctly and double. We see, in short, only one point of any object distinct and single, and when we thus see it, the optic axes, as they are called, or lines passing through the centre of the pupil and the centre of the crystalline lens, are converged upon or meet at that point, and the visible distance of the point thus viewed is the distance of the point of convergence of the optic axis from the eye. Although we cannot see distinctly and singly the nose, the eye, and the ear at the same moment, yet such is the rapidity with which the two eyes converge their optic axes upon each of these points in succession, and upon every other point in succession, that every point of the bust is seen distinctly and singly, and at the distance corresponding to the distance of the point of convergence. The bust is, therefore, seen in relief.

3. We have already seen that the stereoscope simply displaces each picture, carrying the left-eye one to the right, and the right-eye one to the left, and laying the one above the other at a point half-way between each. *It does nothing more*, the stereoscopic effect, or the relief, being produced solely by the movements of the two eyes.

If the refractive displacement of the two pictures has been such as to unite the two corresponding points at the tip of the nose, whose distance we call 2·4 inches, it will not have united the two corresponding points in the two eyes, the distance of which we may suppose to be 2·5 inches; and still less will it have united the two corresponding points at the tip of the ear, which we may suppose to be 2·6 inches, the eye and the ear points being respectively *one-tenth* and *two-tenths* of an inch distant.

When the two pictures thus combined by the lenses are viewed with both eyes, the tip of the nose will be seen distinctly at the distance of the point of convergence. The eyes will instantly, by means of their power of convergence, unite the separated points of the eyes, and then the still more separated points of the ears, running over every part of the bust with the rapidity of lightning, and uniting all the corresponding points in succession, precisely as it does in looking at the bust itself. The effect thus described may be represented as in fig. 16, where the points R, L

Stereoscope.

represent the two corresponding points in the *nose* united by the lenses; L′R′ the corresponding points of the *eye* not united, but distant $\frac{1}{10}$th of an inch; and L″R″ the corresponding points of the *ear* not united, but distant $\frac{2}{10}$ths of an inch.

When the corresponding points united by the lenses are those of the *eye*, 2·5 inches distant, the effect upon the other points of the bust will be as shown in fig. 17, where

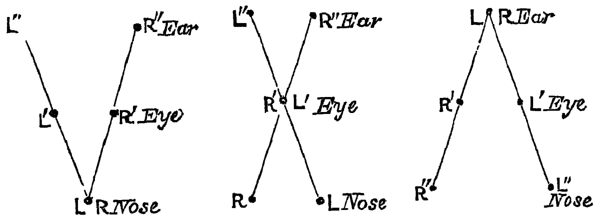

Fig. 16. Fig. 17. Fig. 18.

R′L′ are the *eye* points united; R″L″ the *ear* points brought nearer by $\frac{1}{10}$th of an inch, but still $\frac{1}{10}$th distant; and RL the *nose* points, the right-eye point having passed the left-eye point by $\frac{1}{10}$th of an inch.

When the corresponding points united by the lenses are those of the *ear*, the effect upon the other points of the bust will be as in fig. 18, where R″L″ are the *ear* points united; R′L′ the eye points, distant $\frac{1}{10}$th of an inch, the two having passed one another; and RL the nose points, distant $\frac{2}{10}$ths of an inch, having passed one another still farther.

Now, in all these cases the points L″R″, L′R′ (fig. 16), R″L″ (fig. 17), where L and R have not come up to one another, will be united by the eyes directing their axes to a point beyond the plane of the picture; while the points RL (fig. 17), and R′L′, R″L″ (fig. 18), which have passed one another, will be united by the eyes directing their axes to a point nearer the eye than the plane of the picture.

By whatever means the two pictures are laid upon one another,—whether by the straining of the eyes—directing their axes to points beyond the picture, or between the picture and the eye; by reflexion from mirrors or prisms, or by the refraction of prisms or lenses,—the relief, or stereoscopic effect, is produced in the manner we have now explained.

This theory of the stereoscope, or rather this explanation of the production of relief by the union of two dissimilar pictures, was first given by Sir David Brewster in the *Transactions of the Royal Society of Edinburgh*,[1] where he has pointed out the incorrectness of the explanation given by Mr Wheatstone.[2]

Method of taking stereoscopic pictures.

As no artist, however skilful, is capable of executing two pictures of any individual object, or group of objects, as they are seen by each eye separately, the stereoscope was of little value before the art of photography enabled us to take such pictures with the most perfect accuracy. If these pictures are not perfectly correct when taken upon a plane surface, their incorrectness, when combined so as to reproduce the object in relief, must be increased. In the exercise of the stereoscopic art, therefore, we must ascertain what is a true representation, of a statue for example, as seen with one eye through a pupil $\frac{1}{8}$th of an inch in diameter. It is doubtless a photograph taken with a lens $\frac{1}{8}$th of an inch in diameter. Every larger lens will give a photograph showing parts of the statue not visible to the eye, and consisting of a number of incoincident pictures as seen from every point of the lens.[3] But notwithstanding this defect, the artist is obliged to use a larger lens than this, in order to accelerate the process; but it is to be hoped that more sensitive materials may soon enable him to use a lens of the smallest size, and thus obtain perfectly correct right and left eye pictures. With the large lenses now in use, 2, 3, and even 4 inches in diameter, no correct stereoscopic pictures can be obtained.

But the right and left eye pictures must not only be taken with apertures as nearly as possible equal to that of the pupil, they must be taken by apertures placed at the same distance as that of the two pupils, that is, at the distance of $2\frac{1}{2}$ inches. All pictures taken otherwise are false, incorrect, and out of all accurate proportion. With this essential property, the stereoscopic camera cannot have lenses more than $2\frac{1}{2}$ inches in diameter, for they would just touch one another when of this size. With this information, we are now prepared to describe the binocular camera.

Binocular camera.

The camera must consist of two perfectly similar lenses, in order to give two pictures of the same size; but as it is difficult for the most skilful optician to make two lenses of the same focal length and magnifying power, Sir David Brewster, who was the first to describe a binocular camera, proposed to construct it of achromatic semi-lenses, that is, of an achromatic lens cut in two, and so placed that the distance of the centres of the apertures may be $2\frac{1}{2}$ inches.

Several of these cameras were made in London, and give the most perfect stereoscopic photographs; but professional artists have not found it their interest either to use small lenses, to make each single photograph as perfect as possible, or to place lenses at the distance of $2\frac{1}{2}$ inches, in order to combine these pictures into proper relief. Their object has been to use lenses of such a size as to make the time of taking the picture as short as possible, and produce a startling degree of relief by placing the lenses at great distances. Although these stereoscopic pictures may please persons of neither taste nor judgment, yet they are most incorrect representations of nature, which men of science instantly discover. In all stereoscopic pictures taken at angles above that which corresponds to a distance of $2\frac{1}{2}$ inches, the distances are all drawn out, as it were. A street is made twice as long; and all buildings or objects stretching from the eye are enormously increased in length. The head of a portrait is drawn forward from the neck, and the dress of a lady is made to project forward from her bust.

As every artist places his lenses at the distance he pleases, and as very few employ the proper distance, the thousands of stereoscopic photographs, nay, the millions now circulating in Europe, have no real artistic or geometrical value. If we knew for certain that the distance of the lenses employed were correctly $2\frac{1}{2}$ inches, or even if we knew that it was 4, 6, 8, or 10 inches, we could deduce from each pair of pictures, by nice micrometrical measures, the actual forms of the statue or person, or building or landscape, which it represents, as the actual distances of the corresponding points in the two pictures would thus give us a measure of the distances of these parts from the eye; the distance between the tips of the nose, for example, and the points of the ears, and the pupils of the eyes, being measures of the distances of these points from any plane perpendicular to the eye, provided the distance of the lenses was known. A sculptor could thus obtain, even from one stereoscopic photograph, assistance in modelling a bust, and a surveyor might make an approximate plan of a landscape from even one correct stereoscopic representation of it.[4]

A very great improvement in the art of taking single as well as binocular photographs has been made by Mr Thomas

---

2 This is demonstrated in a more popular manner in Sir D. Brewster's *Treatise on the Stereoscope*, chap. v.

3 See our art. OPTICS, vol. xvi.

4 For further information on this subject, see Sir David Brewster's *Treatise on the Stereoscope*, chap. viii.

Skaife, Vanbrugh House, Blackheath, the only artist who has carried out the views of Sir David Brewster, as given in his address to the Photographic Society of Edinburgh.[1] In the instrument which he has invented for this purpose, and which he calls a *Pistolograph*, he uses lenses only an inch in diameter, the focal length of the combination being also an inch. The lens-tube, ABCD, of the pistolograph, as shown of its real size in the annexed figure, in which AB is the front and BC the back, LL a cemented achromatic lens of flint and crown glass, and *l l* an uncemented one, differing only from the ordinary portrait-back combination in being ground—that when the two lenses of which it is composed are together, they touch only at the margin of their inner surfaces. The solar focus of the combined lenses is $1\frac{1}{2}$ inches behind the right-hand surface of the lens *l l*.

Mr Skaife's pistolograph.

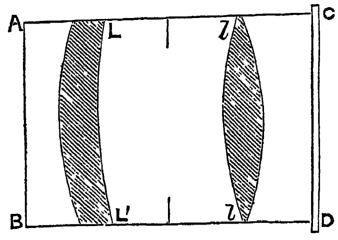

Fig. 19.

Owing to the small size of this instrument, and the small thickness of the glass through which the light passes, the actinic rays are so powerful that the photograph is taken almost instantaneously, and portraits are not deformed by the errors occasioned by the use of large lenses.[2] The small pictures, or pistolograms, as Mr Skaife calls them, when not used for rings, lockets, or bracelets, may be magnified by the enlarging camera without losing any of their sharpness.

The pictures thus obtained are enclosed between two plates of glass, "and when subjected for a definite time to a heat short of that which is required to melt glass, the three substances form but one, as hard and homogeneous as a single piece of crystal." To the picture thus enclosed and preserved from the air, Mr Skaife gives the name of Chromo-crystal. Some of those which we have seen are extremely beautiful.[3]

Mr Macraw's improvement.

A very ingenious improvement upon the binocular camera has been made by Mr Macraw, of Edinburgh, by which he can take two pairs of stereoscopic pictures upon a prepared plate, which of course must be double the length required for a single pair of pictures. For this purpose the prepared plate is inserted in an inner frame AB, which slips in a

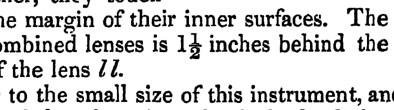

Fig. 20.

groove in the outer rim of the slide MN, with room at CD equal to one of the four spaces, 1, 2, 3, 4, of the plate. When the plate is placed as in the figure, the spaces 2, 4, are opposite the lenses, and receive the picture; and when AB is pushed up to N, the spaces 1, 3, will be opposite the lenses, and receive the second picture. (D. B.)

STEREOTYPE. See PRINTING.

STERLING, JOHN, a man whose reputation will rest henceforth much more on the fact of his having had Thomas Carlyle for his biographer than on any high merit of his own, was born at Kaimes Castle, Isle of Bute, Scotland, on the 20th July 1806. His father, Edward Sterling, originally from the county Waterford, in Ireland, but of Scottish descent, who had been educated for the Irish bar, but who had subsequently taken to soldiering, was now located among the shaggy mountains and sunny mists of Bute, as a sort of gentleman-farmer; and who became afterwards co-proprietor and chief editor of the *Times* newspaper. His mother, Hester Coningham, a native of Londonderry, and likewise of Scottish origin, was a beautiful, delicate, pious woman, from whom Sterling inherited the "delicate aroma" of his nature. He was the second child of seven, five of whom died while he was still a youth. In 1809, the Sterling family moved south to Llanblethian, in Wales. Here Edward Sterling began to write letters to the *Times*, when his interest in politics induced him to remove his family to Paris during the peace of 1814. Driven from the French capital next year by the return of Napoleon from Elba, he settled down with his family in London, and engaged in the profession of journalism. This brave, blustering, noisy individual, whom Carlyle was accustomed to call "Captain Whirlwind," has been thus graphically delineated by the same hand. "He was broad, well built, stout of stature; had a long, lowish head, sharp grey eyes, with large, strong aquiline face to match; and walked or sat in an erect decisive manner. A remarkable man." After having attended various schools in London or the neighbourhood, John Sterling was sent, when he was turned of sixteen, to the University of Glasgow, whence he was removed next year to Trinity College, Cambridge. He did not distinguish himself as a scholar in any particular branch while he resided at Cambridge, but under the tutorship of Julius C. Hare (subsequently Archdeacon of Lewes), he made very considerable progress, and displayed a quick, keen, piercing intellect, and great nobility of character. He particularly shone in connection with the Union Debating Club of Cambridge, of which Maurice, Trench, Spedding, J. M. Kemble, Venables, Charles Buller, and Monckton Milnes, were members. It is reported of Sterling, that he was the acknowledged chief of this club in all matters pertaining to speaking and arguing. Sterling left Cambridge without having taken his degree, and joined his friend Maurice in the intention of studying law. These two aspiring youths, in 1828, became possessors of the *Athenæum*, which they laboured hard to write into public favour, but the enterprise did not succeed, and the journal came into the hands of the present proprietor. Sterling about this period gained the friendship of Coleridge, whose influence over his mind was great and abiding, as Sterling's novel of *Arthur Coningsby* still testifies. Regarding this, his first regular contribution to literature, Carlyle remarks—

Sterling.

"It was in the sunny days, perhaps in May or June of this year, (1833), that *Arthur Coningsby* reached my own hand, far off amid the heathy wildernesses; sent by John Mill: and I can still recollect the pleasant little episode it made in my solitude there. The general impression it left on me, which has never since been renewed by a second reading in whole or in part, was the certain prefigurement to myself, more or less distinct, of an opulent, genial, and sunny mind, but misdirected, disappointed, experienced in misery;—nay crude and hasty; mistaking for a solid outcome from its woes what was only to me a gilded vacuity. The hero an ardent youth, representing Sterling himself, plunges into life such as we now have it in these anarchic times, with the radical, utilitarian, or mutinous heathen theory, which is the readiest for inquiring souls; finds, by various courses of adventure, utter shipwreck in this; lies broken, very wretched: that is the tragic nodus, or apogee of his life-course. In this mood of mind, he clutches desperately towards some new method (recognisable as Coleridge's) of laying hand again on the old Church, which has hitherto been extraneous and as if non-extant to his way of thought; makes out, by some Coleridgean legerdemain, that there actually is still a Church for him; that this extant Church, which he long took for an extinct shadow, is not such, but a substance; upon which he can anchor himself amid the storms of fate;—and he does so, even takingorders in it, I think. Such could by no means seem to me the true or tenable solution. Here clearly, struggling amid the tumults, was a loveable young fellow-soul; who had by no means yet got to land; but of whom much might be hoped, if he ever did. Some of the delineations are highly pictorial, flooded with a deep

[1] *Journal of the Photographic Society*, vol. iv., p. 83.

[2] We could recommend the use of smaller lenses of rock crystal. (See *Treatise on the Stereoscope*, pp. 138–140.)

[3] See *Instantaneous Photography, including Practical Instructions on the Manipulation of the Pistolograph*, by T. Skaife, Greenwich, 1860.

ruddy effulgence; betokening much wealth, in the crude or the ripe state."

Sterling's means did not compel him to adopt a profession, and from the nature of his talents, which were airy, graceful, and light-flowing; and from slight symptoms of pulmonary disease, he was withheld from binding himself down to any form of steady labour. He married in November 1830, and, taking suddenly ill shortly afterwards, he was forced to seek a more genial climate than England afforded. He accordingly started for the Island of St Vincent in the West Indies, where part of a valuable sugar estate had been bequeathed to him by a maternal uncle. Returning again to England in August 1832, he resolved to make a short tour in Germany. Chancing to meet his old tutor, the Rev. Julius C. Hare, at Bonn, he was persuaded to enter the English Church, and he was accordingly ordained deacon at Chichester in 1834, and immediately afterwards became curate of Herstmonceaux in Sussex, where his friend Hare was rector. Sterling remained in the Church for eight months, when, on the plea of ill health, he gave up his curacy, and possibly from some radical change in his opinions, real or imaginary, bade good-bye to the Church for ever.

Going to London in February 1835, he chanced to meet Thomas Carlyle for the first time, who had settled in London the previous summer. Carlyle describes Sterling as he then appeared, as follows: "A loose, careless-looking, thin figure, in careless dim costume, sat in a lounging posture, carelessly and copiously talking. I was struck with the kindly but restless, swift-glancing eyes, which looked as if the spirits were all out coursing like a pack of merry eager beagles, beating every bush. The brow rather sloping in form, was not of imposing character, though, again, the head was longish, which is always the best sign of intellect; the physiognomy in general indicated animation rather than strength." From this time Carlyle began to occupy the place of Mentor to Sterling, which had been so long held by Coleridge. Art, as Carlyle has remarked, was Sterling's *forte*, and not devotion in any form. Literature was henceforward his chief pursuit. His exceedingly precarious state of health caused him to lead a nomadic kind of life, which alternated between London and some warmer climate. In 1836 he went to the south of France; next year to Madeira, which he revisited again in 1840. Part of 1838 and 1839 he spent in Italy, and on his return to England he sought Clifton, and ultimately Falmouth. Carlyle, in his *Life of John Sterling*, says,—

"Sterling's bodily disease was the expression, under physical conditions, of the too vehement life which, under the moral, the intellectual, and other aspects, incessantly struggled within him. Too vehement;—which would have required a frame of oak and iron to contain it: in a thin though most wiry body of flesh and bone, it incessantly "wore holes," and so found outlet for itself. He could take no rest, he had never learned that art; he was, as we often reproached him, fatally incapable of sitting still. Rapidity, as of pulsing auroras, as of dancing lightnings; rapidity in all forms characterised him. This, which was his bane, in many senses, being the real origin of his disorder, and of such continual necessity to move and change,—was also his antidote, so far as antidote there might be; enabling him to love change, and to snatch, as few others could have done, from the waste chaotic years, all tumbled into ruin by incessant change, what hours and minutes of available turned up."

Sterling had meanwhile contributed to *Blackwood's Magazine* and to the *Westminster Review*, then under the charge of John Stuart Mill. "He had," says Carlyle, "an incredible facility of labour. He flashed with most piercing glance into a subject; gathered it up into organic utterability with truly wonderful despatch, considering the success and truth attained, and threw it on paper with a swift felicity, ingenuity, brilliancy, and general excellence, of which, under such conditions of swiftness, I have never seen a parallel." In order to meet a number of his literary friends on occasion of his hasty visits to London, the "Sterling Club" was formed, of which Carlyle, J. C. Hare, G. C. Lewis, John S. Mill, Tennyson, and others, were members. In 1839 he published a small volume of poems, which were almost ignored by the public, and in 1841 he again tried it with the *Election, a Poem in seven books.* In 1843 he published *Strafford, a Tragedy.* He had the great affliction during the same year to lose both his mother and his wife, who died within two hours of each other.

"If Sterling," says Carlyle, "has done little in literature, we may ask, What other man than he, in such circumstances, could have done anything? In virtue of these rapid faculties, which otherwise cost him so dear, he has built together, out of those wavering boiling quicksands of his few later years, a result which may justly surprise us. There is actually some result in those poor two volumes gathered from him, such as they are; he that reads there will not wholly lose his time, nor rise with a malison instead of a blessing on the writer. Here actually is a real seer-glance, of some compass, into the world of our day; blessed glance, once more, of an eye that is human; truer than one of a thousand, and beautifully capable of making others see with it. I have known considerable temporary reputations gained, considerable piles of temporary guineas, with loud reviewing and the like to match, on a far less basis than lies in those two volumes. Those also, I expect, will be held in memory by the world, one way or other, till the world has extracted all its benefit from them. Graceful, ingenious, and illuminative reading, of their sort, for all manner of inquiring souls. A little verdant flowery island of poetic intellect, of melodious human verity; sunlit island founded on the rocks;—which the enormous circumambient continents of mown reedgrass and floating lumber, with *their* mountain-ranges of ejected stable-litter however alpine, cannot by any means or chance submerge: nay, I expect, they will not even quite hide it, this modest little island, from the well-discerning; but will float past it towards the place appointed for them, and leave said island standing."

He was engaged during his last days on another poem, entitled *Cœur de Lion*, which he did not survive to complete. Sterling died at Ventnor, in the Isle of Wight, on the 18th September 1844, aged thirty-eight years.

Carlyle has the following remarks on Sterling's general appearance and manner:—

"Sterling was of rather slim but well-boned wiry figure, perhaps an inch or two from six feet in height; of blonde complexion, without colour, yet not pale or sickly; dark-blonde hair, copious enough, which he usually wore short. The general aspect of him indicated freedom, perfect spontaneity, with a certain careless natural grace. In his apparel, you could notice, he affected dim colours, easy shapes; cleanly always, yet even in this not fastidious or conspicuous: he sat or stood, oftenest, in loose sloping postures; walked with long strides, body carelessly bent, head flung eagerly forward, right hand perhaps grasping a cane, and rather by the middle to swing it, than by the end to use it otherwise. An attitude of frank, cheerful impetuosity, of hopeful speed, and alacrity; which indeed his physiognomy, on all sides of it, offered as the chief expression. Alacrity, velocity, joyous ardour, dwelt in the eyes too, which were of brownish gray, full of bright kindly life, rapid and frank rather than deep or strong. A smile, half of kindly impatience, half of real mirth, often sat on his face."

To Archdeacon Hare and Thomas Carlyle were committed the care of Sterling's literary character and printed writings. In 1848 appeared accordingly *Essays and Tales*, in two vols., by John Sterling, with a memoir prefixed by Archdeacon Hare. This biography had the misfortune to represent merely the character of Sterling as a clergyman; and Carlyle, who had loved the man with all the depth and fervour of no ordinary nature, resolved to re-write his biography, taking care to present Sterling in something like the human aspect which he wore among men. This work was published in one vol. in 1851. It is perhaps the greatest biographical achievement of this century.

STERNBERG, a town of the Austrian Empire, Moravia, in the circle and 10 miles N.N.E. of Olmütz. It is for the most part well built; and has an old castle of the princes of Liechtenstein, a church, Augustinian convent, military school, &c. Cotton and hosiery are manufactured here; and

as the town stands at the junction of several roads, there is a considerable trade, chiefly in linen. Pop. 12,400.

STERNE, LAURENCE, an eminent writer of fiction, has left behind him a sketch of the principal events of his life, and some particulars of his family history. From that outline it appears that he was born at Clonmel, in the south of Ireland, on the 24th November 1713. His father was a lieutenant in the army, and grandson of Dr Richard Sterne, archbishop of York. When his son was about eight years of age, Lieutenant Sterne placed him at a school in Halifax, to which town he had been conducted by his professional duties. That officer died in 1731, and in the following year, young Sterne, by the bounty of a relation and namesake of his own, was transferred from the school of Halifax to Jesus College, Cambridge. Having completed his studies at the university, he proceeded to York; and his uncle, Dr Jacques Sterne, prebendary of Durham, and canon residentiary and precentor of York, procured him the living of Sutton, and afterwards a prebend at York. At York he formed an acquaintance with the lady who afterwards became his wife, under circumstances sufficiently romantic. From a friend of hers he obtained the living of Stillington, but continued for twenty years to reside at Sutton, relieving the burden of his double charge, as he informs us, "by books, painting, fiddling, and shooting." In the library of Shelton Castle, the residence of his friend and relation, John Hall Stevenson, author of a licentious production, entitled *Crazy Tales*, Sterne found among the dross of antiquity many a brilliant gem, which he transferred without scruple to his own pages. In this stolen garb he cut a most imposing figure, until Dr Ferriar of Manchester, twenty years after the death of the celebrated plagiary, restored the pilfered trappings to the rightful owners. (See Dr Ferriar's *Illustrations of Sterne*, Lond., 1790, 8vo.)

In 1759, Sterne produced the first two volumes of *Tristram Shandy*, which procured him both money and reputation. In these volumes there was abundance of matter which every one could relish; and what was unintelligible was thought profound. Much ingenious speculation was squandered upon the black leaves and marbled pages, which were long contemplated with wonder, before they were discovered to mean nothing. "The republic of dark authors," says Swift, "have been peculiarly happy in the variety, as well as extent, of their reputation." Before this period Sterne had only printed two sermons. The two volumes of *Tristram Shandy* were succeeded by two volumes of *Sermons*. In 1761 appeared the third and fourth volumes of the novel, and the fifth and sixth in the year following. The seventh and eighth volumes were published in 1765; but these monstrous births had by that time ceased to please. Four volumes of *Sermons* were produced in 1766; and in 1767 these were followed by the ninth and last volume of *Tristram Shandy*. In 1768 Sterne returned from Italy, whither he had repaired in the hopes of finding relief for a consumptive complaint with which he had long been afflicted. He only survived to prepare for the press the first part of his *Sentimental Journey*, which was published in 1768. In the month of March of that year he expired at his lodgings in Bond Street, surrounded by strangers, a mode of death which he considered as most desirable.

The English writer to whom the author of *Tristram Shandy* is most indebted for his matter is Burton; and his manner bears some resemblance to the capricious, whimsical, and digressive *Tale of a Tub*. He even mimics Swift in sneering at "the great Dryden;" but in the writings of his prototype he might have found many things infinitely more worthy of imitation. In order to make room for his pathos, however, he eschewed the misanthropy of the dean of St Patrick's, and set up for a lover of his species, to which character his claims were less than equivocal, for his philanthropy did not extend so far as to his own mother. That sensibility is worthy only of ridicule that bestows a tear with greater promptitude than a shilling.

The humour of Swift and Rabelais, whom Sterne pretended to succeed, came from them as naturally as song from a bird; they lose nothing of their manly dignity in laughing their great laugh as nature bade them. But Sterne, who can make you laugh and cry by turns, who will not permit you any repose, he is but a great jester rather than a great humourist. Yet, nevertheless, a critic who refuses to see in many charming descriptions of Sterne's, wit, humour, pathos, and sometimes even real sentiment, must be hard to please. If the last words the famous author wrote were bad and wicked, the last words written by the stricken man were for pity and pardon.

STERNHOLD, THOMAS, was born in Hampshire towards the latter half of the fifteenth century. He had his education at Oxford, was chosen groom of the robes to Henry VIII. and retained the same office under his successor, and died in August 1549.

Sternhold's only claim to distinction is his having executed part of an English metrical version of the Psalms usually attached to the Book of Common Prayer, and characterized by all the bad taste and vulgar bathos of a street-ballad. His version of fifty-one of the Psalms was published after his death in 1549, and bore the title of, *All such Psalm of David as Thomas Sternholde did in his Lyfe drawe into English Metre*, 8vo, London. Sternhold was likewise the author of *Certain Chapters of the Proverbs of Solomon* drawen into metre, 8vo, London, 1549. Sternhold found even a ruder hand than his own to continue the metrical labour which he had begun. The edition of Sternhold and Hopkins appeared in 1562 with the title of *The whole Booke of Psalmes, collected into English metre*. As Campbell observes, in his *Specimens of English Poetry*, these men, "with the best intentions and the worst taste, degraded the spirit of Hebrew Psalmody by flat and homely phraseology, and, mistaking vulgarity for simplicity, turned into bathos what they found sublime." (See also Warton's *History of English Poetry*, vol. iii., edition of 1840.)

STESICHORUS (Στησίχορος), a famous Greek poet, said to have been born in Himera in Sicily B.C. 632. He was accordingly a contemporary of Sappho, Alcæus, Pittacus, and Phalaris. His father was probably a native of Mataurus, which would go far to explain the tradition of his being sprung from Hesiod, for it is well known that in that district there lived a race of epic poets who claimed kindred with the most ancient singer of Greece. The name which this poet is said first to have received was Tisias, and afterwards it was converted into Stesichorus, from his first having established a chorus for singing to the harp. Like all great poets his birth is said to have been accompanied by an omen. A nightingale is said to have sat upon the babe's lips and sung. Little is known regarding his life with certainty. The myths of Suidas unfortunately render the authentic portion of his narrative quite untrustworthy. Stesichorus probably died at Catanna sometime between 560 B.C. and 552 B.C., at the age of eighty, or, probably, eighty-five. He was one of the nine great lyric poets recognised by the ancients. His choral odes contained all the essential elements of perfect choral poetry. He was the first to break the monotony of the strophe and antistrophe, by the introduction of the epode. Kleine, who has furnished by far the most useful edition of the fragments of Stesichorus (Berolini, 1828), has classified his extant poems into mythical poems, hymns, erotic poems, pastoral poems, fables, and elegies. The fragments of Stesichorus were first printed together with the works of Pindar in 1560. Among recent editions are those of Suchfort, Schneidewin, Bergk, Blomfield, and Gaisford.

STETHOSCOPE, a wooden cylinder about eighteen inches long, invented by M. Laennec of Paris in 1823, and used by modern medical practitioners to ascertain the healthy or morbid condition of the organs within the chest. It is well known that wood is an excellent conductor of the vibrations that give the sensation of sound, and that, if a person scratch one end of a log of wood many yards in length, another person, by putting his ear to the other extremity, will distinctly hear every sound emitted. On this principle, the stethoscope has been invented. It is now frequently made of gutta-percha. The heart, by its violent and incessant action, imparts a motion and thrilling to the walls of the chest, which an observer can loudly hear by applying the ear to the left side; and the Stethoscope enables him to obtain the same information, with less trouble to the patient, and without anything disagreeable to the most delicate feelings. Hence, those who are well practised in the use of the stethoscope, and who have compared their observations on the living body with the appearances found in the dead bodies of those who have died of diseases of the heart, are enabled to detect enlargement of that organ, ossification of its valves, or aneurism of the great vessels. In diseases of the lungs, likewise, and even of the abdominal viscera, the stethoscope is a most valuable means of diagnosis.

STETTIN, a fortified town of the Prussian dominions, capital of the province of Pomerania, on the left bank of the Oder, which is here crossed by two bridges, leading to the suburb of Lastadie on the other side, 78 miles N.E. of Berlin. Immediately below the town the Oder expands into the wide lake of Stettin, through which it falls into the Baltic. The fortifications of the town are strong, and include part of the suburbs across the river. They are entered by five principal and several smaller gates; two of the former, the King's Gate and the Berlin Gate, are richly adorned with emblematical figures, and are among the finest structures of the kind in Germany. The town is old, and in general well built, containing several large and handsome squares. The public buildings, however, are not very conspicuous or remarkable. Among these, the most important is the ancient castle, which was the residence of the Dukes of Pomerania from 1575 till the line became extinct in 1637. In the chapel of the castle is the ducal vault. The castle contains a collection of northern antiquities, now in course of formation, and has a lofty tower which commands a fine prospect over the town and neighbourhood. In one of the public squares of Stettin stands a fine marble statue of Frederick the Great, and another of Frederick William III. of the same material. The town-hall, exchange, and theatre are among the chief edifices of the town. Its churches are not very noteworthy, if we except the massive and venerable St James', which occupies a conspicuous position on a hill near the centre of the town. The oldest part of this building goes back as far as the 13th century. The other Protestant churches are four in number, and there is one belonging to the Roman Catholics. Stettin is the see of a bishop, and has a court of law and public offices. There is a gymnasium, with a library, museum, and observatory attached to it, several other schools of various kinds, a workhouse, hospitals, and other benevolent institutions. The manufactures of the town are very extensive, including linen, woollen, and cotton cloth, canvas, leather, hosiery, hats, soap, tobacco, beer, and sugar. Ships and boats are also built here, and ship's anchors are forged for all the vessels of the Prussian states. The trade of Stettin is great and rapidly increasing. It is not only one of the chief ports of Prussia, but at the same time the most important commercial town on the shores of the Baltic. The following table exhibits the quantities and values of the principal articles exported and imported at Stettin in the year 1854:—

Articles.	Imports.		Exports.	
	Quantity	Value.	Quantity.	Value.
		L.		L.
Bones.....................(cwt.)	...	...	60,871	136,809
Coffee.................... „	56,942	290,404	...	...
Grain, of diff. kinds (bushels)	503,590	101,074	1,854,340	554,201
Herrings..............(barrels)	140,740	188,999	...	...
Iron of all kinds.........(cwt.)	451,896	184,051	797	703
Oil of different kinds and oil-cakes............(cwt.)	232,258	689,480	45,629	28,171
Rice.................... „	151,815	158,105	...	...
Wine.................... „	104,584	251,001	...	...
Wood.................... „	2,738	2,053	...	306,653

And the total value of the exports and imports for each year from 1850 to 1854 was as follows:—

	1850.	1851.	1852.	1853.	1854.
	L.	L.	L.	L.	L.
Imports	2,070,123	1,724,487	1,956,946	2,697,143	2,459,160
Exports	1,023,980	1,205,895	1,324,522	1,872,403	1,314,310

The total number of vessels, exclusive of those in the coasting trade, that entered at the port in 1852 was 720, tonnage, 150,404; and of those that cleared in the same year the number was 723, and the tonnage 160,148. Stettin is a place of great antiquity. It owes its origin to a Wendish castle, and as early as 830 there was a considerable village on the spot. In those early ages a temple of the Wendish idol Trigloff, which stood here, was several times destroyed and rebuilt again, while Christianity and Paganism by turns got the upper hand in their struggle for the country, and when Christianity was finally introduced, about the beginning of the 13th century, immense treasures of gold, silver, and precious stones were found stored up in it. The town shared in the vicissitudes of this part of Pomerania, which are narrated in the article POMERANIA, belonging at one time to Denmark, at another to Sweden, and finally to Prussia. Two Russian empresses, Catherine the Great, and Maria Feoderowna, wife of Paul the successor of Catherine, were born here. Pop. (1858) 53,103.

STEUBENVILLE, a town of the United States of North America, capital of Jefferson county, in the state of Ohio, on the Ohio, 35 miles W. by S. of Pittsburg. It occupies an elevated position, in the midst of a beautiful country, and contains county buildings, numerous churches, an academy and a school, two banks, and several newspaper offices. The manufactures of the town are extensive, including woollen and cotton fabrics, paper, glass, machinery, &c. There are also several iron-foundries and flour-mills. The whole manufactories employ more than 1000 hands. Pop. (1850) 6139.

STEVENSON, ROBERT, an eminent civil engineer, was born at Glasgow in 1772, and died at Edinburgh in 1850. The death of his father, a West India merchant, left him while yet an infant in very disadvantageous circumstances; but, by the energy and self-denial of his mother, who had designed her only child for the church, he obtained a good education, and acquired some tincture of classical learning. The bent of his mind, however, was decidedly towards the physical sciences; and having early imbibed an enthusiastic admiration of Smeaton, which he retained through life, he resolved to follow the profession of a *civil engineer*. In spite of many discouragements, which he bore with hopefulness and patience, he succeeded in prosecuting his studies, first in the Andersonian Institution, then recently opened at Glasgow, and afterwards at the University of Edinburgh, under Robison, Dugald Stewart, and Playfair. In 1797 he became engineer to the Board of Northern Lighthouses, an office which he

held for nearly half a century; and during his incumbency, he erected no fewer than *twenty-three* lighthouses, including that of the Bell Rock, which alone is sufficient to stamp his reputation as an engineer. Some description of this remarkable rock will be found under the head LIGHTHOUSES, and it is not needful, in this place, to do more than say that Mr Stevenson displayed, in its design and execution, great mechanical skill and practical sagacity, as well as untiring perseverance and indomitable courage. Following the model of the Eddystone, which he greatly revered, he yet made some important improvements in framing his own design, and in particular he succeeded in converting the floors of the apartments, whose outward disruptive thrust, Smeaton had contrived to counteract by an ingenious expedient, into really conservative bonds or ties for the whole edifice. He also greatly improved the optical and mechanical arrangements of the lighthouses, and added some valuable distinctions, especially the *flashing* and *intermittent* lights, for enabling the mariner to identify the lights on a coast.

In the course of his general practice as a civil engineer, he designed and executed many important works in various parts of the United Kingdom, and among others bridges at Glasgow and Stirling. The fine approach to the city of Edinburgh by the Calton Hill was also designed by him and formed under his eye. He traced and designed the lines of many canals and railways, which have since been executed much in accordance with the recommendations in his numerous printed reports. There is scarcely a harbour or navigable river in Britain about which his advice, which was often also called for in Ireland, was not at some time given. His printed reports and other contributions to the knowledge of engineering extend, when collected, to five thick quarto volumes.

He was not naturally of a scheming turn of mind, yet he occasionally assumed the character of an inventor, as in the case of his ingenious suggestion of a new form of suspension-bridge for small spans, in which, by passing the chains *under* the roadway, the necessity for tall piers is avoided. Several bridges have been executed on this plan. For timber bridges, also, he proposed a simple and beautiful construction of arch, in which the *ring course* consists of layers of thin planks bent to the circular form, and stiffened by means of the vertical frame-work supporting the horizontal beams on which the level roadway rests. This kind of bridge has come into very general use on railways. He is, moreover, entitled to the merit of first having pointed out the advantage of using malleable iron for the rails of our *iron ways*. He also first called attention to the interesting fact which he first detected at the mouth of the Dee, in Aberdeenshire, that even in the case of our small rivers the fresh water they bring down floats for some distance on the surface of the sea before mingling with the salt water. This fact he demonstrated by the use of an instrument which enabled him to take water from any depth and draw it to the surface, unmixed with any of the intermediate fluid.

Robert Stevenson possessed great sagacity, buoyant fortitude, and untiring perseverance; and he was early remarkable for scrupulous punctuality in all his engagements. In private life he was a man of sterling worth, and full, even in his last years, of that genial unselfishness and generosity which in so many men do not outlive their boyhood. His whole mind was elevated by habitual and unobtrusive piety. The remembrance of his early struggles never left him, but seemed to influence him much in his unwearied efforts to forward the progress of young men through life, a duty which he considered as sacred and in which he greatly delighted, and from the prosecution of which no personal inconvenience ever made him swerve. Towards himself he practised something like the old Roman self-denial; and up to the close of his long and laborious life, he would never permit his age to be pleaded as a reason for shrinking from the calls of duty. (A. S.)

STEWARD, an officer appointed in another's stead or place, and always taken for a principal officer within his jurisdiction. Of these there are various kinds. The greatest officer under the crown is the lord high steward of England, whose office was anciently the inheritance of the earls of Leicester, till forfeited by Simon de Montfort to King Henry III. But the power of this officer is so very great, that it has not been judged safe to trust it any longer in the hands of a subject, excepting only for a particular occasion, as to officiate at a coronation, or at the arraignment of a nobleman for high treason or felony. During his office the steward bears a white staff in his hand, and when the trial is ended he breaks the staff, and with it his commission expires. There is likewise a lord-steward of the king's household, who is the chief officer of the king's court, has the care of the king's house, and authority over all the officers and servants of the household except such as belong to the chapel, chamber, and stable. The court of the lord high steward of Great Britain is a court instituted for the trial of peers indicted for treason or felony, or for misprision of either.

STEWART, DUGALD, was born in Edinburgh, 22d November 1753. He was the son of Dr Matthew Stewart, at that time the eminent Professor of Mathematics in the University, and of Marjory, only child of Archibald Stewart of Catrine, writer to the signet in Edinburgh. Mr Stewart's father and grandfather were both clergymen of the Church of Scotland,—the former having been minister of Rothesay for upwards of fifty years, and the latter having held the charge of Roseneath, before his appointment, as the successor of Colin Maclaurin, to the chair of mathematics in the University of Edinburgh.

Mr Stewart received the principal part of his early education at the High School of his native city, where, under the instruction of the celebrated Dr Alexander Adam, he laid the foundation of those classical tastes and accomplishments which he cherished through life, and the influence of which was so strongly marked in the course of his subsequent career as thinker, professor, and author. From the High School, Mr Stewart passed to the University of Edinburgh, where he studied for four sessions, from 1765-66 to 1768-69. The two names which the young student of arts in the metropolitan university of last century heard mentioned with the greatest reverence, and was taught to honour above all others, were Bacon and Newton. The assiduous pursuit of physical and mathematical science, after the manner of the great Restorer of learning and his disciple, was the most notable feature of university life in Edinburgh during the first half of the eighteenth century. This change in the character of the university studies, from the more abstract and technical culture of the preceding century, was chiefly due to the energy and enthusiasm of the three Gregorys and of Colin Maclaurin. The general method of scientific research, by which results so splendid as those of Newton had been achieved, naturally attracted a large share of attention. Accordingly we find that at the period of Mr Stewart's attendance at the university, the character of the Inductive Method formed a special topic in the prelections of the Professor of Natural Philosophy (James Russell), while, in the lectures of the Professors of Logic and Moral Philosophy, the importance of the application of the same method to the Science of Mind was impressively inculcated. By those influences was the youthful mind of Stewart powerfully moulded. He thus naturally imbibed that admiration of the spirit, method, and aims of Bacon, which so strongly predominated through his entire life, intellectual and moral, and at the same time acquired that taste for physical and mathematical science

which he conjoined with his distinctive attachment to reflective studies.

It was, however, in the Logic and Moral Philosophy class-rooms that Mr Stewart found objects of study more immediately congenial to his taste and capacities. John Stevenson, the Professor of Logic, though not an original thinker, was nevertheless a careful and efficient instructor, as has been gratefully commemorated by more than one pupil, who afterwards rose to eminence in life. Stevenson, during Stewart's attendance on his course of lectures, showed the greatness of his mind by candidly giving up, as insufficient and in part erroneous, doctrines which he had inculcated during the greater portion of a long life, when, in his later years, he became convinced, on grounds adduced by another, of their inadequacy,—an exemplification of the philosophical spirit which gained the admiration and lived in the memory of his youthful auditors. The preceptor by whom Mr Stewart was most strongly influenced at this period was doubtless Adam Ferguson, the accomplished Professor of Moral Philosophy. With Ferguson Stewart had much in common. The pupil naturally and cordially sympathised with the admiration of classical antiquity, the fervid eloquence, the liberal political doctrines, and, above all, the lofty and ennobling ethical views, which characterised his instructor. Dr Ferguson, moreover, very early discovered and appreciated the peculiar capacity of his pupil for reflective studies. About this period Mr Stewart appears to have entertained the design of studying for the Church of England. The University of Glasgow then, as at present, afforded facilities to young men of talent and application for pursuing a course of study at Oxford. Stewart accordingly entered that university in 1771-72, partly with a view to the Snell Exhibition, but also, influenced by the recommendation of Ferguson, that he might enjoy the privilege of the prelections of Dr Thomas Reid, whose *Inquiry into the Human Mind* (1764) was already regarded by thinking men as the inauguration of a new epoch in Speculative Philosophy. Reid occupied a chair which had been rendered celebrated by his predecessors, Hutcheson and Adam Smith. Its influence and lustre were destined even more greatly to increase during Reid's professoriate. While powerfully combating the fundamental doctrines of Locke, Berkeley, and Hume, the prelections of Reid were admirably fitted to evoke and regulate the philosophical capacity of his pupils. In a style lucid, simple, and devoid of technicality or much speculative refinement, he inculcated a philosophy of the nature, origin, and bounds of human knowledge, at once independent and restrained, and bearing in all its parts strong traces of that fresh and vigorous reflection, manliness, earnestness, and lofty aim by which he was so eminently characterised. Stewart caught the spirit of his instructor, and intelligently appreciated his philosophical method and purpose. During a long lifetime, consecrated to Philosophy, Stewart nourished that spirit in Scotland, and continued and extended the application of the method with a freshness, power, delicacy, amplitude of learning and illustration, all his own,—evincing that he was no mere inheritor of a dead tradition, but a true disciple, in whose mind principles quickened and grew, until they effloresced in all the fulness and variety of life and beauty.

In 1772, Mr Stewart, at the early age of nineteen, undertook the charge of the mathematical classes in the University of Edinburgh, in room of his father, whose health was beginning to decline. These classes he conducted with marked ability and success. After acting for three years as his father's substitute, he was formally elected conjoint Professor of Mathematics, June 14th 1775. During session 1778-79, Mr Stewart conducted the class of Moral Philosophy, at the urgent request of Professor Ferguson, who had engaged to accompany the American Commissioners as their secretary on their mission to the colonies. Mr Stewart commenced an original course of lectures on Morals after only a week's notice. He was at the same time engaged for three hours daily as Professor of Mathematics, giving during the session a course of lectures on Astronomy for the first time. His brilliant appearances in this new and congenial sphere as a lecturer in Philosophy were long remembered by his auditors. In 1783 he visited Paris for the first time along with his friend, Lord Ancrum, afterwards Marquis of Lothian. On his return to Scotland in the autumn of the same year, he married Helen, daughter of Mr Neil Bannatyne, Glasgow. Mrs Stewart died in 1787, leaving an only child, afterwards Lieutenant-Colonel Matthew Stewart. Mr Stewart again married in 1790 Helen D'Arcy Cranstoun, daughter of the Hon. George Cranstoun, and sister of the Countess Purgstall and of Lord Corehouse. On the resignation of the professorship by Dr Ferguson in 1785, Mr Stewart was transferred from the Chair of Mathematics to that of Moral Philosophy. From his appointment to this chair until his retirement from active academical duty in 1810, Mr Stewart exercised by his teaching alone, without taking into account the concurrent and more general impression made by his published writings, a wide, powerful, and peculiarly elevating and refining influence. Among his students were to be found not only the youth of Scotland, but many, and these of the highest rank, from England. The continent of Europe and America likewise furnished a number of pupils.

The sphere of investigation which Mr Stewart proposed to himself in the Chair of Moral Philosophy was far from being limited by the science of Ethics proper. The ground-plan of his course was a study of the human mind in the totality of its phenomena; or, to use more recent phraseology, the science of General Psychology. With this as a basis, or root, he connected Metaphysics proper, or the science of First Principles; the application of these principles in Natural Theology; Ethics proper; the theory of Taste; Politics, including the theory of Government and Political Economy. As a philosophical lecturer, Stewart must be allowed to have held a high place, though the character of his mind was not severely analytic or abstract. Without habitually offering a definite determination of the questions which he discussed, he had the faculty of unfolding comprehensive fields of thought, and thus of exciting, in a high degree, the intellectual activity of his students. He possessed, moreover, and wielded with the ease of a master, the power of sketching ideals of human life and action, which inspired in many of his youthful hearers an enthusiasm at once so intense and continuous as to influence and mould their whole future character. His mode of lecturing, that of speaking from notes, was well suited to the character of his mind, and to his treatment of philosophical themes. It allowed full scope for the imagination and feelings, and left unimpeded the flow of a versatile and abundant eloquence, which, as occasion required, was graceful, tender, and sublime. "Dugald Stewart," says Lord Cockburn, himself a pupil, "was one of the greatest of didactic orators. Had he lived in ancient times, his memory would have descended to us as that of one of the finest of the old eloquent sages. But his lot was better cast. Flourishing in an age which required all the dignity of morals to counteract the tendencies of physical pursuits and political convulsions, he has exalted the character of his country and generation. No intelligent pupil of his ever ceased to respect philosophy, or was ever false to his principles, without feeling the crime aggravated by the recollection of the morality which Stewart had taught him."

Mr Stewart gave from the beginning of his career as professor lectures on Politics proper, or the Theory of Government, in connection with his course of Moral Philosophy. In the winter of 1800, he commenced a separate

course of lectures on Political Philosophy, which, in addition to Politics proper, embraced also the recent science of Political Economy. In his lectures on Political Economy, Mr Stewart accepts in general the results of the speculations of the French economists and of Adam Smith. He concurs with the economists and Smith in advocating the propriety of allowing the freest scope for individual interest and effort in the matter of trade, and the unrestricted exchange between nations of the varied products of their industry. On this point, indeed, Stewart sought to give to the principles of the *Wealth of Nations* a wider application than their author had allowed; for he maintained against Smith the impolicy of those restrictions known as the navigation laws, which were only finally abolished in 1850. To the political teachings of Stewart, the present generation owes more than it can well appreciate. At a time when the mere discussion of the fundamental principles of Politics and Political Economy was sufficient to excite suspicion of disaffectedness to the interests of the country, and of sympathy with revolutionary tendencies, Stewart had the courage, in his place as a university professor, to canvass those questions, and to seek to inculcate on the intelligent youth of the land opinions of so advanced a character, that they did not meet with general appreciation and acceptance until long after the period of their promulgation.

In March 1792, Mr Stewart gave to the world the first volume of *Elements of the Philosophy of the Human Mind.* This volume was his earliest contribution towards that scheme of a comprehensive delineation of the human mind, which he had proposed to himself as the grand aim of his life. The volume is chiefly psychological; and, after preliminary remarks on the nature, ends, and utility of philosophy, deals with the powers of Knowledge, embracing External Perception, Attention, Conception, the Laws of Association, Memory, and Imagination. At the period of the publication of the first volume of the *Elements*, philosophical speculation, at least in England, was of the lowest sensational school. The theorists in philosophy of that time sought to explain the mental phenomena by the material hypothesis of vibrations and vibratiuncles, and by an exaggerated application of the principle of Association. Nothing, accordingly, could be more opportune than the appearance of the first volume of Mr Stewart's writings at the period in question. In spirit and matter, the kind of thinking which these writings successively exemplified, was fitted to impart an elevated tone to the current speculation and feeling of the age, alike in Psychology, Metaphysics, and Morals.

In 1793 Mr Stewart read before the Royal Society his *Account of the Life and Writings of Adam Smith.* His Memoir of Principal Robertson, and that of Dr Reid, were read before the same body,—the former in 1796, the latter in 1802. In 1805 appeared his first pamphlet on what was known as the Leslie case, entitled, *A Statement of Facts, &c.;* and, in December of the same year, he added a second pamphlet, entitled, *Postscript to Statement of Facts.* The *Statement of Facts*, though hastily written, is remarkable for the clearness and ability with which it disentangles the real point at issue from the mass of irrelevant matter which, as usually happens, was raised in the popular discussion of a purely philosophical question. On general and historical grounds Mr Stewart seeks to vindicate, within certain limits, the doctrine of Causation, the approval of which by Mr Leslie was made the ground of objection to his appointment to the Chair of Natural Philosophy. Mr Stewart especially endeavours to show that the doctrine which teaches that the utmost we can observe in physical sequences is simply invariable antecedence and consequence, is both theologically innocuous, and the only safe opinion. The controversy was finally decided in favour of Mr Leslie.

In 1806, Mr Stewart received the appointment of the writership of the *Edinburgh Gazette*, as a recognition of the services which he had rendered to education and philosophy. The salary attached to the office was L.300 per annum. In the summer of this year, he accompanied Lord Lauderdale on his mission to Paris, which he had previously visited before and at the commencement of the Revolution, and where he had acquired a large circle of friends, distinguished in philosophy, literature, and politics, among whom may be mentioned the Abbé Morellet, the Baron de Gerando, &c. Mr Stewart's health, which had been delicate for some years, received a severe blow from the death of his second son, George, in 1809. He was unable to lecture during a great part of session 1809-10. Dr Thomas Brown, at his request, acted as his substitute. Mr Stewart finally withdrew from active professorial duty at the end of that session. Dr Brown was appointed conjoint-professor of Moral Philosophy, Mr Stewart's name still remaining in the commission. Shortly after the death of Dr Brown, in 1820, Mr Stewart formally resigned the professorship, which was conferred upon Mr John Wilson. From the year 1809 until the close of his life, Mr Stewart lived in comparative retirement at Kinneil House, Linlithgowshire, which was kindly placed at his disposal by his friend the Duke of Hamilton. His retirement was almost exclusively devoted to maturing and arranging the philosophical labours of his previous life; his reflective activity being interrupted only by friendly intercourse, and the calls of those strangers whom the lustre of his name led to pay a passing visit at Kinneil. From Kinneil were dated, in 1810, the *Philosophical Essays;* in 1813 (but only published in 1814), the second volume of the *Elements;* in 1815, the first, and, in 1821, the second part of the *Dissertation;* in 1826 (but only published in 1827), the third volume of the *Elements;* and, in 1828, a few weeks before his death, the *Philosophy of the Active and Moral Powers.* The last mentioned work, with the relative part of the *Outlines*, embody the results of his ethical speculations. His *Lectures on Political Economy* were first published in his *Collected Works*, edited by the late Sir W. Hamilton. In January 1822, Mr Stewart was struck with paralysis. "The malady," says his son, "which broke his health and constitution for the rest of his existence, happily impaired neither any of the faculties of his mind nor the characteristic vigour of his understanding. As soon as his health was sufficiently re-established, he continued to pursue his studies with his wonted assiduity; exhibiting, among some of the heaviest infirmities incident to age, an admirable example of the serene sunset of a well-spent life of classical elegance and refinement, so beautifully imagined by Cicero: 'Quiete, et pure, et eleganter actæ ætatis, placida ac lenis senectus.'" Mr Stewart died in Edinburgh on the 11th June 1828, after a brief illness, and fresh shock of paralysis. His remains were interred in the family vault on the west side of the churchyard of Canongate, not far from the grave of Adam Smith.

Among Scottish philosophers Mr Stewart stands prominently out as a psychological observer. On questions properly metaphysical he has left little which can be regarded as essentially his own. The field within which he chiefly laboured was that of the phenomena of the mind, intellectual, moral, and æsthetical, as these appear under the modifications imposed on them by the general circumstances of human life, — education and society. In careful, delicate, and original observation, within this sphere, he has seldom been equalled; and though led into diffuse composition both by the character of his mind and the habits of the academical teacher, there are few writers in the English language whose beauties of style, and living sympathy with what is best in human life and in its aspirations, are more fitted to refine the taste and quicken the moral sensibilities. (J. V.)

STEWART, *Matthew*, an eminent mathematician, and father of Dugald Stewart, the eminent Scottish philosopher, noticed above, was born in 1717 at Rothesay in the Isle of Bute, of which parish his father was minister. Being intended for the church, he passed through the usual course of a grammar-school education, and was in 1734 received as a student into the University of Glasgow. There he had for his preceptors in moral science and mathematics the celebrated professors Hutcheson and Simson, by the latter of whom he was instructed in what may be called the *arcana* of the ancient geometry.

His views making it necessary for him to remove to Edinburgh, he was introduced by Dr Simson to Maclaurin, and he attended his lectures with such advantage as might be expected from eminent abilities, directed by the judgment of him who made the geometry of Newton intelligible to ordinary capacities. From his intimacy with Simson he had, however, acquired such a predilection for the ancient geometry, as the modern analysis, however powerfully recommended, could not lessen; and he kept up a regular correspondence with his old master, giving him an account of his progress and his discoveries in geometry, and receiving in return many curious communications respecting the *Loci Plani*, and the porisms of Euclid.

While the second invention of porisms, to which more genius was perhaps required than to the first discovery of them, employed Dr Simson, his pupil pursued the same subject in a different and new direction. In doing so, he was led to the discovery of those curious and interesting propositions, which were published under the title of *General Theorems* in 1746. They were given without the demonstrations, but did not fail to place their discoverer at once among the geometers of the first rank. They are for the most part porisms, though Stewart, careful not to anticipate the discoveries of his friend, gave them no other name than that of theorems.

Before this period he had entered the church, and through the patronage of the Duke of Argyle and the Earl of Bute, he obtained the living of Roseneath, a retired country parish in the west of Scotland; but in 1747 he was elected to the mathematical chair in the University of Edinburgh, which had become vacant the year before by the death of Maclaurin. The duties of this office gave a turn somewhat different to his pursuits, and led him to think of the most simple and elegant means of explaining those difficult propositions which were hitherto only accessible to men deeply versed in the modern analysis. In doing this, he was pursuing the object which of all others he most ardently wished to attain, namely, the application of geometry to such problems as the algebraic calculus alone had been thought able to resolve. His solution of Kepler's problem was the first specimen of this kind which he gave to the world; and it was impossible to have produced one more to the credit of the method which he followed, or of the abilities with which he applied it. On this problem the utmost resources of the integral calculus had been employed. But though many excellent solutions had been given, there was none of them at once direct in its method and simple in its principles. Stewart was so happy as to attain both these objects; and his solution appeared in the second volume of the *Essays of the Philosophical Society of Edinburgh* for the year 1756. In the first volume of the same collection there are some other propositions of Stewart's, which are an extension of a curious theorem in the fourth book of Pappus. They have a relation to the subject of porisms, and one of them forms the ninety-first of Dr Simson's restorations. They are besides very beautiful propositions, and are demonstrated with all the elegance and simplicity of the ancient analysis.

The prosecution of the plan which he had formed of introducing into the higher parts of mixed mathematics the strict and simple form of ancient demonstration, produced the *Tracts, Physical and Mathematical*, which were published in 1761, and the *Essay on the Sun's Distance*, which was published in 1763. In this last work it is acknowledged that he employed geometry on a task which geometry cannot perform; but while it is granted that this determination of the sun's distance is by no means free from error, we may venture to affirm that it contains a great deal which will always interest geometers, and will always be admired by them. Few errors in science are redeemed by the display of so much ingenuity, and what is more singular, of so much sound reasoning. The investigation is everywhere elegant, and will probably be long regarded as a specimen of the most arduous inquiry which has been attempted by mere geometry. The *Sun's Distance* was the last work which Dr Stewart published; and though he lived to see several animadversions on it made public, he declined entering into any controversy. His disposition was far from polemical; and he knew the value of that quiet which a literary man should rarely suffer his antagonists to interrupt. He used to say, that the decision of the point in question was now before the public; that if his investigation was right it would never be overturned, and that if it was wrong it ought not to be defended. A few months before he published the essay just mentioned, he gave to the world another work, entitled *Propositiones Geometricæ more Veterum demonstratæ*. This title, it is said, was given to it by Dr Simson, who rejoiced in the publication of a work so well calculated to promote the study of the ancient geometry. It consists of a series of geometrical theorems, for the most part new; investigated first by an analysis, and afterwards synthetically demonstrated by the inversion of the same analysis. Dr Stewart's constant use of the geometrical analysis had put him in possession of many valuable propositions which did not enter into the plan of any of the works that have been enumerated. Of these not a few have found a place in the writings of Dr Simson, where they will for ever remain to mark the friendship of these two mathematicians, and to evince the esteem which Simson entertained for the abilities of his pupil.

Soon after the publication of the *Sun's Distance*, Dr Stewart's health began to decline, and the duties of his office became burdensome to him. In the year 1772, he retired to a small demesne which he possessed in Ayrshire, where he afterwards spent the greater part of his life, and never resumed his labours in the university. But though mathematics had now ceased to be his business, they continued to be his amusement till a very few years before his death, which happened on the 23d of January 1785, at the age of sixty-eight.

The habits of study, in a man of original genius, are objects of curiosity, and deserve to be remembered. Concerning those of Dr Stewart, his writings have made it necessary to remark, that from his youth he had been accustomed to the most intense and continued application. In consequence of this application, added to the natural vigour of his mind, he retained the memory of his discoveries in a manner that will hardly be believed. He rarely wrote down any of his investigations till it became necessary to do so for the purpose of publication. When he discovered any proposition, he would put down the enunciation with great accuracy, and on the same piece of paper would construct very neatly the figure to which it referred. To these he trusted for recalling to his mind at any future period the demonstration or the analysis, however complicated it might be. Experience had taught him that he might place this confidence in himself without any danger of disappointment; and for this singular power he was probably more indebted to the activity of his invention than the mere tenaciousness of his memory. Though he was extremely studious, he read few books, and verified the observations of M. d'Alembert, that of all men of letters, mathematicians read least of

the writings of one another. His own investigations occupied him sufficiently; and indeed the world would have had reason to regret the misapplication of his talents had he employed in the mere acquisition of knowledge that time which he could dedicate to works of invention.

STEWARTON, a town of Scotland, Ayrshire, on the right bank of the Annock, 6 miles N. by W. of Kilmarnock, and 18 S.S.W. of Glasgow. It is generally well built, consisting of one main street about a mile long, with several smaller streets. There is a town-hall, a jail, places of worship belonging to the Established Church, the Free Church, and the United Presbyterians, and schools with libraries connected with each of the churches. Extensive and flourishing manufactures are carried on here, especially of Highland bonnets, carpets, linen, damask, and spindles for cotton and worsted. There are also mills for carding and spinning wool; and considerable quantities of steel clock-work are made and exported from Stewarton. Pop. of the town, 3164.

STEYER, or STEYR, a town of the Austrian empire, Upper Austria, at the confluence of the Steyer and the Enns, 19 miles S.E. of Linz. It stands between the two rivers, and is connected by bridges with the suburbs Ennsdorf and Steyerdorf on either side. On a hill above the town stands the castle, belonging to Prince Lamberg, and on another hill near the suburb Steyerdorf is a Jesuits' college, now suppressed. In the cathedral, which was built in 1443 on the model of St Stephen's in Vienna, there are some beautiful specimens of painted glass, and a fine old bronze font. Steyer is celebrated for its manufactures, especially of hardware; which are so extensive as to have procured for the town the name of the Austrian Sheffield. There are also paper-mills, cotton-factories, manufactories of woollen cloth, &c. A considerable trade is carried on in the exportation of these articles. Steyer was the birthplace of the satiric poet Blumaner. It was at one time the capital of Styria. Pop. 10,414.

STICCATO (*Ital.*), a rude musical instrument, formed of a number of sticks of hard wood of different lengths, generally attached to each other by strings at the ends, but so as to hang separate from one another when suspended by the top. It is played upon by striking the sticks with rods of cane or whalebone tipped with ivory balls. Mersenne, in his *Harmonia Universalis*, calls this instrument *ligneum psalterium*.

STIEGLITZ, CHRISTIAN LUDWIG, an eminent architectural writer of Germany, was born at Leipzig on the 12th of December 1756. In his youth he had his mind familiarized with pictures, cabinets of medals and minerals, in his father's collection, which was the means of forming the lad's taste for those ultimate walks which he found so congenial. When pursuing his studies at the university he directed his attention mainly to jurisprudence. He likewise wrote poems, tales, and romances. In 1784 he took the degree of Doctor of Laws, and in 1786 appeared his first architectural work entitled *Versuch über die Baukunst.* In 1792, the same year in which he was made a member of the council of Leipzig, he brought out his *Geschichte der Baukunst der Alten*, and shortly after appeared his *Encyclopadie der bürgerl. Baukunst*, in 5 vols., 1792–98. Passing over his specimens of modern architecture as feeble and generally insipid, we come to a really excellent work published in 1820, called *Altdeutsche Baukunst*, which contributed in a large degree to the diffusion of that taste for mediæval art which is so general in Germany at the present day. His *Geschichte der Baukunst* appeared in 1827. After having contributed various articles to different journals and to Ersch and Gruber's *Encyclopädie*, and having produced other works of more or less merit, Stieglitz died in his native town on the 17th of July 1836.

STIFEL. See ALGEBRA.

STIGLIANO, a town of Naples, in the province of Baslicata, 29 miles S.W. of Matera. It contains several churches and convents, and has some trade in cattle, wine, and oil. Pop. 4200.

STIGLMAYER, JOHANN BAPTIST, an eminent metal-founder of Munich, was the son of a poor blacksmith, and was born at Fürstenfeldbrück, near Munich, on the 18th October 1791. The boy originally acquired the art of drawing by copying some illustrative wood-cuts of an old convent in possession of his father. Having been placed with a goldsmith of Munich, he by his industry and good conduct recommended himself to the director of the Bavarian mint, who procured him admission into the academy in 1810. This was the means of introducing him to the notice of the king, who in 1819 sent him to Italy to complete his studies. While in Rome Stiglmayer's attention was drawn to the art of metal-founding by Ludwig, then crown-prince of Bavaria. After spending a year or two in the study of metal castings he returned to Munich in 1822, and set to work in 1826 at the royal bronze-foundry, and turned out more extensive castings than any other man of modern times. He executed numerous monuments of his own planning, but generally he preferred following the designs of Schwanthaler, Thorwaldsen, and Rauch. He died on the 2d of March 1844, the day on which his nephew, assistant and successor, Ferdinand Miller, cast the colossal statue of Goethe, designed by Schwanthaler, for the city of Frankfort.

STILL, JOHN, said to be the author of *Gammer Gurton's Needle*, was a native of Grantham in Lincolnshire, and was born in 1543. He became a student of Christ's College, Cambridge, where he duly graduated and took orders. He was appointed in 1570 Lady Margaret's professor in his university, subsequently held livings in Suffolk and Yorkshire, and was master successively of St John's College and of Trinity College. Still was elevated to the bishopric of Bath and Wells in 1592, and after enjoying considerable fame as a preacher and disputant, he died, leaving a large fortune from lead-mines discovered in the Mendip Hills.

To Bishop Still is ascribed the authorship, on somewhat slight grounds, of the earliest comedy but one in the English language. This is *Gammer Gurton's Needle*, which bears on the title-page, "Made by Mr S., Master of Arts," which was first published in 1575. Perhaps the introduction to the second act of that coarse play, which consists of the oldest drinking-song in the English language, has made the jolly bishop more widely known than his loudest disputations would ever have rendered him. This exquisite old song, commencing,

> "I cannot eat but little meat
> My stomach is not good,"

has been found, on more recent research, to belong to an earlier date than the era of Bishop Still. (See Dyce's *Life of Skelton*, vol. i., pp. 7–9.)

STILLING, JOHANN HEINRICH JUNG commonly called, a famous German Pietist, was the son of a poor charcoal-burner, and was born at Gründ in Westphalia in 1740. He originally worked at his father's occupation, but afterwards selected the trade of a tailor. He soon afterwards relinquished this business in favour of a teacher's situation. He alternated between the ferula and the needle for some time, until some rich persons, attracted by his simplicity and his modest devoutness, made him tutor to their children. Having saved a little money, he now went to the university of Strasburg, where he studied medicine, and subsequently became a physician at Elberfeld. Jung became famous as an oculist, and is said by the poet Matthisson to have restored upwards of 2000 poor blind people to their sight. He was as liberal as he was skilful, and hundreds of the

German poor knew the hand of the generous philanthropist who had heard nothing of his skill as a physician. In 1778 he was chosen professor at Lautern, in 1787 at Marburg, and in 1803 at Heidelberg. He died at Carlsruhe in 1817.

When a student at Strasburg, Stilling had accidentally taken the attention of Goethe by his simplicity, his earnestness, and the humble devoutness with which he entered into everything which he undertook. Goethe remained his warm friend throughout life, and has sketched his character with much fondness in various passages of his *Dichtung und Wahrheit*, books ix. and x. (See also Lewes's *Life of Goethe*, vol. i., p. 105.) Stilling was a voluminous writer. The most popular of his works are his autobiography (*Lebensgeschichte*) and his *Theorie der Geisterkunde*, which have both been rendered into English by Jackson. But he has attained his greatest fame as a mystical writer and thinker. His works have been published by Grollman at Leipzig, 13 vols., 1835.

STILLINGFLEET, Edward, Bishop of Worcester, and "renowned," according to Lord Macaulay, "as a consummate master of all the weapons of controversy," was born at Cranborne, in Dorsetshire, in 1635. He was educated at St John's College, Cambridge; and having received holy orders, was, in 1657, presented to the rectory of Sutton in Nottinghamshire. In 1659 appeared his first work, entitled, *Irenicum, or the Divine Right of particular Forms of Church Government Examined*. By publishing his *Origines Sacræ*, one of the ablest defences of revealed religion that has ever been written, he soon acquired such reputation, that he was appointed preacher of the Rolls Chapel; and in January 1665 was presented to the rectory of St Andrews, Holborn. He was afterwards chosen lecturer at the Temple, and appointed chaplain in ordinary to King Charles II. In 1668 he took the degree of D.D.; and was soon after engaged in a dispute with those of the Romish religion, by publishing his discourse concerning the idolatry and fanaticism of the Church of Rome, which discourse he afterwards defended against several antagonists. In 1680 he preached at Guildhall Chapel a sermon on Phil. iii. 26, which he published under the title of *The Mischief of Separation;* and this being immediately attacked by several writers, he, in 1683, published his *Unreasonableness of Separation*. In 1685 appeared his *Origines Britannicæ, or the Antiquities of the British Churches*, in folio. During the reign of King James II., he wrote several tracts against popery, and was prolocutor of the convocation, as he had likewise been under Charles II. After the Revolution he was advanced to the bishopric of Worcester, and was engaged in a dispute with the Socinians, and also with Mr Locke; in which last contest he is generally thought to have been unsuccessful. He died at Westminster in 1699, and was interred in the cathedral of Worcester, where a monument was erected to his memory by his son, bearing a highly eulogistic Latin epitaph from the pen of Bentley, who had been his chaplain. Dr Stillingfleet wrote other works besides those here mentioned, which, with the above, have been reprinted in six volumes, folio, 1710.

STILLINGFLEET, *Benjamin*, an ingenious naturalist, born in 1702, was the grandson of Dr Stillingfleet, Bishop of Worcester. His father, Edward Stillingfleet, M.D., was fellow of St John's College, Cambridge, and Gresham professor of physic; but marrying in 1692, he lost his lucrative offices and his father's favour; a misfortune that affected both himself and his posterity. Benjamin, his only son, was educated at Norwich school, which he left in 1720, with the character of an excellent scholar. He went to Trinity College, Cambridge, at the request of Dr Bentley, the master, who had been private tutor to his father, domestic chaplain to his grandfather, and much indebted to his family. Here he was a candidate for a fellowship, but was rejected, as he believed, by Bentley's influence. Perhaps, however, this seeming ingratitude was not of any real disservice to Stillingfleet. By being thrown into the world, he formed many honourable and valuable connections. He dedicated some translations of Linnæus to the late Lord Lyttelton, partly, he says, from motives of private respect and honour. Lord Barrington gave him, in a very polite manner, the place of master of the barracks at Kensington; a favour to which Stillingfleet, in the dedication of his *Calendar of Flora* to that nobleman, alludes with the warmest gratitude. His *Calendar of Flora* was formed at Stratton in Norfolk in the year 1755, at the seat of his friend Marsham, who had made several observations of that kind, and had communicated to the public his curious observations on the growth of trees. But it was to Wyndham of Felbrig in Norfolk that he appears to have had the greatest obligation; he travelled abroad with him, spent much of his time at his house, and was appointed one of his executors (Mr Garrick being another), with a considerable addition to an annuity which that gentleman had settled upon him in his lifetime.

Stillingfleet's genius seems, if we may judge from his works, to have led him principally to the study of natural history. In his walk of learning he mentions as his friends, Dr Watson, Dr Solander, Mr Hudson, Mr Price of Foxley, and some others; to whom may be added the ingenious Mr Pennant.

Stillingfleet published a volume of *Miscellaneous Tracts* in 1759. They are chiefly translations of some essays in the *Amœnitates Academicæ*, published by Linnæus, interspersed with some observations and additions of his own. His *Essay on Conversation*, a poem, was published in the first volume of Dodsley's *Collection*. His London residence was in lodgings in Piccadilly, where he died in 1771, at the age of sixty-nine, leaving several valuable papers behind him. Coxe has written a notice of his life and works, 1811.

STILPO, a celebrated philosopher of Megara, who flourished during the second century B.C. In his youth he had been addicted to licentious pleasures, from which he religiously refrained from the moment when he ranked himself among philosophers. When Ptolemy Soter, at the taking of Megara, offered him a large sum of money, and requested that he would accompany him into Egypt, he accepted but a small part of the offer, and retired to the Island of Ægina, whence, on Ptolemy's departure, he returned to Megara. That city being again taken by Demetrius the son of Antigonus, and the philosopher required to give an account of any effects which he had lost during the hurry of the plunder, he replied that he had lost nothing; for no one could take from him his learning and eloquence. So great was the fame of Stilpo, that the most eminent philosophers of Athens took pleasure in attending upon his discourses. His peculiar doctrines were, that species or universals have no real existence, and that one thing cannot be predicated of another. With respect to the former of these opinions, he seems to have taught the same doctrine as the Nominalists of more modern times. In ethics he seems to have been a Stoic, and in religion he had a public and a private doctrine, the former for the multitude, and the latter for his friends. He admitted the existence of a Supreme Divinity, but had no reverence for the Grecian superstitions. (See *Diog. Laërt.*, ii., c. 12.)

STIRLING, one of the most ancient towns in Scotland and capital of the county of the same name, is built on the slope and around the base of a ridge of rock situated in the carse or plain watered by the river Forth; Long. 5° 45′ west, Lat. 56° 6′ north. It is chiefly interesting for its antiquities, its historical associations, and its singularly beautiful, picturesque, and central situation. The town is, from the nature of the ground, very irregular, and the houses in one part, or what may be called the old town, are antiquated and

Stirling. destitute of all architectural beauty, with narrow and confined streets; while in the other, or new town, quite the reverse is the case. Towards the south and south-west, extensive suburbs are springing up containing many large and handsome villas. Numbers of new streets and terraces have been projected, and some promise to be speedily completed. Great improvements have and still are taking place, and the streets are now well paved and kept in good order. The old rickety and unsightly houses are being demolished one by one, and new and substantial ones built in their stead. A plentiful supply of pure water was a few years ago led in from the Touch Hills, about 4 miles distant, by means of cast-metal pipes.

The Castle. The Castle, the most prominent place of interest in Stirling, is built on the western extremity of the ridge on which the town is situated, and is of much greater antiquity than the town itself. It is defended on three sides by the precipitous rocks on which it is built, and on the fourth, or town side, by a deep broad fosse, crossed by a drawbridge, and two strong walls, the approach being commanded by flanking batteries. In the centre of the castle stands the old Parliament-House, now used as barracks; on the left is the palace of James V., a magnificent structure, the hall of which is now also converted into barracks, but still known as the "King's room," the remainder being used as officers' rooms, canteen, sutlery, &c. The building to the west of the palace is of much older date, and contains the well-known "Douglas room," (so called from James II. having killed William earl of Douglas in it). This room, along with other portions of the building, was burned down in 1857, but has been rebuilt in its original form in every respect, except that the ornaments are iron instead of wood, in case of further accidents. Adjoining this building is the Chapel-Royal of James VI., now used as an armoury.

Monuments. Near the castle is the Lady's Hill and Valley, where in olden time the joists and tournaments were held. They have now, in the course of improvement, been inclosed in the new cemetery, but have not lost their distinctive features. In this cemetery is a most beautiful and chaste group of statuary, erected by William Drummond of Rockdale Lodge to the memory of the martyred Margaret Wilson and her sister Agnes. At the head of King Street is a monument, by Mr Handyside Ritchie of Edinburgh, to Wallace, and presented to the town by Mr Drummond. In front of the First U.P. Church is a beautiful Corinthian monument to Ebenezer Erskine, the founder of the Secession body in Scotland, and the first minister of that congregation.

Public buildings. The public buildings are the East and West Churches, both in the Gothic style (the upper windows, however, of the latter have Saxon arches), with a modern erection between, which adds nothing to their beauty, and which it is contemplated to remove. The West Church was erected in 1494 by James IV.; the East at a later period by Cardinal Beaton. Close beside these churches is a ruin called "Mar's Work." It was a mansion-house commenced by the Earl of Mar out of the stones of Cambuskenneth Abbey, but was never completed. Near it is the ancient palace of the Argyle family, and now converted into a military hospital under the name of "Argyle-House." In Broad Street stands the ancient town-house, with its spire and old jail attached. In the town-house are still kept the pint jug, the ancient standard for liquid measure in Scotland; and in the court-room are about a dozen fine ancient carvings on oak, known as the Stirling heads which formerly adorned the hall of the palace of James V., and are believed to represent the king's family and courtiers. The county sheriff-court and also the justice of peace court are held here, and the circuit court meets here twice every year. The new jail is a strong handsome building, lately erected in room of the old one, which was too small and insecure. It is one of the finest buildings in Stirling. The Athenæum is a good building in King Street, with a spire 120 feet high; and in it is a public reading-room and a library of about 7000 volumes. The North Church is decidedly the most elaborate building in town. The Free North Church and the Second U.P. Church are both handsome buildings, and the National Bank is also a fine building.

Parks. To the south of the Castle was the Royal Gardens, of which nothing now remains except the trace of the terraces rising the one above the other, in the centre of which is an octagonal mound called the "King's Knote." To the south of the gardens is the "King's Park," where the kings of Scotland used to keep their deer. It is now given over by government to the town as a public park. The Gowlan Hills to the north of the Castle was the place where, in very early times, justice was administered, where at a later period executions took place, and where, later still, James V. used to slide or "hurle" down its steep sides on a cow's-head, hence called "Hurly Hawkie," another name for the same hill. Between this hill and the castle is a pass called Ballengeich or "windy-gowl," from which James V. took the cognomen of "The gudeman of Ballengeich." The public walks about Stirling are unrivalled in Scotland. The oldest and best of them runs along the top of the rock on which the town is built, and is known as the Back Walk.

Stirling Bridge. Stirling Bridge is the most noted structure of the kind in Scotland for its antiquity and the historical events connected with it. It was till within about 30 years the only access for wheeled carriages into the north of Scotland. Its age is unknown, but it was in existence in 1571. It is of very antique structure, being narrow, high in the centre, and is composed of 4 arches. Formerly it had two gates, one at each end, each gate being flanked by two small towers. The gates are now removed, though the towers still remain. This bridge, though once very strong, is now beginning to show signs of decay, and large rents are appearing in it.

Manufactures and commerce. Stirling has, since the introduction of railways, become a place of great importance. The Scottish Central Railway runs past it, and it is the terminus of other three lines: the Stirling and Dunfermline, the Forth and Clyde, and the Dunblane, Doune, and Callender, the two latter being single lines. Though a place of no great commercial importance in itself, it has, through its central situation, both in regard to Scotland and the rich agricultural, mining, and manufacturing districts around, become one of the most important towns in Scotland. There are three considerable wool-mills and one carpet and shawl manufactory connected with the town; also two extensive coach factories, a number of timber-yards, and two tanneries. Drummond's Agricultural Museum holds a prominent place in the town as a seed and implement warehouse, exporting to all parts of the globe. Though the Forth flows past the town, shipping is necessarily very limited on account of the shallowness of the water, it being confined to a few small sloops and an occasional vessel of between one or two hundred tons. A line of passenger-steamers runs between Stirling and Granton, but the business has since the railway opened greatly fallen off. There are two weekly newspapers, the *Stirling Journal* and *Stirling Observer*. There are seven banks, all of them doing a large business, and a very prosperous savings-bank.

Religion and education. There are in the town 3 Established churches, 2 Free churches, 2 United Presbyterian, 1 Reformed Presbyterian, 1 Episcopalian, 1 Congregational, 1 Baptist, 1 Methodist, and a Roman Catholic—in all, 13 places of worship. Connected with the religious element is the Stirling Tract Enterprise, instituted by Mr Peter Drummond in 1848, and which alone increases the revenue of the Stirling Post Office by upwards of L.2000 annually. In education the town stands high. A new academy was built in 1854, having a classical master, a master of modern languages, an English master, a mathematical master, a drawing master, a gymna-

Stirlingshire.

sium, and between 300 or 400 pupils. There is also a school, known as Allan's School, for the education of the poorer classes, besides several other private educational establishments, all of which are well attended. There is a Ragged School sustained by public liberality, which contains between 60 and 70 outcast children.

Hospitals.

Among the charitable endowments are Spittal's Hospital, with an income of nearly L.1000 derived from land, which is expended on the aged poor belonging to the seven incorporated trades; and Cowan's Hospital, which has an income of about L.4000, also derived from land, and which is expended on the decayed members of the Incorporation of Guildry. The finest hall in the town is the Guild Hall, belonging to the latter of these institutions, and was originally built for the accommodation of twelve decayed guild brethren; but as no one would inhabit it, the funds accumulated till they now produce the above sum. The house has now been turned into a hall for the meetings of guildry. Allan's and Cunningham's mortifications have incomes of L.600 and L.200 respectively, wholly devoted for the education of youth.

History.

Stirling as a town, or rather a place of defence, is of unknown antiquity. It is even believed that it was used as a place of defence at a time when all the Low Country was under water. It first emerges into history as one of the four burghs forming what is now called the Convention of Royal Burghs. Its history since then has been so intimately connected with the history of Scotland, that it is unnecessary to give a sketch of it here.

Government.

The town is governed by a provost, 4 magistrates, and 16 councillors, 21 in all, a third retiring every year.

Population, &c.

The population is 12,837; inhabited houses, 1270; annual value of real property in 1859–60, L.36,791 (exclusive of railways); parliamentary constituency, 592; municipal constituency, 475. Stirling is united with the burghs of Dunfermline, Culross, Queensferry, and Inverkeithing in returning a member to Parliament.

STIRLINGSHIRE, one of the most beautiful counties in Scotland, situated on the isthmus between the Firths of Forth and Clyde, is bounded on the north by the counties of Perth and Clackmannan, east by the Firth of Forth and Linlithgowshire, south by Lanarkshire and Dumbartonshire, and west by Dumbartonshire. Its greatest length from Linlithgow Bridge to Loch Lomond is 45 miles, and its greatest breadth 18 miles, though in many places it is not above 1 to 3 or 4 miles broad. Its area is 462 square miles, or 295,875 acres, divided into 21 entire parishes, and portions of 4 others which partly belong to other counties. It lies on both sides of the boundary line between the Highlands and the Lowlands, but in its general features is mountainous, although there are two extensive carses or plains in it, called the carses of Stirling and Falkirk. About two-thirds of Stirlingshire is unfit for cultivation, owing to its hilly nature, but affords excellent pasturage for sheep. The remainder is among the most fertile portions of Scotland.

Hills.

The principal chain of hills is the Lennox Hills, otherwise called the Campsie Fells, and Fintry Hills; and, in the neighbourhood of Stirling, the Touch Hills. This range runs across the county from Dumbartonshire to nearly Stirling, but never attains a higher elevation than about 1500 feet. Ben Lomond on the north-west, on the banks of Loch Lomond, is 3191 feet high, and Ben Cleuch, in the parish of Alva, 2400 feet high. To the north and east of the Lennox Hills the country is low, and much of the land along the Forth is only a few feet above the level of the river. Towards the western and southern extremities the surface is more varied, presenting tracts of heath, moss, and green pastures, intermixed with cultivated land, the latter confined for the most part to the banks of the streams.

Rivers.

The streams of Stirlingshire are the Forth, Avon, Allander, Kelvin, Endrick, Carron, Allan, Devon, and Bannock. Of these the principal is the Forth, which rises from a spring on the northern side and near the summit of Ben Lomond, and pursues a course of 8 or 10 miles under the name of the Water of Duchray. It then passes into Perthshire under the name of *Avendhu*, or Black River, and soon after returns to the county, and thenceforward obtains the name of the Forth. Pursuing its way through what is called the Vale of the Forth in a slow and sluggish manner, after winding round the base of Craigforth, it receives the clear waters of the Teith, which forms a fine contrast to the dark muddy waters of the Forth. Further on it is joined by the Allan, a brawling, brattling stream, which is only in the county a mile or two of its course, and shortly afterwards passes Stirling, forming from that place to Alloa what is known as the Links of the Forth, so called from the extraordinary number of windings it makes. These links are one of the finest and most picturesque sails in Scotland. At one time the Castle of Stirling appears right in front, and in a few minutes it is away behind, then at one side, then at the other, and in fact the traveller, until he becomes familiar with it, is quite bewildered. After passing Alloa, the river becomes an estuary, and is known as the Firth of Forth. The Carron, the next in importance, rises in the interior, pursues an easterly course, and joins the Firth of Forth at Grangemouth. It is navigable for vessels of 200 tons up to the village of Carronshore, the shipping place of the Carron Company, about 2 miles above its confluence with the Forth. The Avon makes two separate stretches on the boundary. The Endrick is principally a county stream, and pursues a very sweet and romantic course in the western district. The Allander and Devon are only for a very short distance within the county. The Bannock, famous for its battle of the same name, which gave liberty to Scotland, is wholly a county stream, and joins the Forth a little below Stirling.

Lakes.

The lakes of Stirlingshire, with the exception of Loch Lomond, are neither large nor of much importance. The one-half, and the most picturesque half of this, the queen of Scottish lakes, belongs to the county, and contributes to it the islands Inchcailloch, Inchfad, Inchcruin, and several others of lesser importance. Loch Coulter, in the parish of St Ninians; Loch Elrigg, Black Loch, and Little Black Loch, in Slamannan, are all small. Loch Katrine touches the county for a distance of two miles.

Geology.

Stirlingshire is one of the richest counties in Scotland for minerals. The north-west boundary of the great coal-field which extends from Kintyre to Fifeshire, runs along the base of the Lennox Hills, and is extensively worked at Plean, Bannockburn, Greenyards, Denny, Carron, Slamannan, and, in fact, the whole of the south-east corner of the county, but is nowhere found in the north and west. Ironstone is found in almost inexhaustible quantities, a fact which influenced Dr Roebuck, after he had examined the whole of Scotland, to fix on the neighbourhood of Falkirk as the site for the now magnificent Carron Iron-works. The richest variety is found at Kilsyth, and owing to its occurring in rounded masses in the form of a flat-topped loaf, varying in size from a quarter of an inch to a foot in diameter, is called fall ironstone. The hill of Craigforth, near Stirling, is almost one mass of pure ironstone. Limestone, in many instances, accompanies the coal in two strata, the one above and the other below the coal, the former being always the best quality. Copper is found, but not in sufficient quantities to be workable, although mines were opened at Kilsyth and Logie, which however were soon abandoned. Veins of silver were discovered nearly 100 years ago at Logie and Alva, and were worked for some time, but were soon given up. Cobalt, arsenic, and lead are also found in very small quantities. Sandstone abounds in the south and east districts, and is

Stirlingshire.

extensively quarried. Trap-rocks, particularly basalt, are found north-west of the coals, and rise up in nodulated hills through various parts of the coal-fields. The rock on which the town and castle of Stirling are built, and the neighbouring well-known hill, the Abbey Craig, which, though not in Stirlingshire, touches it, are examples of this volcanic action. Precipitous columnar cliffs and extensive ranges of basaltic colonnade exist in solitary protrusions, as in the broad mass of the Lennox Hills. The rocks of the north or Highland district are principally schistose. One remarkable feature traceable in all the hills lying in or near the carse of Stirling is, that the rocks on the west and south-west sides are bare and precipitous, while the eastern and northern sides have a gentle slope, and are covered with herbage. The reason assigned is, that at one time the waves of the Atlantic Ocean rolled through the Low Country into the German Ocean, and washed the soil from the exposed sides of these rocks and deposited it on the protected sides.

Climate.

The climate of the eastern division of the county is milder than that of the west, partly owing to the inferior elevation, and partly because of the superior shelter afforded it by the trees and hedges, but principally because in summer the German Ocean is 5° warmer than the Atlantic. The west, however, escapes those fogs which infest the east during the prevalence of the east winds.

Soil.

Stirlingshire has every variety of soil common to Scotland, and may be classified into carse, dryfield, hill, moor, and moss. The carse extends along the line of the Forth, from half-a-mile to 5 miles in width, making altogether 56 square miles, or nearly 36,000 imperial acres of the very best grain-producing land in the kingdom. It consists of the finest argillaceous earth, perfectly free of stones, and originally of a bluish colour, and of a soapy or mucilaginous consistency; but after cultivation becomes of a hazel colour, and of a loamy friability. It is of the depth of between 20 and 30 feet, and is seldom more than 25 feet above the level of the sea. It contains beds of shells, moss, and clay marl. In it, in a stratum of moss, have been found at various times the entire skeletons of two whales and the part of another, deers'-horns, bones, &c., some of which had evidently been used as instruments of the chase. One of the skeletons is now in the Zoological Gardens of Edinburgh. The dryfield is a darker and more sandy earth, in some places of some depth, and in others only a few feet. The hilly and moorish lands are of considerable extent and unfit for cultivation, both from elevation and from want of a regular sufficient depth of soil. The moss-lands were at one time of some extent, but they were let out in small portions at little or no rent to cottars, who got the produce of the ground for the clearing away of the moss, and were generally known by the name of moss lairds. These moss-lairds are fast dying out, the grounds thus cleared being let out as regular farms.

Agriculture.

Agriculture is in a very high state; but owing to the varieties of the land, it is various in its modes. The Carse farmers produce a great quantity of wheat and beans, for the growing of which their soil is peculiarly adapted, as it is strong and heavy. The dryfield farmers, on the contrary, on account of their land being lighter, and not so well adapted for the growth of strong-strawed serials, never thought of sowing either wheat or beans till the potato disease made its appearance, when they introduced them as fills-up, but are quite unable to obtain the heavy crops Carse farmers do. On the other hand, the dryfield farmers have the advantage over their Carse brethren in the production of potatoes and turnips, which, before the disease, were cultivated in immense quantities and with great success. The other grains grown are oats and barley, and mangel-wurzel is being introduced for the feeding of cattle. Stirlingshire takes the lead of all Scotch counties for its agricultural improvements. The arable farms range in extent from 40 to 100 or 150 acres; while the hill-farms, where sheep and cattle are kept, are sometimes 4000 acres. Almost all the Highland district, or the mountains of Buchanan and Drymen, the Lennox Hills, &c., are disposed as sheep-walks, and produce excellent pasturage. The cattle are mostly Highland and country cattle, and the sheep blackfaced, a breed of the Cheviot's called the Linton breed, and Leicesters. Few horses are reared. There are several agricultural societies for the promotion of agriculture in the county, the principal of which is the Stirling Central Union, a very extensive society, numbering about 300 members. It has a cattle show in June which is one of the finest in Scotland, both for quantity and quality, and it has a seed-grain competition both in the spring and autumn of the year. The Falkirk Trysts, the largest cattle and sheep markets in the kingdom, are held on Stenhouse Muir, near Falkirk, on the second Tuesday and Wednesday of August, September, and October, for cattle and horses; and the previous Monday for sheep, in September and October.

Woodlands.

There is a good deal of the less valuable ground covered with oak coppice, which yields a regular income every 21 years for bark. These coppices are in some cases divided into 21 hags or portions, one of them being cut down every year, leaving only a few reserves for standard timber. These hags yield on an average 2½ tons of bark per acre, which, selling at L.8 per ton, yields an income of L.20 per acre every 21 years, or 19s. a year, instead of from a shilling or two up to ten, if they were used for any other purpose. About 30,000 or 40,000 acres are thus occupied.

Manufactures.

The manufactures are carpets, tartans, plaidings, shawls, and other woollen goods, which have obtained a world-wide celebrity, and which are chiefly made in Stirling, Bannockburn, St Ninians, and the neighbouring villages. Blankets and serges are manufactured at Alva. Large cotton-mills occur at Fintry, Balfron, and Milngavie. Printfields exist at Denny, Kincaid, Milngavie, Lennoxtown, and Strathblane. Several paper-mills are situated at Denny and Bridge of Allan. There are several chemical works at Stirling and Falkirk. Tanning is carried on extensively in Stirling, St Ninians, and Falkirk. Distilleries are large and extensive. Nail-making is a considerable trade in St Ninians and the surrounding villages; but the grand staple manufacture is that of iron goods, cast and malleable, at the stupendous works of Carron, the largest iron-foundry in the world. It is situated on the River Carron, about 3 miles above Grangemouth, and was established by royal charter in 1760, under the management of Gascoigne, Caddell, and Company, and has passed through several managements, and is now principally in the hands of the Messrs Dawson and Stainton. The property is divided into 600 shares of L.250 each. The ironworks cover an extent of 40 acres, and contain four large furnaces for smelting the ore—three by hot blast and one by cold blast, perhaps the only one now in Scotland. These furnaces were at one time blown by water-blast, but steam is now used instead; and we believe that the first steam-engine of any size ever made is still to be seen at these works. There are five cupolas and about forty air-furnaces for smelting the pig-iron, also two large forges for tilting scrap iron, for making axle-blocks, &c. This company employ 1200 men at their works, and about 1000 more in pits and mines at Carronhall, Quarrole, Kinnaird, and Netherwood, in the county, besides large fields in other parts of the country. They have now a world-wide connection, and have obtained their position by the manufacture of ordnance for the various European governments, but especially of the once celebrated carronades, which were invented there. They have

Stjernstolpe || Stobæus.

large warehouses in London, Liverpool, Glasgow, and Leith; have five large and powerful steamers plying between Grangemouth and London; seven trading sloops; and about thirty lighters on the Forth and Clyde Canal, which is in connection with the works by means of a railway. They have also railway connection with the Edinburgh and Glasgow line. Owing to its magnitude, Carron has always such a supply of coal and iron as to be quite independent of the fluctuation of these articles in price, and of strikes. The Falkirk Ironworks may be considered an offshoot of the Carron Works. It was established in 1825, employs about 400 men, and covers 10 acres of ground, but has no blast furnaces to manufacture its own iron. There are other two foundries of lesser importance near Camelon.

Roads and railways. The Scottish Central Railway enters the county near Bridge of Allan, and joins the Edinburgh and Glasgow at Greenhill, passing in its route Bridge of Allan, Stirling, Bannockburn, and Larbert. The Edinburgh and Glasgow Railway traverses the county from Linlithgow Bridge to Castlecary, and passes Polmont and Falkirk. The Forth and Clyde Railway, starting from Stirling, runs along the Vale of the Forth, and passes out of the county beyond Kilmaronock. This railway, though by no means a paying one, is eminently useful, as it opens up an extensive tract of county hitherto almost inaccessible except by county roads. The Stirling and Dunfermline Railway is only for 2 or 3 miles within the county. The Stirlingshire Midland Junction was made for the purpose of uniting the Edinburgh and Glasgow at Polmont with the Scottish Central at Larbert, thus shortening the way to Edinburgh. The Denny Junction, a branch of the Scottish Central, runs from Larbert to Denny. The Edinburgh and Glasgow are making a branch line to Grangemouth. The great northern highway runs through the county from a little to the north of Stirling Bridge to Linlithgow Bridge, through Bannockburn, Larbert, Camelon, Falkirk, &c., but is now little used. The Glasgow Road runs through St Ninians and Denny, and the Dumbarton Road through Kippen, Bucklyvie, &c.

Canals. The Forth and Clyde Canal, from Grangemouth to Glasgow, traverses the county a great portion of its length, and is joined near Lock 16 by the Union Canal from Edinburgh, which is also in the county for a number of miles.

Government. Stirlingshire is governed by a lord-lieutenant, a vice-lieutenant, and a court of lieutenancy, a sheriff, two sheriffs-substitute, and two procurators-fiscal.

Population, &c. The principal towns in Stirlingshire are—Stirling, Falkirk, Denny, Grangemouth, Kilsyth, Campsie, and Balfron. The village of Bridge of Allan has obtained great celebrity within the last twenty years for the medical properties of its mineral-waters, which are drunk in great quantities by an immense number of visitors who frequent it. It is unquestionably the greatest watering-place in Scotland. The population of the county, in 1851, was 86,237; the inhabited houses, 11,312; and the valuation for 1859-60, L.276,060. The county returns a member to Parliament, and has a constituency of 1670.

The religion of the county is principally Presbyterian, and is represented by 37 parish and quoad sacra churches, 21 Free Churches, 24 United Presbyterian, 3 Independent, 3 Baptist, 2 Reformed Presbyterian, 5 Scottish Episcopalian, and 4 Roman Catholic. In education the county is well supplied, there being parochial schools in every parish, besides many others belonging to the various denominations and to private individuals. (G. J.)

STJERNSTOLPE. See Scandinavian Literature.

STOBÆUS, Joannes, whose compilations have been found so highly valuable, is supposed to have been born at Stobi, a city of Macedonia. Heeren has endeavoured to render it probable that he must have lived between the years 450 and 500. He does not appear to have been a Christian. From about 500 writers, in verse as well as prose, he extracted and digested an immense collection of passages, which has most commonly been considered as one work divided into four books, the two first being described as *Eclogæ Physicæ et Ethicæ*, and the other two as *Sermones;* but, according to Heeren, they constitute two distinct compilations. As many of the books quoted by Stobæus have scarcely left any other vestiges behind them, his merit in preserving these numerous and variegated reliques of antiquity cannot well be too highly estimated. Of the third and fourth books, otherwise called the *Florilegium*, the Greek text was published by Victor Trincavellus, Venet., 1536, 4to. An edition, accompanied with a Latin version, was published by Conrad Gesner, Tiguri, 1543, fol. It was reprinted at Basel in 1549, and at Zurich in 1559. Of the *Eclogarum Libri Duo*, the Greek text was first published, together with a Latin version by Canter, Antverp, 1575, fol. The editor made use of two manuscripts belonging to Sambucus and Sirlet; and hence a certain bibliographer has described this as Sirlet's edition. A valuable edition of the *Eclogæ* was long afterwards published by Heeren, Gotting., 1792-4, 2 tom., 8vo. The *Florilegium* and the *Eclogæ* had been published in the same volume, under the title of *Stobæi Sententiæ, ex Thesauris Græcorum Delectæ*, Lugduni, 1608, fol. Some copies have a new title, with the date of 1609. We must not overlook the elegant labours of Grotius, *Dicta Poetarum quæ apud Stobæum Exstant, Emendata, et Latino Carmine Reddita*, Paris, 1623, 4to. The editions have all been nearly superseded by that of Gaisford, Oxon., 1822, 4 tom., 8vo. The text, which has been adjusted with great industry and skill, is not accompanied with a Latin translation.

Stockholm.

STOCKHOLM, an important city in the north of Europe, the capital of Sweden, occupying a fine position on the strait that connects Lake Mälar with the Baltic, about 36 miles from the sea by water, 380 miles N.E. of Copenhagen, and 440 W.S.W. of St Petersburg, N. Lat. 59. 20; E. Lon. 18. 3. It has been called the Venice of the north; and there is some reason for the appellation from the similarity of its situation, partly on the mainland and partly on several small islands. Though inferior in general effect to that beautiful Italian city, Stockholm presents from some points a very imposing aspect; and the natural beauties of its environs far surpass those of Venice. It consists of three parts; the city proper, occupying three islands, which are so united as to form to all appearance but one; the northern suburb, *Norrmalm*, and the southern suburb, *Södermalm*, which stand on the mainland on either side of the strait. The islands are known by the name of Holms, those on which the city proper is built are Stockholm (the Castle Island), or Staden (the City), which is the largest of the three; Riddarholm (Knight's Island), to the west; and Helgeandsholm (Holy Ghost Island), to the north. There are also several other islands, covered in whole or in part with buildings; such as Kungsholm (King's Island), to the west of the northern suburb; Blasiiholm, which has been converted into a peninsula; Skeppsholm, (Ship Island), and Kastellholm (Castle island), all lying to the east of the city proper. All of these subdivisions of the city are connected with the mainland, and with one another by numerous bridges, the finest of which is the new bridge of granite, from the city proper to the northern suburb. On the mainland to the north the ground rises gradually as it recedes from the water, while to the south the cliffs are more bold and abrupt, and many of the houses nestle amid overshadowing trees in the various ledges of the rocks. Although the ground on which a great part of Stockholm is built is hard and rocky, yet all the lower portions of the city are founded on piles. The streets, espe-

Stockholm. cially in the city proper, which is the oldest portion, are very narrow and irregular; though in the other parts of the town and suburbs, more attention is paid to straightness and uniformity, yet even there they are of no great width. The houses in the city are in general built of stone; those in the suburbs of brick, and in the more remote portions sometimes only of wood. There are several public squares and market-places; some of them of considerable size. The public buildings are numerous, but most of them are not very remarkable. By far the largest and finest of these is the palace, which occupies the northern part of the Staden Island, and is conspicuous for its immense size and slightly elevated position. It was begun in 1697 and completed in 1753, after the designs of Count Tessin; and from whatever point it is viewed it presents an aspect imposing from its simple and massive grandeur. The lowest story is of granite, the rest of brick covered with stucco. Its form is quadrangular, with two projecting wings towards the north-east. The finest front is that facing south-east, which has a portico of six Corinthian columns. On the north-west it is approached by the new bridge leading from the northern suburb; and on the north-east, where it faces a spacious quay, there is between the two wings a terrace beautifully laid out as a flower-garden. The palace contains a picture gallery, sculpture gallery, royal museum, royal library of about 70,000 volumes, cabinets of antiquities, &c. The chapel is profusely decorated, but not in very good taste. The royal apartments occupy the north-east side of the quadrangle, and are approached by a fine staircase. The royal wardrobe and armoury, containing many suits of armour and of clothes which belonged to former monarchs and famous men, has been removed to a large building in the Gustavus Adolphus market, in the northern suburb; and the royal stables, which can accommodate 146 horses, stand on the Helgeandsholm. South of the palace is an esplanade, called the Slottsbacken, in which stand a tall granite obelisk, and a bronze statue of Gustavus III. Here also is the Cathedral of St Nicholas, the most ancient church in Stockholm, whose lofty tower has a very picturesque effect. In the interior there are two large pictures, and an altar-piece richly carved in ebony, and adorned with ivory, gold, and silver. Much more interesting is the Riddarholms Church, on the island of that name. It is an old Gothic building, but has been considerably altered by various additions and restorations, and it is now only used as a royal mausoleum. The aspect of the interior is very impressive, but quite different at first sight from that of a church. All round the walls there are equestrian figures, clothed in complete suits of armour, worn by the several sovereigns of Sweden. The figures are eleven in all: one is clothed in the heavy armour of Birger Jarl, the founder of Stockholm; another wears the helmet of Charles VIII., with a vizor in the form of a man's face; and a third, a richly wrought suit of armour, said to have been made by Benevenuto Cellini for Charles IX. In a side chapel of this church is the tomb of Gustavus Adolphus, surrounded by a multitude of flags and other trophies of his victories. Here are also preserved the clothes that he wore when killed on the field of Lützen. Opposite to this is another chapel, containing the remains of Charles XII., in a marble tomb; and here also are to be seen the cloak and hat worn by the hero in the trench before Fredrickshald, the latter pierced by the bullet that terminated his existence. Many other Swedish monarchs lie in the vaults of this church, and among their tombs not the least interesting is that of Bernadotte or Charles XIV. Many noble and distinguished Swedes, not of royal lineage, are interred in this church; and the shields of the knights of the seraphim are hung round the choir. Of the other churches in Stockholm, of which there are 20, none are very remarkable; in one of them, that of Adolphus Frederick, there is a monument to Descartes, who died at the Swedish court. The Riddarhus, or house of assembly for the nobles, is a plain and not very elegant structure, with many interesting historical associations. The hall of the assembly is hung round with the escutcheons of the nobility, and contains a president's chair, of fine Dutch workmanship in ebony and ivory. Stockholm has two theatres, one of which is a large and handsome building in the northern suburb, opposite the palace. Beside this building is the square of Gustavus Adolphus, containing a fine bronze statue of that monarch. The principal other public buildings are the governor's house, the town-hall, exchange, post-office, arsenal, and barracks. On the Skeppsholm stand most of the buildings connected with the admiralty. The educational institutions of the city are numerous, including a medical college, technological institution, naval and military schools, and several others. There are numerous scientific, literary, and artistic societies; and many hospitals, infirmaries, and other charitable establishments. Stockholm is the chief seat of the manufacturiug industry of Sweden; it produces metal fabrics, silk, woollen cloth, hosiery, cotton, linen, sugar, tobacco, &c. There are here, too, a porcelain manufactory and numerous printing-presses, and many mathematical and optical instruments are prepared. The southern suburb, which is occupied chiefly by tradespeople, contains an immense iron magazine, and a large dock. The trade of the city is very considerable. The chief articles of export are—iron of various kinds, steel, copper, lead, grain, timber, leather, oil-cakes, and butter. Among the imported goods are—coals, cotton, wool, raw silk, coffee, sugar, spices, tea, wine, and spirits, &c. The following table exhibits the total declared value of the exports and imports of Stockholm for several years from 1851 to 1857:—

	Imports.	Exports.
1851	L.948,844	L.533,508
1853	831,432	548,092
1855	1,412,518	709,575
1856	1,829,380	629,466
1857	1,295,568	615,502

In 1857 the exports and imports were distributed among different nations, as follows:—

	Imports.	Exports.
Great Britain and colonies	L.269,846	L.175,026
Hanse Towns	306,034	92,732
Russia	225,472	8337
Prussia	100,322	72,354
Brazil	137,886	12,627

There are more than 200 vessels belonging to the port of Stockholm. In 1856 the number that entered was 1711, with an aggregate tonnage of 196,350; the number that cleared, 1662; tonnage, 171,740. The harbour is somewhat difficult of entrance, but very large and excellent; the quays are spacious, and the largest vessels can lie close to them. Numerous steamers ply between Stockholm and Lubeck, Stettin, St Petersburg, and other places. In the environs of the city there are many beautiful and much frequented parks and promenades. One of the finest of these is the *Djurgård*, or deer-park, which occupies an island to the east of the city, and is easily accessible by ferry-boats. In this park stands the palace of Rosendal, built by Bernadotte; and there are here also many theatres, ball-rooms, and coffee-houses. The *Ladugardsgård*, or review-ground, lies to the north of this, across a narrow arm of the sea; the Haga Park, to the north-west of the city, is another favourite resort; as also is the park of Carlsberg, which contains a favourite palace of Charles XII., now occupied by the military academy. At a somewhat

Stocking. greater distance from Stockholm there are several other royal and baronial residences, occupying beautiful situations on the islands or shores of Lake Mälar. Stockholm was founded about the year 1260, by Birger Jarl, who made it his residence. But even before this time the site had been occupied; Odin had built here the city Sigtuna, which flourished for several centuries before the introduction of Christianity; but is now entirely perished, save a few scattered ruins. It was near this site, also, that the first Christian colony was settled in Sweden; but their abodes also have almost entirely perished. Stockholm was strongly fortified, and sustained several sieges. One of the most memorable of these took place in 1501 and 1502, when it was held for nearly six months by Queen Christina of Denmark against the Swedish insurgents, but was at last surrendered after the garrison had been reduced from about 1000 to 80 in number. A still more noble defence of the city was made in 1520, by Christina Gyllenstierna against Christian II. of Denmark. It was surrendered after a siege of four months; but the terms of the surrender were violated soon after by the conqueror ordering the execution of all the most distinguished Swedes in the town. This and similar acts of treachery and cruelty led to the final expulsion of the Danes by Gustavus Vasa. It was not till the seventeenth century that Stockholm became the capital of Sweden, Upsala having previously to that time enjoyed that distinguished honour. Pop. (1859) 101,502.

STOCKING, that part of the clothing of the leg and foot which immediately covers them from the cold. Anciently, the only stockings in use were made of cloth, or of milled stuffs sewed together; but since the invention of knitting and weaving stockings of silk, wool, cotton, thread, &c., the use of cloth stockings is quite discontinued. Dr Howell, in his *History of the World*, vol. ii., p. 222, relates, that Queen Elizabeth, in 1501, was presented with a pair of black knit silk stockings by her silk-woman, and thenceforth she never wore cloth ones any more. The same author adds, that King Henry VIII. ordinarily wore cloth hose, except there came from Spain, by great chance, a pair of silk stockings. His son, King Edward VI., was presented with a pair of long Spanish silk stockings by Sir Thomas Gresham, and the present was then much taken notice of. Hence it should seem that the invention of silk knit stockings originally came from Spain. Others relate, that one William Rider, an apprentice on London Bridge, seeing at the house of an Italian merchant a pair of knit worsted stockings from Mantua, took the hint, and made a pair exactly like them, which he presented to William earl of Pembroke, and that they were the first of that kind worn in England, anno 1564. The modern stockings, whether woven or knit, are formed of an infinite number of little knots, called stitches, loops, or meshes, intermingled in one another. Knit stockings are wrought with needles made of polished iron or brass wire, which interweave the threads, and form the meshes of which the stocking consists. At what time the art of knitting was invented, it is perhaps impossible to determine, though it has been usually attributed to the Scots, as it is said that the first works of this kind came from Scotland. It is added, that it was on this account that the company of stocking-knitters established at Paris in 1527 took for their patron St Fiacre, who is said to have been the son of a king of Scotland. But it is most probable that the method of knitting stockings by wires or needles was first brought from Spain.

Woven stockings are generally very fine. They are manufactured on a frame or machine made of polished iron, the structure of which it is needless to describe, as it may be seen in almost every considerable town in Great Britain. The invention of this machine is, by Mr Anderson, attributed to William Lee, M.A. of St John's College, Cambridge, at a period so early as 1589. Others have given the credit of the invention to a student of Oxford at a much later period, who, it is said by Aaron Hill,[1] was driven to it by dire necessity. This young man falling in love with an innkeeper's daughter, married her though she had not a penny, and he by his marriage lost a fellowship. They soon fell into extreme poverty; and their marriage producing the consequences naturally to be expected from it, they became miserable, not so much on account of their sufferings, as from the melancholy dread of what would become of their yet unborn infant. Their only means of support was the knitting of stockings, at which the woman was very expert. "But sitting constantly together from morning to night, and the scholar often fixing his eyes, with steadfast observation, on the motion of his wife's fingers in the dexterous management of her needles, he took it into his imagination that it was not impossible to contrive a little loom which might do the work with much more expedition. This thought he communicated to his wife, and joining his head to her hands, the endeavour succeeded to their wish. Thus the ingenious stocking-loom, which is so common now, was first invented; by which he did not only make himself and his family happy, but has left his nation indebted to him for a benefit which enables us to export silk stockings in great quantities, and to a vast advantage, to those very countries from whence before we used to bring them, at considerable loss in the balance of our traffic."

Stockport. STOCKPORT, a market-town, parliamentary and municipal borough of England, in Cheshire, on the borders of Lancashire, at the confluence of the Mersey and the Tame, 5 miles S.E. of Manchester. It occupies a pretty steep hill, washed on two sides by the Mersey; and the houses rise in irregular tiers from the base to the summit, so as to present, especially by night, when the factories and other buildings are lighted up, a very picturesque appearance. The older part of the town occupies the central and most elevated position, where there is a spacious market-place on a pretty, flat piece of ground. From this the various streets, which are for the most part steep and narrow, diverge in different directions. The Mersey is crossed by four bridges, and the Tame by one, which connect the town proper with several extensive suburbs on their other sides. Heaton-Norris, Edgeley, and Portwood are the names of the largest of these. The old bridge over the Mersey consists of one lofty arch. Below this is another, recently built, with 11 arches, crossing not merely the river, but many of the streets, at an elevation of 40 feet above the water. Much loftier is the viaduct of the London and North-Western Railway, which is supported by 26 arches, the central one 110 feet above the river. The principal building in Stockport is the parish church, which stands near the market-place. It was originally built in the fourteenth century, but has been almost entirely rebuilt in modern times, in the perpendicular style. The chancel retains the original decorated architecture, and was restored in 1848; it contains fine stone stalls and some interesting tombs. This church has also a lofty pinnacled tower, with a peal of eight bells. St Thomas's church is a fine Grecian building, with a tower and cupola. The other churches belonging to the Establishment are 6 in number within the limits of the borough; besides which, there are numerous dissenting places of worship, 15 belonging to different sects of Methodists, 5 to Independents, 3 to Baptists, and 1 each to Roman Catholics, Unitarians, and Mormonites. Another conspicuous edifice in the town is the new market-house, which has a handsome front, and contains a spacious hall, roofed with

[1] See an *Account of the Rise and Progress of the Beech Oil Invention*, &c., 8vo, 1715.

iron and lighted from above. Other public buildings are the court-house, barracks, theatre, and news-room. Some of the schools also occupy large and handsome edifices. Chief among these is the free grammar-school, founded in 1487, and under the patronage of the Goldsmith's Company of London. The school-house was rebuilt in a handsome style in 1832. A national school, which was founded here in 1805, has a large and fine building. There are, besides these, British and infant schools, and Sunday schools belonging to the different denominations. One of the last-mentioned occupies an enormous building, containing 84 class-rooms, and attended by about 4000 children. Stockport has a mechanics' institute; an infirmary, with a Grecian front, occupying a prominent position in the town; a dispensary; almshouses; poorhouse; and other charitable institutions. The cotton manufacture has one of its chief seats in this town; where it has supplanted the silk trade that formerly used to flourish here, but has very much declined. For spinning and weaving cotton there are in the town and suburbs about 100 houses, employing in all more than 3800 horse-power. One of the factories is an immense building, 300 feet by 200, having six storeys and about 600 windows. In addition to these there are three houses for printing cotton, two for bleaching, and several for dyeing. Silk goods, thread, hats, brushes, spindles, &c., are also manufactured here: the casting of brass and iron, the making of machinery, and brewing are carried on, and there are several brick-fields in the vicinity. Manufacturing industry is greatly favoured by the abundance of coal found in the neighbourhood. Markets are held weekly, and fairs four times a year. The town stands on a branch of the Manchester and Ashton Canal, and is the place of junction of several important lines of railway. The borough is governed by a mayor, 13 aldermen, and 42 councillors; and returns two members to Parliament. Stockport is believed to occupy the site of an old Roman station, which stood at the junction of several roads, and was thus a place of considerable importance. A Roman fort probably stood on the place afterwards occupied by a castle, which has now entirely disappeared. It was held in 1173, by Geoffrey de Constantin against Henry II. During the civil war of the seventeenth century, Stockport was the scene of some fighting: it was taken from the Parliamentarians by Rupert in 1644, but retaken by Lesley in the following year. In 1745, the town was occupied by Prince Charles Edward. It was first made a municipal and parliamentary borough by the Reform Act of 1832. Pop. of the borough (1851) 53,835.

STOCKS, or PUBLIC FUNDS *in England*. See FUNDING SYSTEM.

STOCKTON-UPON-TEES, a market-town and municipal borough of England, in the county of Durham, on the left bank of the Tees, about 4 miles from its mouth, and 18 miles S.E. of Durham. It is for the most part substantially built of brick, and regularly laid out, having one main street nearly a mile in length, running from north to south. At the south end of this street a handsome stone-bridge of five arches crosses the river into Yorkshire. A short distance below this bridge the river bends towards the north, where it is lined by a wharf running parallel to the main street, and connected with it by numerous smaller streets. West of the principal street there are many handsome new streets and buildings, and in the north-east of the town is a large square, planted with trees, and lined with good houses. The parish church is a large edifice of brick, erected in 1710 on the site of one as old as 1234. It has a tower 80 feet high, and contains a theological library. Trinity Church is a neat Gothic building, with a square tower and octagonal spire. Stockton also contains places of worship for Independents, Methodists, Presbyterians, Quakers, Baptists, Roman Catholics, and Unitarians. Several of these have Sunday schools attached to them; and there are, besides, National, British, and infant schools; a bluecoat charity school, school of industry for girls, a library, newsroom, and mechanics' institute. Among the charitable institutions there are several almshouses and a dispensary. The town-hall, a square building with a clock-tower, stands in the market-place, and near it is a handsome Doric column, 33 feet high, which occupies the site of the old market-cross. Stockton has also a custom-house, theatre, assembly-rooms, and billiard-rooms. The manufactures and trade of the town are both very extensive. Among the former, the most important are those of linen and sailcloth, ropes, and worsted, along with the building of ships and boats, the casting of brass and iron, brewing, &c. The town imports from foreign countries masts, spars, and timber, iron, hemp, flax, tallow, and hides; from British ports, groceries, wine, spirits, and colonial wares. The chief article exported to foreign lands is lead; to London and other ports in this country are sent flour, butter, cheese, linen, yarn, timber, and coal. In 1857, there were registered as belonging the port, 137 sailing-vessels, tonnage 28,261; and 30 steamers, tonnage 2986. In the same year there entered the port 1180 sailing-vessels, tonnage 122,411; and 129 steamers, tonnage 28,680: and there cleared 2683 sailing-vessels, tonnage 259,560; and 180 steamers, tonnage 45,191. The river is navigable for some distance above the town, and its navigation has been improved by a cut made just below, which avoids a considerable bend in the river, and facilitates the access of vessels to the town. Ships of 300 tons burden can come up to the quays of Stockton. The town is connected by railway with all the lines in Great Britain; and the line from this to Darlington was the first that was constructed, having been opened for goods in 1825, and at a later period also for passengers. Stockton is an ancient place; it was at one time the residence of the bishops of Durham, who had a castle here, of which, since its demolition in 1652, only a few traces remain. The town was plundered by the Scotch in 1325; and in the civil war of Charles I. it adhered to that monarch, but was taken by the Scotch in 1644. The borough is governed by a mayor, 5 aldermen, and 18 councillors. Pop. of the borough, 10,459; of the town, 9808.

STODDART, SIR JOHN, was born in 1773, and was educated at the grammar-school of Salisbury, under Dr Skinner. Having made considerable proficiency at that institution, he entered Christ Church, Oxford, in 1790, where he studied divinity; but subsequently preferring the law, he commenced the study of it, and took the degree of D.C.L. in 1801. In 1796 and 1798 he had engaged in a joint translation of the *Fiesco* and *Don Carlos* of Schiller with Dr Noehden. Taking, at the outset, a favourable view of the French Revolution, he had published in 1797 a translation of a French work on the Executive Directory of France. In 1801 he wrote *Remarks on Local Scenery and Manners in Scotland, during the years* 1799 *and* 1800, 2 vols. 4to. Stoddart having entered the College of Advocates, was appointed in 1803 King's Advocate and Admiralty Advocate in Malta, where he remained for the next four years. In 1810 he commenced writing on politics in *The Times* newspaper, which in 1812 led to his appointment as political editor of the same journal. With much energy, great knowledge, a clear style, and a great deal of bluster, he wrote such vigorous and often absurd articles in "the great Thunderer," as led to his being burlesqued and caricatured by the wits of London as the great Dr Slop of Printing-House Square. The proprietors of *The Times* disapproving, it is said, of the rancour of his fulminations against the exiled Emperor N. Buonaparte, dissolved his connection with that newspaper in 1816. In 1817 he made an attempt to revive his decadent political glory by the publication of the *New Times*. The English people did

not regard his fire and fury, and allowed it quietly to burn itself out. In 1826 he was made a knight, and was appointed Chief-Justice and Judge of the Vice-Admiralty Court of Malta, where he remained during the next thirteen years. On his return to England he went into retirement, where he is said to have been much and widely esteemed. He wrote *An Introduction to General History*, and a *Universal Grammar* for the *Encyclopædia Metropolitana*, which have also appeared as separate works. Besides writing political pamphlets on various subjects of popular note, he took a lively interest in the amendment of law; and at the first meeting of the Law Amendment Society after his death, which occurred on February 16, 1856, Lord Brougham pronounced a eulogium on his memory.

STOICS, the name given to that sect of Grecian philosophers founded by Zeno of Citium, from Στοα, the porch in Athens where he taught.

STOKE-UPON-TRENT, a market-town and parliamentary borough of England, in the county and 16 miles N. by W. of Stafford, 148 miles N.W. of London, on the Trent. The borough is much more extensive than the town, and includes a large portion of the district known by the name of the Potteries, comprising several distinct parishes and townships. The town of Stoke has been of late much improved, and is now very well built: the town-hall is an elegant edifice, and the parish church is a fine specimen of the later English architecture, with a beautiful painted window and several monuments, including that of the celebrated Wedgwood. The Baptists, Quakers, and several sects of Methodists, have also places of worship in the town. Education is provided for by National and Diocesan schools. The principal manufactures of the place are those of china and earthenware, in which a very large proportion of the people is employed. There are also extensive coal-works in the vicinity. Markets are held weekly, and are well supplied with all kinds of provisions. The borough has been represented in Parliament by two members since the Reform Act of 1832. Dr Lightfoot, the celebrated and learned divine, was born at the rectory of Stoke-upon-Trent in 1602. Pop. of the borough, 84,027; of the parish, 57,942.

STOLBERG, THE BROTHERS. COUNT CHRISTIAN STOLBERG, who was the eldest of the two celebrated men who bore this name, was born of an ancient family in Germany on the 15th October 1748. LEOPOLD FRIEDRICH STOLBERG, who was the younger brother, was born on the 7th November 1750. They prosecuted their studies together at the University of Göttingen, where they cultivated literature and allied themselves with that band of poets who were then rising into fame, of whom the chief were Bürger, Voss, and Holty. They became distinguished for their classical taste; were enormous admirers of Klopstock, and judged Ossian divine. The younger brother executed a very tolerable translation of Homer's *Iliad*, and subsequently published a translation of a portion of Æschylus. The two brothers made a tour with Goethe through Switzerland and part of Italy, and returned by way of Copenhagen. Christian having now married, the two brothers had to separate. After composing some dramas on the classical models, and serving under the prince-bishop of Lubeck, Friedrich likewise married in 1782. In 1785 he was intrusted by the Danish court with a mission of importance to the court of Russia. On his return he retired to Neuenburg in Prussia, where he wrote *Der Island*, a sort of novel, containing dialogue, reflection, description, and recommendation. In 1789 he was again invited by the Danish court to act as its minister to the court of Prussia. He continued to reside in Berlin after his embassy was at an end, and made another tour through Germany, Switzerland, Italy, and Sicily, of which he published an account in four discursive volumes in 1794. He was subsequently employed on various embassies between the courts of Denmark and Russia. Friedrich had hitherto been a zealous Protestant, but the aspects of the French Revolution seemed to have awakened alarm within his breast. The Protestants of Germany for the most part eyed favourably that baptism of blood and fire which the French nation was undergoing, and from this, or perhaps from some deeper cause, he went over with his whole family to the Church of Rome. After his conversion he wrote his *Geschichte der Religion Jesu Christ*, which was published in 15 volumes in 1806. His works, which are very varied, consist of odes, satires, hymns, elegies, translations, dramas, histories, and novels. He died on the 5th September 1819. His brother Christian wrote poems, dramas, translations, and biographies, and died on the 18th of January 1821. The younger brother had the most ability, but both, in many of their writings, display noble sentiment, kindly feeling, and lofty aspiration.

STOLPE, a town of the Prussian monarchy, Pomerania, in the government and 38 miles N.E. of Cöslin, on the river Stolpe, about nine miles above its mouth. It has a castle, built in 1507, and is surrounded by walls and entered by four gates. Here are four churches, a nunnery, several hospitals, a court of law, and public offices. One of the churches is remarkable for its antiquity, and another for a very lofty tower. Stolpe is the chief seat in Pomerania of the manufacture of amber articles, and carries on a considerable trade in these, as well as in linen, timber, and fish. At the mouth of the river stands its port, Stolpemünde, which has a considerable navigation and fishery. The river abounds in salmon. Pop. 11,340.

STONE, EDMUND, a distinguished self-taught mathematician, was born in Scotland, but neither the place nor the time of his birth is well known; nor have we any memoirs of his early life, except in a letter from the Chevalier Ramsay to Father Castel, a Jesuit of Paris, and published in the *Mémoires de Trevoux*. Born the son of a gardener of the Duke of Argyle, he was eight years of age before he learned to read. By chance a servant having taught him the letters of the alphabet, there needed nothing more to expand his abilities. He applied himself to study, and arrived at the knowledge of the most sublime geometry and analysis, without a master, without a conductor, without any other guide but the light of his own mind. He was author and translator of several useful works, viz., *A New Mathematical Dictionary*, in 8vo, first printed in 1726; *Fluxions*, in 8vo, 1730; the Direct Method is a translation from the French of De l'Hospital's *Analyse des infiniment Petits*, and the Inverse Method was supplied by Stone himself; *The Elements of Euclid*, in 2 vols. 8vo, 1731. Stone was a fellow of the Royal Society, and had inserted in the *Philosophical Transactions* (vol. xli., p. 218) an "Account of two species of lines of the 3d order, not mentioned by Sir Isaac Newton or Mr Stirling." In 1758 he published "The Construction and principal Uses of Mathematical Instruments;" translated from the French of M. Bion. In 1742 or 1743 his name was withdrawn from the list of the Royal Society; and in his old age he appears to have been left to poverty and neglect. He survived till March or April 1768.

STONEHAVEN, a burgh of barony and market-town of Scotland, in the county of Kincardine, at the mouth of the rivers Carron and Cowie, in a small bay on the German Ocean, 15 miles S. by W. of Aberdeen. It consists of an old and a new town, the former on the right and the latter on the left bank of the Carron, which is here crossed by a bridge connecting them. The old town has one principal street, broad but irregular, and is in general but ill built; the new town, on the contrary, has a spacious square and several streets running in straight lines parallel or at right angles to each other. In the square stands a fine market-house, and the houses in this part of the town are for the

most part superior to those in the older portion. In the vicinity of Stonehaven stand the parish churches of Dunottar and Fetteresso, and there are also others belonging to the Free Church, the United Presbyterians, and the Scottish Episcopal Church. The town has several schools, a literary institution, library, court-house, and jail. Cotton and linen fabrics are manufactured here, and there are also a distillery and a brewery. Haddock and herring fishing give employment to many of the people. The harbour is a natural basin, but has been improved by the erection of piers; it is, however, only accessible to small vessels. Two miles further south, on a rock overhanging the sea, and separated from the mainland by a deep chasm, stand the ruins of Dunottar Castle, once the seat of the Earls Marischal. Pop. 3240.

STONEHENGE, a singular and gigantic remnant of antiquity, consisting of enormous stones, in an upright or horizontal position, in Salisbury Plain, Wiltshire, about 2 miles W. of Amesbury, and 9 N. of Salisbury. When seen from a distance its appearance is somewhat insignificant, on account of its position on a wide, unbroken plain; and even when close at hand, it requires some careful examination before its magnitude can be fully appreciated. It is the prevailing opinion among antiquarians that Stonehenge owes its origin to the Druids, and it has attracted much attention, as it is of great extent, and in some respects very different from other remains of the same general character. The plain in which it stands is covered with a great number of mounds or barrows, many of them containing ancient British remains. Stonehenge itself is enclosed by a double mound or ditch, circular in form; and there is an avenue or approach leading from the north-east, and bounded on each side by a similar mound and ditch. The outer mound is 15 feet high, the ditch nearly 30 feet broad, the whole 1009 feet in circumference, and the avenue 594 yards long. The whole fabric consists of 2000 circles and two ovals. The outer circle is about 108 feet in diameter, consisting, when entire, of 60 stones, 30 uprights and 30 imposts, of which remain only 24 uprights, 17 standing and 7 down, 3½ feet asunder, and 8 imposts. Eleven uprights have 5 imposts on them by the grand entrance. These stones are from 13 to 20 feet high. The smaller circle is somewhat more than 8 feet from the inside of the outer one, and consisted of about 30 smaller stones (the highest 6 feet), of which only 19 remain, and only 11 standing: the walk between these two circles is 300 feet in circumference. The central portion is an oval formed of 10 stones (from 16 to 22 feet high), in pairs, with imposts, which Dr Stukeley calls *trilithons*, and each pair separate, and not connected as the stones in the outer circle are. Within these were a number of smaller single stones, of which only 6 are standing. At the upper end of the adytum is the altar, a large slab of blue coarse marble, 20 inches thick, 16 feet long, and 4 broad; pressed down by the weight of the vast stones that have fallen upon it. The whole number of stones, when the structure was complete, is calculated to have been about 140. Many of the stones have been more or less hewn, and they appear to have been brought from Marlborough Downs, 15 or 16 miles off, as they appear to be of the same hardness, grain, and colour, generally reddish, with the Gray Weathers still found there. The heads of oxen, deer, and other beasts, have been found on digging in and about Stonehenge, and human bodies have also been discovered in the circumjacent barrows. There are three entrances from the plain to this structure, the most considerable of which is from the north-east, and at each of them were raised on the outside of the trench two huge stones, with two smaller within, parallel to them.

It has been long a dispute among the learned, by what people and for what purpose these enormous stones were collected and arranged. The first account of the structure we meet with is in Geoffrey of Monmouth, who, in the reign of King Stephen, wrote the history of the Britons in Latin. He tells us that it was erected by the counsel of Merlin, the British enchanter, at the command of Aurelius Ambrosius, the last British king, in memory of 460 Britons who were murdered by Hengist the Saxon. The next account is that of Polydore Vergil, who says that the Britons erected this as a sepulchral monument of Aurelius Ambrosius. But other writers in the 12th century discredit all these accounts; and it appears that even at that early time all knowledge of its origin and intention had passed away. Inigo Jones is of opinion that it was a Roman temple, from a stone, 16 feet long and 4 broad, placed in an exact position to the eastward, altar-fashion. Dr Charlton attributed it to the Danes, who were two years masters of Wiltshire. Many other theories have been since propounded, and supported with more or less ingenuity and plausibility; but in a matter so obscure little more than a probable conjecture of the truth can be hoped for. It seems most likely that Stonehenge was erected by the ancient Britons for solemn religious rites; and from the art displayed in its construction, it could not have been much earlier than the time of the Roman conquest. In the vicinity of Stonehenge are the remains of what seems to have been an ancient race-course; and as in early times the public games were generally connected with religious celebrations, it is highly probable that this was in connection with the temple at Stonehenge.

STONEHOUSE, a village of Scotland, Lanarkshire, 15 miles S.E. of Glasgow. It consists chiefly of thatched houses, and contains an Established church, a Free church, and a United Presbyterian church. The people are largely employed in weaving silk, cotton, and woollen fabrics, and there are in the vicinity coal-pits, lime-kilns, and brick-works. Pop. of the parish, 2781.

STONEHOUSE, a village of England, in the county of Gloucester, 3 miles W. of Stroud. It has an old parish church, places of worship for Wesleyans and Independents, an endowed school, and manufactories of cloth. It stands on the Stroudwater Canal, and is a station on the Great Western Union Railway. Pop. of the parish, 2589.

STONEHOUSE, a suburb of Plymouth. See PLYMOUTH.

STONE-MASONRY.

History.

Definition and derivation.

1. Stone-Masonry is the art of building in stone. The word *mason* is derived directly from the French *maçon*, which signifies indifferently a bricklayer or mason. Du Cange attributes the origin of the word to the low Latin *maceria*, a wall; others have endeavoured to show that it comes from *machina*, because builders use machines for hoisting materials; but by far the most probable derivation is that of the French *maison*, a house; thus *maisonner* is to build houses, and the *maçon*, the man who builds them. Among ourselves, at present, we reckon three sorts of artificers—rubble or rag-stone masons, freestone masons, and marble masons. This last branch, however, is rather that of the carver or statuary. The art of working or reducing stone to the proper shape for the mason to *set*, or place them in the walls, &c., has generally been called *stone-cutting*, and depends very much on the nature of the stone for its details.

Origin and history.

2. The art of building with stone is of very great antiquity; it was originally, no doubt, suggested by the holes in the rocks, or natural caves, in which our forefathers sheltered themselves from the inclemencies of the weather. The perishable nature of their wooden huts afterwards suggested an imitation of them in stone as a durable material; and the trunks of trees, and the beams laid across them, were probably the prototypes of columns and architraves.

Cromlechs, &c.

3. Among rude and barbarous people there seems to have been always a great desire to erect huge masses of stones, either as memorials of some event, or for the purposes of religion, and the early history of almost every country treats of some of these structures. (See *Cromlechs*, *Stonehenge*, *Architecture*, p. 423, &c.) The treatises of Dr Lukis, and other papers in *Archæologia*, give the fullest account of these structures.

Cyclopæan masonry.

4. The necessity for defence against predatory tribes seems to have given the next impulse to building with stone, and to this we probably owe those extraordinary walls, commonly called Cyclopean or Pelasgic (*Architecture*, p. 439). These are huge polygonal blocks of stone, carefully cut so as to fit exactly to each other without mortar, and forming walls which must have been impregnable at that time. An idea of their size may be gathered from the fact that in the Etruscan walls at Rusellæ, Mr Dennis (*Cities and Cemeteries of Etruria*, vol. ii.) measured a stone 12 feet 8 inches long by 2 feet 10 inches high. Most of the blocks forming these walls would weigh from 6 to 8 tons. It seems very difficult to understand in that state of civilization how they were hoisted and set. Pausanias (ii. 25), describing those of Argolis, says,—"The walls, the only remains of the city left, are the work of the Cyclops, and are made of rough blocks of such size that a yoke of mules would be unable to move the smallest."

Nineveh, Persepolis, &c.

5. At Nineveh the walls seem mostly of unburned brick, but they are lined with huge slabs of marble, or rather a species of alabaster, the working and carving of which show a very great advance in art. (See Nineveh.) The architecture of the Hindus, Persians, Phœnicians, and Jews, will be found under their respective heads. (Art. Architecture.) But there is nothing about their *masonry* differing from that of other similar structures on which it would be profitable to dwell.

Egyptian masonry.

6. The Egyptians, however, seem not only to have used gigantic masonry, but also to have had the power of working, carving, and polishing granite in a way which we certainly cannot at present attain to. The most marvellous fact connected with their masonry seems to be that the whole work was executed with copper or rather bronze tools, which seem to have answered their purpose better than even our best and hardest steel. Such seems to have been the facility with which they worked this, to us untractable material, that they were not content to cut and polish huge slabs and masses of granite, but they covered them all over with the most delicate and sharp-cut hieroglyphical inscriptions.

Greek masonry.

7. The masonry of the Greeks yet remaining is chiefly of beautiful marble. The workmanship is of the most exquisite character, the joints, &c., of the greatest truth. The artistic beauties of the carving, &c., have been unrivalled at any period. It seems difficult to believe that so enlightened a people were ignorant of the use of the arch, especially as it is clear it was known not only to the Egyptians, but was used at Nineveh. However, no example of a Greek arch exists at this time, as an architectural feature, although, as has been said before (art. Arch, § 8, p. 401), for necessary purposes (as covering drains), and concealed in the walls (as discharging arches), examples are to be found in Greek works. (See Ferguson's *Hand-Book*, p. 252; *Architecture Suppl.*, § 2, p. 500.) It is probable that, as they had plenty of marble in blocks of almost any size, they preferred to use it in horizontal bearings, to working it into arch forms.

Roman masonry.

8. It was, however, the contrary with Roman masons; although it is true many of their temples were Greek in character, and most of them rivalled those of that nation in size and in the vastness of their material.[1] But in general there was less of that ponderous strength that characterized the Egyptian and the Grecian Doric; and much more science in the construction, particularly as regarded economy; though in point of artistic beauty they were far below the Greeks. To what nation or race the invention of the arch may be attributed, it is clear the Romans were the first to bring it into general use; and though we read of a species of dome among the Greeks called θολος, and though the Hindus delight in domical construction, it is clear the Romans were the first in Europe to use the true dome in covering their temples. Besides this, they had not only good lime but plenty of pozzolano, and therefore their mortar and cement were of first-rate quality. To these advantages we may attribute the vast works which to the present day amaze the spectator, who cannot view their cloacæ, aqueducts, amphitheatres, basilicæ, walls, towers, tombs, domes, harbours, without wonder at the enterprise of the people and the skill of their masons.

Mediæval masonry.

9. After the ruin of the Roman empire, and the irruption of the savage hordes over the whole of civilized Europe, the art of masonry, like all others, declined to the lowest ebb. In fact, except for the erection of rude forts and towers, it became almost extinct. In England we owe its first revival to the works of the Norman invaders; and next, no doubt, to the return of the crusaders, who had witnessed with admiration the marvellous lightness of the buildings in the east, and who brought back with them the arts and learning of the Arabians, especially their mathematical science. From these sources, no doubt, pointed architecture took its rise, and massive cylindrical pillars, composed of many small pieces of stone; small circular-headed windows; walls of vast thickness, with very shallow buttresses; and plain groining without ribs, gradually became changed to

[1] There are pieces of the architrave of the Temple of the Sun now lying on the Quirinal at Rome, measuring 16 ft. 6 in. long by 9 ft. 6 in. high, and about 6 ft. thick, or nearly 50 tons in weight.

History.

light shafted piers, and delicately moulded arches; windows rich with varied tracery; pannelled walls, with bold buttresses, surmounted by niches, and crowned with pinnacles; and groined roofs, fretted with a net-work of ribs, and studded with richly floriated bosses.

Masonry of the sixteenth and seventeenth centuries.

10. The revival of classic architecture threw the arts into another channel, and the masons had hardly forgotten their old traditions when Jones and Wren introduced them to new details. The latter, in particular, formed an excellent school of masonry. The works at St Paul's, and his other public buildings, are executed in a very superior manner. He seems to have been very choice in the selection of his stone. Among all his buildings is scarcely a failure, or a defective block. Besides this, by the assistance of Gibbons, he formed an excellent school of architectural carvers.

Eighteenth and nineteenth centuries.

11. The art of masonry was well upheld by Hawksmoor, Vanburgh, and Chambers; but shortly began to languish, when the inordinate use of cements, first introduced by the Adamses, came into vogue. Besides this, the heavy duties imposed on the transport of stone by sea, and the high prices which all materials bore during the war, threatened to reduce masonry to its lowest. The revival of Gothic architecture has renewed the use of freestone, and has taught our masons the art of working tracery, groined roofs, flying buttresses, and such use of stone as was supposed, scarce a century ago, to be one of the lost arts. Besides this, the abolition of duties, and the introduction of many facilities of transport by steam, both by land and water, has so reduced the price of stone, that in many places the use of cement is a false economy. Again, our intercourse with the Continent has brought us into more familiar acquaintance with the great works of classic antiquity, and of the Italian Renaissance. In addition to these causes, the vast engineering works, our docks, harbours, lighthouses, bridges, and, above all, our railroads, which have lately been constructed all over the country, have given a vast impetus to the study and practice of constructive masonry on the largest scale; and the consequence is, we now have in Great Britain a body of masons of higher and more varied skill then perhaps ever was known in this country at any time, both as regards constructive ability and elegant taste.

State on the continent. Italy.

12. In Italy the old customs and traditions are still closely followed, and masonry is extremely well but slowly executed. The fine viaduct lately built at Albano is, however, a favourable example of Italian engineering in stone; and as railways gradually spread over the country we may expect still greater progress.

France.

In France masonry has always flourished, stone being so abundant, especially in the neighbourhood of Paris. The late works at the Great Exposition, particularly the beautiful bridge over the Seine, and the noble buildings which unite the Tuileries and Louvre, form probably the finest palace in the world, and speak highly of the state of the art in France.

Germany.

In Germany we may note the fine works at Munich, particularly the Valhalla, the Pinacothek, and the Glyptothek; at Berlin, the beautiful buildings of Shinkel;

Russia.

and in Russia the vast improvements at St Petersburg, particularly the cathedral of St Isaac, the dome of which is surrounded by twenty-four columns, each of one single piece, and each weighing more than 60 tons, and standing at the height of 150 feet above the ground. (See art. St Petersburg, vol. xvii., p. 490.)

Divisions of the subject.

13. It is now proposed to treat this subject under the following heads:—

I. Materials used in masonry.—1. The various kinds of stone. 2. Their durability and causes of decay. 3. Mortars and cements.

II.—Of the principles of stability and strength in masonry. Under this head it is proposed to give the whole of the scientific article written by the late Professor Robison expressly for this work.

III.—Of foundations.—1. On land. 2. In the water.

IV.—On stone cutting and setting.—1. General. 2. Mediæval.

V.—On artificial stones, and on the induration of soft stones.

Materials used in Masonry.

I.—Of Materials Used in Masonry.

Materials.

14. In our article on Mineralogical Science, vol. xv., p. 155, we have given an epitome of the various rocks which compose the fabric of the globe. We purpose to go through this list, showing those used in building as they occur *seriatim*, with some practical remarks upon each, which will give a complete epitome of the materials used by masons in all ages.

Igneous rocks of volcanic origin.

15. Of *Igneous Rocks* of volcanic origin, the varieties which have been used are those light stones called tufa and pumice, and that stone called peperino. The two former of these were extensively employed by the Romans in the filling in of vaulting, on account of their great lightness. The latter stone, which is obtained in large quantities near Rome; and which, though of volcanic origin, resembles a sort of coarse oolitic conglomerate, was used by that people extensively, particularly for substructures, for which it is fitted, being obtained in large blocks.

Trappean.

Of the second division of igneous rocks, the *trappean;* porphyry, and serpentine have been used, but chiefly as ornamental coloured stones, and have been generally classed as marbles.

Super-silicated stones.

Of this third division the granite alone is in use, and is now very extensively employed, not only in bridges and engineering works, but in public buildings and dwellings.

Granite.

It is got from the quarries by splitting the blocks with wedges, and is so hard it cannot be cut by any ordinary saws. It can only be worked first with large hammers, and then reduced by pointed chisels, and consequently is very expensive in building. Some very good specimens come from Cornwall and Devonshire, but by far the best are from Dundee and Aberdeen. A variety of the latter, called Peterhead, is only to be equalled by the finest oriental granites.

Aqueous rocks. Gravel and sand.

16. *Of Aqueous Rocks—Mechanically formed*, and of the *Arenaceous* varieties.—Gravel is used by masons for concrete, and sand in making mortar. Sandstones and gritstones are very extensively used.

York paving.

These are either laminated, as the York stone, and used generally for paving, as it can readily be split into large surfaces of small relative thickness;

Old red sandstone.

or compact as old red sandstones, which stand very well internally, but perish sadly with the weather, as may be seen at Chester cathedral.

Tunbridge sandstone.

The new sandstones, the best of which is the Calverley stone, got near Tunbridge Wells. These stones are easily quarried, but, if sawn, the wet saw and sand must be used.

Compact sandstone.

The finer grained compact sandstones, which are comparatively free from iron, and form very good building-stones, are very numerous. We name a few. These are the Bramley Fall, used by engineers for bridge copings, &c.; the Park Spring, Elland Edge, and Whitby, all from Yorkshire. Scotland can boast of some of the finest quarries of sandstone, the best of which, perhaps, is the Craigleith, much used at Edinburgh. The college, courts of law, registry, custom-house, royal exchange, national monument, and many churches and private residences there, are built of this excellent material, which has also been extensively exported to Hamburg, Altona, Gottenburg, and the continent.

Humbie.

Humbie stone has also been extensively used, both at Edinburgh and at Glasgow, where it forms the Royal Exchange and bank. It is easier to work than Craigleith.

Glammis.

Glammis is also a fine sandstone. The castle there, as well as those at Inverquharity and Cortachy, and Lindertis House, are built of this.

Culello.

In Fifeshire, at Culello, are

Materials used in Masonry.

quarries from whence the stones for the monument to Lord Melville at Edinburgh, and that to Lord Nelson at Yarmouth, were obtained. In addition to beauty and durability, these stones have the merit of being capable of receiving the finest and smoothest forms from the chisel of the workman. Another class of sandstones are commonly called *firestones*, as they endure the action of fire better than most others.

Reigate firestone.

Of these the best known is the Reigate stone, which is the principal material used at Windsor Castle, Hampton Court, and in many old buildings round London.

Argillaceous clunch.

Of *aqueous stones* classed as *argillaceous*, the Clunch only is used in building. It may be seen in Ely and Peterborough cathedrals, and many other mediæval buildings, and is a beautiful material for carving, but will not stand the weather.

Chemically formed. Travertine.

Of those *aqueous stones*, classed as *chemically formed*, and of the subdivision, the *calcareous*, we have none of note but the Travertine, or, properly speaking, Tiburtine. This is a coarse grained stone, of warm colour, found in large blocks, and extensively used at Rome, both in ancient and modern buildings; the great cathedral of St Peter's may be cited as an instance; but it is unknown in England.

Calcareous.

Of *aqueous rocks, organically derived*, and of the first subdivision, the *calcareous* claims our principal attention.

Limestones.

The chief of these are the *limestones*, which are generally considered by architects as compact, magnesian, or oolitic limestones. Of the former the best, in the south of England,

Chilmark.

is that called Chilmark, of which Salisbury Cathedral and Wilton Abbey, and many other fine buildings, have

Tottenhoe.

been erected. In the midland counties the Tottenhoe stone, of which Dunstable Priory, Woburn Abbey, Luton church, &c., are built, is an excellent stone. There is also a stone of high quality got near Wirksworth in Derbyshire, used at Chatsworth, Belvoir, Drayton Manor &c., &c.

Magnesian. Anstone. Tadcaster.

Of magnesian limestones we may name the Anstone, or Bolsover Moor stone, used formerly at Southwell Minster, and lately at the houses of Parliament; the Tadcaster stones, used at York, Beverley, and Rippon Minsters, and very many other buildings;

Roche Abbey.

and the Roche Abbey, used at the building of that name, and very many other churches in Yorkshire and Lincolnshire. These stones contain a great deal of carbonate of magnesia, from which they take their name, and are of beautiful texture, and stand well in the country as building-stones; but fail in London, from a cause which will shortly be stated.

Oolitic stones.

We now come to the most important subdivision of the limestones used in masonry—the *oolitic*—so called because they resemble, when broken, a conglomerate of globular eggs, also frequently called roe-stones, because they resemble what is called the hard roe of a fish. (See art. GEOLOGY, vol. xv., p. 146.) Very good examples of these

Barnack.

are the Barnack stone from Northamptonshire, of which Peterborough Cathedral, Croyland Abbey, Burleigh House,

Ketton.

&c., &c., are erected. Ketton stone, used at most of the colleges in Cambridge, and at Bury St Edmunds, Bedford, Stamford, &c., &c. But the principal English oolites used

Bath.

in masonry are the Bath and Portland. The former, as its name imports, is found in the neighbourhood of Bath. The chief quarries are the Box, Combe Down, Farleigh Down, and Corsham Down; all these quarries vary in quality at different depths. The Corsham Down is said to produce the finest in quality, and the Box Ground stone to be the hardest; but everything in the use of this stone depends on the judgment in selection.

Caen.

Large quantities of a similar stone are imported from Caen, in Normandy. They are more compact in texture than Bath, and therefore fitter for carving; but do not appear to stand the weather of our climate so well. The best variety of this stone is said to be D'Aubigny stone. Almost all these oolites can be sawn with a common dry saw, which saves a great deal in the labour of conversion. But, without doubt, the best of all this class of stones is that from the Island of Portland; for beauty of texture and for durability, it perhaps exceeds any stone in the world. It seems the only stone unaffected by the smoke of London; and therefore the greater number of its buildings, St Paul's among the rest, are of this

Portland.

stone. It must, however, be sawn by the use of sand and water; and, being of hard texture, is much more expensive to work than the softer oolites. There are between fifty and sixty quarries on the island. The best are said to be those on the north-eastern side; but, like all stone, there is good and bad in every quarry, and everything depends on the selection. It is said, when Sir Christopher Wren built St Paul's, he had this stone quarried, and exposed to the weather on the sea-beach for three years, before he suffered it to be used. A very excellent limestone for walling, especially for Gothic work, is that called *Kentish Rag*.

Kentish Rag.

It is found in large quantities in the neighbourhood of Maidstone, and is very hard, and worked, like granite, with large hammers instead of the saw. Jambs, strings, and mouldings are sometimes worked out of it, but the hardness makes the work expensive.

Flint.

Of siliceous stones, flint is sometimes used for rough walling; but in England this work is done by the bricklayer, and not the mason. (See BUILDING, p. 737.)

Metamorphic rocks.

17. The only remaining class is that of the *metamorphic rocks*, of which the crystalline and saccharine, and the serpentinous limestone are used; but these are all species of marbles, and used more as ornamental than as constructive

Marble.

building-stones, and need not be dilated upon in this article.

The Durability and Causes of Decay in Stones.

Durability of stones.

18. The causes of durability of stone, and the correspondent causes of failure and decay, are either chemical or mechanical, and may be described either as decomposition or disintegration. Durability also depends much on the power of resistance to wear.

Decomposition.

19. Decomposition is caused by some of the elements of the stone entering into such new combinations with water, gases, or acids as render them soluble either by the air or water. Granite, though the hardest of building-stones, is

Alkalies.

liable to serious decomposition when the feldpars are alkaline (see art. GEOLOGY, vol. xv. p. 136), and will unite with water or acids. Some qualities of this stone are rapidly decomposed by the sea. The same is the case with many of the limestones, as is described in the article above quoted, page 151.

Oxides of iron.

Stones containing iron are also liable to decay. In its native state it is usually in a low state of oxidation, and is liable to be acted upon by additional quantities of oxygen or carbonic acid. This sort of decomposition is much increased by being alternately wet and dry, or by frequent changes of temperature. Stones, however, containing iron in a high state of oxidation, as rosso-antico, porphyry, &c., do not readily become decomposed. The most curious discovery of modern times is with regard to the magnesian limestones and dolomites.

Magnesia.

These were chosen for the new Houses of Parliament on account of their durability. The work at Southwell Minster, 800 years old, bears every mark of the tool to the present day, and every circumstance seemed to justify its selection. It appears, however, that magnesia has a great affinity for sulphur; and the consequence is, the sulphurous acid which

Sulphurous acids.

is present in such quantities in the smoke of London, has already caused serious decomposition in that building, as well as in the Lincoln's Inn Hall. This acid has also so much effect on the softer limestones, that the fronts of several important buildings, Buckingham Palace among the rest, have been obliged to be painted, to save them from decay.

Disintegration.

20. Disintegration, as has before been said, is the separation of parts of stone by mechanical action. The chief cause

Freezing.

is the freezing of minute portions of water which get into the

Materials used in Masonry.

pores, or fissures, or between the laminæ of stones, and swell slowly as crystals of ice are gradually formed, and consequently burst open the pores, or split the grain of the stone. The south sides of buildings, in northern climates, suffer more than others, as their surface becomes thawed and filled with wet in the day, and frozen again at night, more frequently than the others. A very common error in the present day, is the not taking care to set stones with their laminæ, or grain, or, as the workmen call it, "bed," in a horizontal direction. If work be "face-bedded," the action of the weather will cause the laminæ to scale off, one after the other, just as the leaves of a book fall over, if the volume be placed on its back in an upright position. For fuller illustration of the subject of decay and decomposition of rocks, we must refer our readers to the article MINERALOGICAL SCIENCE.

Face-bedded work.

Resistance to wear.

21. Resistance to wear is another obvious cause of durability; but this depends rather on the toughness than the mere hardness of material, a quality often attended with brittleness, as also on its situation. The crushing weight of Portland is about 10,000, while that of York is about 12,000, or one-fifth more; but in many situations Portland steps will last much longer than York. Again, the crushing weight of Peterhead granite is about 18,000, or not quite double that of Portland; whereas, if used as street-paving, it would outlast six sets of the latter.

Of Mortars and Cements.

History of mortars and cements.

22. The use of some material, not only to cause stones to adhere together in building, but to fill up crevices between them, and irregularities in bedding them, is of the remotest antiquity. The earliest mention of mortar is in Genesis xii. 3, where the builders of the Tower of Babel are said to have had "slime for mortar," which the LXX. called ἄσφαλτος (bitumen) and πηλός. Herodotus (Clio, 179) tells us the walls of Babylon were built of bricks, cemented together by hot asphalt. The Egyptians used mortar of lime and sand, almost exactly in the proportions we do, as was proved from an analysis of some taken from the pyramid of Cheops. The Grecian mortars and cements are very fine and strong. Vitruvius gives careful directions how to make mortar (lib. 2, ch. 5), and his instructions are probably the best, and his observations the most sound, of any author, at least till the time of the researches of Vicat and the French chemists.

Definition.

23. Mortar is generally considered under two heads: as common mortar, or that mixture of lime and sand ordinarily used in building; and hydraulic mortar, or that which will set under water. Cement is a name given to the produce of certain argillaceous stones, after calcination, which will set rapidly in the air, and become a hard, adhesive substance in a short time; and which will also set under water, both without admixture of any other substance. The name is also given to certain artificial imitations of these substances, possessing the same properties; and besides, to various bituminous, or oleaginous compositions, used in building for similar purposes.

Lime.

24. Pure lime is an oxide of a metal called calcium, but does not exist in a natural state. It is, however, found abundantly in the conditions of carbonates and sub-carbonates, in chalk, and the various other descriptions of limestones. Its chemical qualities and analysis will be found under the proper heads. The first thing is to drive off the water, which all limestones contain in a greater or less degree, and the carbonic acid gas, which is done by calcining or burning in a kiln at red heat, which must be kept up for several hours, taking care, however, to avoid any approach to vitrification. By this process it is slightly diminished in bulk, and it loses nearly half its weight, and becomes caustic lime.

Materials used in Masonry.

Classification.

25. Limes are generally classed, since the publication of the work of Vicat, as—1. rich limes; 2. poor limes; 3. limes slightly hydraulic; 4. hydraulic limes; and 5. eminently hydraulic limes. In treating of mortar, we have to deal with the first two of this division.

Production of hydrates

26. The lime must next be converted into a hydrate. This is done by a process called "slacking," or throwing water over it from time to time till it hisses and cracks with considerable force, and some noise, gives off a large quantity of hot vapour, and falls into a powder. The rich limes, which are the purest oxides of calcium, increase to double their bulk in the process. The poor limes swell to a much less degree. The hydrates thus formed absorb water, and easily take the form of a paste. They contain rather less than one-third water to two-thirds lime. In this state, if treated with pure water, frequently renewed, every particle of rich limes, and very nearly the whole of the poor limes, will be taken up in solution. In the process of slacking, too much water should not be used, as it "drowns" the lime, according to the expression of the workmen. When in the form of paste it begins to absorb the carbonic acid, which, though no component part of air, is always present in it, in large quantities; and gradually to crystallize again, and so to harden. If the air be excluded from the hydrate of pure lime, it may be kept for almost any length of time. Alberti (lib. 2, cap. 2) says that he once discovered some in an old ditch, which, from certain indications, must have been there 500 years, and was as soft as honey or marrow, and as fit for use as it could be.

Rich limestones.

27. The rich limestones give a white lime, which easily slacks, and increases in bulk; but it is curious that, though the stones differ so much in outward appearance and in texture, the lime, if they be well burned, is the same. The softest chalk, and the hardest rag-stone, or marble, yield an equally good lime, the calcium which they contain being the same mineral. But as chalk generally contains water, irregularly distributed in some places and not in others, and as it is does not exhibit the change that marble or stone does, it is frequently unequally burned, and therefore slacks imperfectly. It is said, however,[1] that lime, made from chalk absorbs the carbonic acid more rapidly than that made from stone; but our own experience does not warrant this conclusion.

Poor limestones.

28. Poor limestones are those which contain silica, magnesia, manganese, or metallic oxides. In consequence of this they are more liable to vitrify in burning, and do not slack so freely. The lime is generally of a browner colour than that from rich limestones, which is said to be a proof of the presence of the above-named metallic oxides. If, however, they be ground so as to facilitate the slacking of every particle, and if used immediately it is made up, poor limes produce a mortar which becomes harder than that from the rich limes, and which resists water better. In fact, works where the latter have been used, have been found to fail entirely by the action of running water, which, as before has been said, will continue to remove the whole of a rich lime, particle by particle.

Use of sand.

29. It is found that the mixture of some kind of hard matter in particles or granules facilitates the setting of mortar, renders it harder and more adhesive than when used alone, besides the saving of limestone and expense of burning. The harder this material, and the sharper the particles the better, as the brick or stone has always some irregularities on the surface, into which these angles or sharp points may enter, and form what is called a key. The substance most generally used is sand, which is generally classed as river-sand or pit-sand. The former is

[1] Higgins *On Mortars and Cements*, p. 29.

Materials used in Masonry.

generally preferred, as it is more free from any earthy matters, particularly soft loams or clay. If pit-sand be used it should be well washed. Scarcely any material is better than crushed quartz, or flint, from the sharpness of the angles of the particles; in fact, it is said, that very sharp sand, with an inferior lime, will make a more adhesive mortar than soft sand with the best lime. For observations on the practical mixing of mortar, see BUILDING, p. 731.

Other materials. Burned clay.

30. Where sand is scarce, other materials may be used, the principal and cheapest of which is burned clay. The Romans used this extensively in the form of pounded brick. At present the custom is to throw up clay mixed with any fuel in loose heaps, and burn it slowly. The French writers at one time asserted that burned clay, if not equal to pozzolano, was very nearly so; and large quantities were used as hydraulic mortars at various public works. Where the water was fresh, as at Strasbourg, the work stood very well; but where these mortars were exposed to the action of sea-water, they failed and went to powder in three or four years. Vicat gave great attention to the subject; and though he attributed much of the fault to the imperfect carbonization of the materials, it appears with but little doubt there is some inherent difference between the pozzolanos and other volcanic products, which will be treated of shortly, and those produced artificially.[1]

Slag and cinders.

31. The vitrified refuse of furnaces, called slag, and the scoriæ from the iron-works, have also been crushed and used instead of sand; and with lime slightly hydraulic, produce good mortar. The former is preferred to the latter, as having sharper and harder particles, and containing much less iron. Coal cinders have been used, and seem to have some hydraulic properties; they should, however, be employed with caution, for it is considered they make the lime "short." Wood cinders are too alkaline to be used with safety. A very excellent mortar, much used by engineers in tunnels, is composed of one part of moderately hydraulic lime, one part of coal ashes, one part of burned clay, and two parts of sharp sand.

Volcanic products.

32. The vitrified and calcined products of volcanoes make most excellent materials for mortars, particularly where required to be eminently hydraulic. The principal of them is the Pozzolano, which abounds in Italy. It is called so from being found in great abundance at Pozzuoli, near Naples, and is, in fact, the basis of all the best Roman mortars, ancient as well as modern. It varies in colour from reddish brown to violet red, and is sometimes grayish. It is usually sent to England from Civita Vecchia. It has a roughly granulated appearance, and sometimes resembles a cinder in texture, and has frequently a spongy appearance. Acids have little effect on it, and it is not soluble in water. A similar earth is found in the centre of France. But one more familiarly known in this country comes from the village of Brohl, near Andernach, on the Rhine; this is called terrass or trass. These materials have a wonderful effect in rendering even the rich limes eminently hydraulic, and in less proportions improving the hydraulic limes. Vicat says, these mortars begin to set under water the first day, grow hard in the third, and in twelve months are as hard as the bricks themselves. The mixture of common lime with these materials, according to the French writers, should be 1 of pounded lime to 2½ of pozzolano, or to 2 of terrass; or 1 of lime to 1 of sand and 1 of pozzolano. The analysis given by them is nearly as follows:—

Pozzolano and trass.

	Terrass.	Pozzolano.
Silica, per cent.	57	44
Alumina	12	15
Lime	3	8
Magnesia	1	4
Oxide of iron	5	12

Cements.

33. In addition to those which we have called hydraulic limes, there is a peculiar class of stones, which, when burned and pulverized, may be used as a species of mortar, without admixture of sand or any similar substance; and which will not only set rapidly under water, but will acquire an unusual degree of hardness and tenacity.

Natural cements.

34. These are called natural cements. The inventor is supposed to have been a Mr Parker, at any rate that gentleman took out a patent about sixty years ago for what he called Roman cement. His material were those argillo-calcareous nodules, or septaria, which are found in the Isle of Sheppey, and commonly called bald-pates. They contain about 70 per cent. of carbonate of lime, about 4 per cent. oxide of iron, 18 per cent. of silica, and 6 or 7 per cent. of alumina. The process is simply to break the stones into small pieces, and burn them in running kilns with coal or coke; they are then ground to a powder, and headed up into casks for use. The success of Parker's cement led to experiments in other places, and the same process was carried on with other argillo-calcareous nodules, as the septaria at Hawick; those in Yorkshire, which produce the cement called Atkinson's; and those in the Isle of Wight, which produce the Medina cement. Similar substances were also discovered, and the same processes carried on in France and in Russia. All these cement-stones effervesce with acids, and lose about one-third of their weight in burning. Parker considered the more the stones were burned short of absolute vitrification the better; but this is not the practice in the present day, though no doubt sound in theory. When taken from the kiln these stones will not slack without being pulverized; and if kept dry, and not exposed to the air, the cement will be good almost any length of time; but it rapidly absorbs both water and carbonic acid if not carefully closed, and falls back into a state of subcarbonate, from which it is said it may be recovered by fresh burning, but it is doubted whether it is ever so good as on the first calcination.

Artificial cements.

35. The great utility of these cements, and the expense of obtaining the stone, induced the manufacturers to endeavour to discover some method of making an article by artificial means which should resemble the natural cements. Mr Frost seems to have been the first who attempted it on a large scale; but though assisted by the talent and science of General Pasley, the results did not come up to the expected standard. Of course, the object was to produce an argillo-calcareous substance, containing the same chemical qualities as the natural nodules, and which might be burned in kilns as they are. The attempt to combine argil in the form of burned clay, to be mixed with lime instead of pozzolano, had partially failed, as has been stated before. Our space will not allow us to relate the various experiments by General Pasley here, nor by Vicat at Meudon in France. They were all based on the principle of mixing together, in a mill, with a quantity of water, masses of chalk and clay, just as the brickmakers do for the production of malm bricks, but in the proportion of about four of the former to one of the latter. The fluid mixture is run out into shallow receivers, and when dry is cut into small blocks or lumps, and burned exactly as the natural nodules are. The difficulty seems to have been to give the materials the full degree of calcination short of vitrification. This seems to have been at last attained by the inventors of the Portland cement, so called from its near resemblance to Portland stone in its colour. It not only possesses the property of setting more quickly, and has greater powers of cohesion than the natural cements, but it may be used with a superabundance of water in the

Portland cement.

[1] After long investigation, Vicat was of opinion that this failure was due to the quantity of hydro-chloride of magnesia always present in sea-water; but in what way this affected the burned clay and not the volcanic products, he was unable to explain.

form of grout, which they cannot; and, above all, it seems to resist the action of sea-water beyond all others. It also forms a very superior cement, as is described hereafter. From a series of trials made on the Portland cement, manufactured by Messrs J. B. White of Millbank, it appeared it required more than two tons to separate two blocks of stone 6 inches cube, which had been put together with a joint of Portland stone, one-eighth to one-fourth inch thick. This gives a resistance of 146 lb. per inch of sectional area, that of Bramley Fall being 76 lb., and Whitby stone 57 lb. Its power to resist compression was tested on blocks 9 inches square and 18 inches long, the pressure being exerted on their ends.

Marble cements.

36. A class of cements capable of taking a brilliant polish resembling marble, and consequently very suitable for internal decoration, had lately been invented. The chief of these is Keene's marble cement, and the Parian cement. They become excessively hard in a short time, and are capable of being painted in a few days. The principal component part is said to be obtained by the precipitation of alum by an alkali, which gives a white powder of great brilliancy. It is, however, more matter for the plasterer than the other building trades.

Oleaginous cements.

37. Cements made by the mixture of oil with various substances were formerly much used both here and abroad. The best known in England was called Hamelin's mastic, that in France the mastic de Dhil. These cements being very expensive, and requiring to be constantly painted, have now gone nearly out of use. For outside plastering they form a very fine clean surface, as may be seen in tbe quadrant in Regent Street.

Bituminous cements.

38. The asphaltum, or mineral pitch (see Asphaltum), have lately come into extensive use for pavings, and for covering the backs of arches, or rendering the walls of basements where wet is likely to soak through. The best is said to be that from Seyssel, in France. For their chemical properties see Bitumen. It is used thus—A bed of concrete, made of the best hydraulic lime, is first prepared, and made fair at top by a rendering of similar mortar. The asphalte will not dissolve with heat by itself, but will calcine in the caldron. A small quantity of pure mineral pitch is therefore first put in; when hot the asphalte is added, and soon dissolves; into this is stirred a quantity of powdered stone-dust, and a small portion of quick-lime. The mixture is then laid hot on the bed of concrete (which must be quite dry), and spread close and fair, some sand being sprinkled over the top and well trowelled in. The best proportions are said to be about 2 pints of mineral pitch to 10 lb. of asphalte, and one-fourth bushel of stone-dust. A very inferior imitation is made by mixing a quantity of sharp sand with gas-tar, heated in a caldron, and then adding some quick-lime. This may do for rendering walls, &c., to keep out wet, but is of very little use in paving.

II.—OF THE PRINCIPLES OF STABILITY AND STRENGTH IN MASONRY.

39. The strength and the stability of stone-work depends partly on its mass or weight, and partly on the resistance of the materials. And, since we cannot imagine incompressible fulcra, nor that the materials of masonry are infinitely hard and inflexible, as writers on elementary mechanics consider them to be, therefore, it is essential that the resistance of materials should be considered, and the effect of their weight allowed for in estimating the power of the straining force.

The resistance of stones being dependent on their state of aggregation, and not on the hardness or density of their elementary parts, their comparative strength cannot be judged of by these qualities; indeed there are few kinds of materials of which the resistance is so uncertain as that of stone, and hence, it is not at all adapted for any support where its resistance depends on its cohesion only, unless it be very carefully examined, and abundant strength be allowed. The resistance of stone to compression is less affected ,by its irregular nature, particularly as it is usually employed in blocks of inconsiderable height; and, in general, there is scarcely any reason to be sparing of a material which it is often more expensive to reduce than to employ in large blocks. When, however, works of great magnitude are to be constructed, the weight of the materials themselves forms the chief part of the straining force; and, consequently, in such cases it becomes desirable to form a tolerably accurate estimate of their power.

40. This power is limited by a property of bodies that has not received that degree of attention which its importance would lead us to expect. We shall in this place make it the basis of an investigation of the power of materials to resist a force applied in any given direction, and show its application to some of the cases where a mason is most likely to need the assistance of calculation.

When any material is strained beyond a certain extent, every time the strain is increased to the same degree, there is a permanent derangement of the structure of the material produced; and a frequent repetition will increase the derangement till the parts actually separate. (See the article Carpentry.) When a small base rests upon a considerable mass of matter, as a pier on the ground, the quantity of derangement will increase only till the mass be compressed to that degree which renders the increase insensible; but in many cases a number of years will elapse before the settlement becomes insensible.

41. The strain which produces permanent derangement in the structure of a material varies from one-fourth to two-fifths of that which would destroy its direct cohesion. In stone the lower value should be taken, on account of its being subject to so many defects; and, for the present, let this strain be denoted by f lbs. upon a superficial foot.

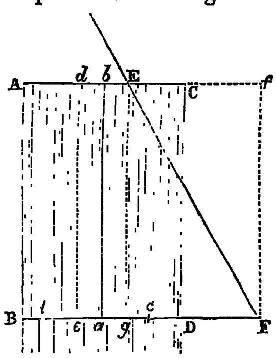

Fig. 1.

42. Imagine ABCD to be a block, fig. 1, strained either in the direction EF or FE, by a force W; and let BDF be a line drawn in the same plane as the direction of the straining force, and perpendicular to the axis ab of the block. Now, if we consider the resistance of the block to be collected at the centres of resistance t and c, then tF will represent a lever acted upon by three forces; that is, the resistance at t and c, and the straining force at F.

If the angle FEg be denoted by α, then the effect of the force W, reduced to a direction perpendicular to the lever, will be expressed by $\cos\alpha$W. . . . . (1.)

Also, if T be the resistance at t, and C the resistance at c, we shall, in the case of equilibrium, have $C - T = \cos\alpha W$. . . (2.)

And, by the property of the lever,

$$\frac{\overline{tc} \times T}{\overline{cF}} = W\cos\alpha \qquad (3.)$$

$$\text{Hence, } \frac{\overline{tc}}{\overline{cF}} = \frac{C}{T} - 1 \qquad (4.)$$

43. Without stopping to notice some maxims furnished by this equation (see the article Bridge), we will proceed to explain the notation used in the investigation which follows:—

$l=$ the length AB.
$d=$ the depth BD, measured in the same plane as the direction of the strain.
$b=$ the breadth.
$z=$ the distance of the neutral point e from the axis ab.
$y=$ the distance of the point g from the axis ab.
$p\left(\frac{1}{2}d-z\right)$, and $p\left(\frac{1}{2}d+z\right)$ the respective distances of the centres of resistance t and c from the neutral point; and, consequently,
$pd=$ the distance, ct, between them. And,
$g\left(\frac{1}{2}d-z\right)$, and $g\left(\frac{1}{2}d+z\right)$ the respective distances of the centres of gravity of the sections into which the neutral axis divides the block, counted from the neutral point.

The leverage cF, expressed in this notation, will be

$\frac{l\sin a}{\cos a}+y-\frac{1}{2}pd+(-p)z$; consequently, equation (4) becomes

$$\frac{pd}{\frac{l\sin a}{\cos a}+y-\frac{1}{2}pd+(1-p)z}=\frac{C}{T}-1 \quad (5.)$$

44. Now, it has been shown, by writers on the resistance of solids, that the resistance of any section, collected at its centre of pressure, is equal to its cohesive force multiplied by the distance of its centre of gravity from the neutral axis, and divided by the distance of the point of greatest strain from the neutral axis. (Emerson's *Mechanics*, prop. 77, 4to ed.)

Accordingly we have $$C=\frac{fbg\left(\frac{1}{2}d+z\right)^2}{\frac{1}{2}d+z} \quad (6.)$$

And $$T=\frac{fbg\left(\frac{1}{2}d-z\right)^2}{\frac{1}{2}d+z} \quad (7.)$$

Therefore $\frac{C}{T}=\frac{\left(\frac{1}{2}d+z\right)^2}{\left(\frac{1}{2}d-z\right)^2}$; which being substituted in equation (5), we obtain

$$(3p-2)z^2-2z\left(\frac{\sin a.\ l}{\cos a}+y\right)+\frac{1}{2}pd^2=o \quad (8.)$$

If the block be rectangular $p=\frac{2}{3}$, and therefore the distance of the neutral point from the axis is

$$z=\frac{d^2}{12\left(\frac{l\sin a}{\cos a}+y\right)} \quad (9.)$$

45. The value of z for a rectangular section being determined, the magnitude of the straining force is easily found, so that it may not exceed the power of the material; for, by the properties of the lever—

$W\cos a=\frac{pdC}{\frac{l\sin a}{\cos a}+y+\frac{1}{2}pd+z(1-p)}$; and since $C=fbg\left(\frac{1}{2}d+z\right)$ by equation (6), and

$z=\frac{d^2}{12\left(\frac{l\sin a}{\cos a}+y\right)}$ by equation (9), and $g=\frac{1}{2}$ by the form of the section, we have

$$W=\frac{fbd^2}{d\cos a+6l\sin a+6y\cos a} \quad (10.)$$

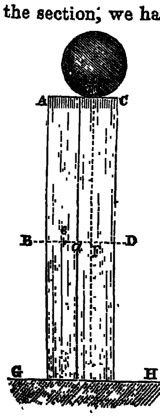

Fig. 2.

46. In particular cases this formula becomes more simple; as, for example, when the distance of the point g from the axis ab is o, that is, when $y=o$,

$$W=\frac{fbd^2}{d\cos a+6l\sin a} \quad (11.)$$

In a column or pillar the section of greatest strain will be at the middle of the length, as at BD in fig. 2; and the direction EF of the straining force is usually parallel to the axis; and then $\sin a=o$, and $\cos a=1$, and therefore,

$$W=\frac{fbd^2}{d+6y} \quad (12.)$$

When the direction of the straining force coincides with the axis, or when $y=o$, the strain on a column or pillar is expressed by the equation $W=fbd$ (13.)

These equations apply also to tensile forces.

When the strain becomes transverse, or when EF is perpendicular to the axis, as in fig. 3, then $\cos a=o$, and $\sin a=1$, hence $W=\frac{fbd^2}{6l}$ . . . (14.)

If the block be supported at the ends, and the load be applied in the middle of the length, as in fig. 4, the fracture will take place at BD; and W in equation (14) will be the pressure on either support, which is obviously half the load in the middle.

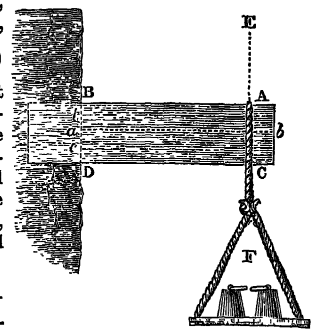

Fig. 3.

47. In any of these equations it is perfectly immaterial how the load be distributed, provided the line of direction be that which passes through the centre of gravity of the mass supported, and the weight be the whole weight of that mass; or, if the strain be the combined effect of several pressures, then the direction must be that of the resultant of these pressures, as determined by the principles of mechanics. (See the article CARPENTRY.)

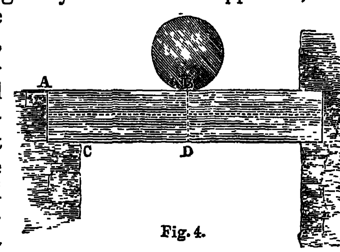

Fig. 4.

48. If a slab of equable thickness and width be supported along two of its sides, as at AC, AB in fig. 5, and it be strained by a force acting at D, in a direction perpendicular to its surface, and DE be made equal to DB, then the fracture will take place in the direction EB; for it may be shown, by the principles of the maxima and minima of quantities, that the resistance, according to that line, is a minimum. And since, in that case, EB $=2$ FD, we shall have, by equation (14), $W=\frac{fd^2}{3}$ . . . (15.)

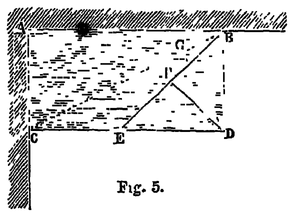

Fig. 5.

A force uniformly diffused over the surface of the slab would fracture it in the direction CB, shown by a dotted line in the figure, and if w be the load in pounds upon a square foot of the surface, then the proper values being substituted for the leverage and breadth in equation (14), $w=\frac{fd^2\left(\overline{CD}^2+\overline{DB}^2\right)}{\overline{CD}^2+\overline{DB}^2}$ . . . (16.)

The strength of a series of steps bearing upon one another, as in the perspective sketch (fig. 6), may be determined with sufficient

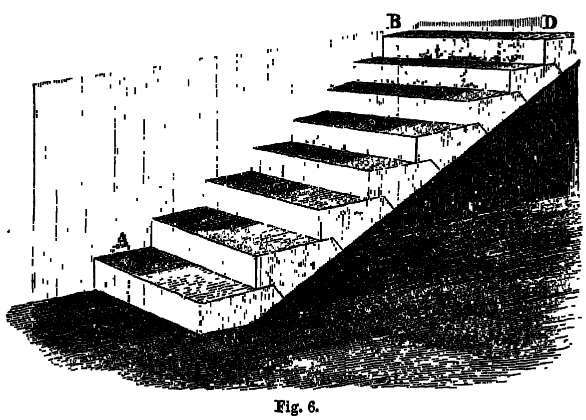

Fig. 6.

accuracy by the last equation, supposing the depth to be the mean vertical depth of any one step; as, for example, taken at GH in fig. 7, the figure showing the ends of the steps.

49. The case to which equation (14) applies, affords the most convenient, as well as the most accurate, means of determining the value of f for any material; and, suppos-

ing it to be one-fourth of the absolute cohesion (§ 34), the last column of the following table of experiments gives its

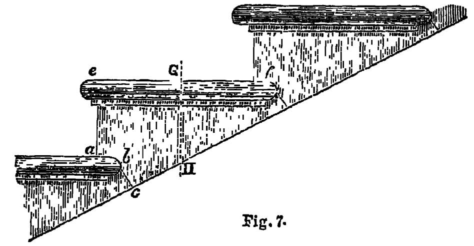

Fig. 7.

value for various stones, mortars, &c., in the nearest simple numbers under the calculated value :—

We have not here availed ourselves of the experiments of Gauthey (Rozier's *Journal de Physique*, tome iv.) on the transverse strength of stones; because those he fixed at one end appear to have been injured in fixing, and only a calculated result is given for the other specimens supported at both ends. As to this, see the article on the Strength of Materials.

50. Several experiments have also been made, with the intention of measuring the direct resistance to extension or compression; but theory indicates so nice an adjustment of the direction of the straining force as necessary in these experiments, that the reader may expect the results to differ as widely amongst themselves as they are found to differ from theoretical calculation.

The experiments, Nos. 3, 4, 5, 6, and 7, are extracted from Rondelet's *L'Art de Bâtir* (tome i. p. 312). Nos. 1 and 2 are by Gauthey (Rozier's *Journal de Physique*, tome iv. p. 414.)

51. In the resistance to actual fracture, from a compressive force, the joint effect of cohesion and friction is concerned, and, therefore, a much greater force is required to crush than to tear asunder the same quantity of material. The resistance to fracture might be investigated on principles analogous to those we intend to employ in determining the pressure of earth against retaining walls, &c. (See the article Carpentry.) But we conceive that it is neither prudent, nor useful, nor necessary, to load the parts of a structure beyond that limit we have made the basis of our investigation. (See § 34.) Rondelet has observed, that the load under which a stone began to split was nearly always two-thirds of that which crushed it; but that stone of some kinds began to split with half the load that crushed it (*L'Art de Bâtir*, iii. 86 et 101). The value of f should, therefore, not exceed one-fourth of the force which splits stone; and, supposing the splitting force to be always half the crushing one, we shall have f = one-eighth of the crushing force.

52. In this, as in the preceding tables, the reader will observe, that the results of all experiments are given in the original weights and measures; but that the value of f and the weight of a cubic foot are in English pounds avoirdupois, and for an English foot. The foreign weights and measures are distinguished by their foreign names.

The experiments, Nos. 1, 21, 22, and 36, were made by Gauthey (Rozier, *Journal de Physique*, tome iv. p. 406). Those numbered 3, 4, 5, 8, 9, 11 to 20, 30, 31, 32, 34, 37, 38, and 39, were made by Mr George Rennie (*Philosophical Transactions* for the year 1818). The others were made by Rondelet (*Traité de l'Art de Bâtir*, tome i. and tome iii.) We have selected those which will be most useful, with others of a more interesting and curious nature; such are Rondelet's experiments on the effect of

beating mortar, the strength and density of ancient mortar, and the resistance of stones used in ancient and in modern structures.

53. It was observed by M. Rondelet, in the course of his very numerous experiments, that it was not the heaviest stones which offered the greatest degree of resistance to compression, but those of a fine even grain and close texture, with a deep colour; that of granites, the most compact and perfectly crystallized was the strongest (*L'Art de Bâtir*, tom. i. 213, 215); and that, when all other qualities were the same, the strength was in proportion to some function of the specific gravity.

The writers who have contributed to our experimental knowledge of the strength of stones are not numerous. The chief are Emerson, in his *Mechanics*, 4to ed., p. 115; Gauthey, in his *Mémoire sur la Charge que peuvent porter les Pierres* in Rozier's *Journal de Physique*, tome iv., 1774, and in his *Construction des Ponts*, tome i., p. 267; Coulomb, in his *Mémoires presentés à l'Académie*, 1773; Rondelet, in his *Traité de l'Art de Bâtir*, tome i. et iii. (the latter volume contains the experiments made by Perronet and Soufflot); Rennie, in the *Philosophical Transactions* for 1818, or *Philosophical Magazine*, vol. liii.; and Tredgold, in the *Philosophical Magazine*, vol. lvi., p. 290.

Actual load put on stone in practice.

54. The last column in each of the three tables of experiments shows the greatest load that we suppose should be borne by a superficial foot of the different kinds of stone contained in those tables. We now propose to give the results of some calculations respecting the extent to which stone has in practice been loaded. The foreign ones are reduced to our own weights and measures, and the whole stated in round numbers.

The pillars of the Gothic church of All-Saints at Angers, of the stone, No. 24, Table III., support on each superficial foot a pressure of 86,000 lb.[1] The pillars of the dome of the Pantheon at Paris, the lower part of which are of Bagneux stone (No. 2151, Table III.), support on each superficial foot 60,000 lb.[2] The pillar in the centre of the chapter-house at Elgin, which is of red sandstone, supports on each superficial foot 40,000 lb.[3] The piers which support the dome of St Paul's in London sustain a pressure on each superficial foot of 39,000 lb.[2] The piers which support the dome of St Peter's at Rome sustain a pressure on each superficial foot of 33,000 lb.[2] The pressure on the key-stone (No. 23, Table III.) of the Bridge of Neuilly has been estimated for each superficial foot at 18,000 lb.[4]

In regard to these examples we have to remark that the calculators of them have considered the pressures as uniformly distributed over the pressed surface; but this can only be true when the direction of the resultant of the straining force coincides with the axis of the pier or pillar; besides, stones cannot be wrought absolutely level, nor bedded in perfect contact. From these circumstances, the strength of piers, columns, pillars, and arch-stones,

Principles of Stability and Strength.

should be estimated by equation (12), and when the line of direction falls within the pier, always making y=half the least dimension of the section, an allowance which will include the effect of the greatest possible inequality of action. We shall, in that case, have

$$\frac{fbd^2}{d+\frac{6d}{2}}=\frac{fbd}{4}=W \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (17.)$$

If the pressure on the Bagneux stone in the piers of the dome of the Pantheon at Paris be estimated by this formula, it will be found that it is sufficient to split the stones, and this has actually happened.[1]

Principles of arches, domes, &c.

55. The chief elements of the theory of arches have already been given in the article BRIDGE (sect. ii.), to which we refer the reader, at the same time expressing a hope that the excellent article referred to will be useful in correcting some absurd notions respecting catenarian and other curves, which are too commonly entertained. The conical support of the lantern of St Paul's is a fine example of an appropriate form, whilst the catenarian dome of the French Pantheon exemplifies a scientific blunder of the first magnitude.[2]

The principles of domes, of groins, and of vaulting of every kind, are the same as those of arches, excepting that each kind has its peculiar manner of distributing the load on the different parts. See prop. M and N, art. BRIDGE.

Of the pressure of Earth, Fluids, &c., against walls.

Pressure of earth against walls.

56. When a high bank of earth, or a fluid, is to be sustained by a wall, as it is often necessary to do in forming bridges, locks, quays, reservoirs, docks, and military works, the construction is very expensive, however economical the means employed may be; hence it is desirable to devote some space to an object of which the importance is manifest.

Let EC, fig. 8, be the line according to which the earth would

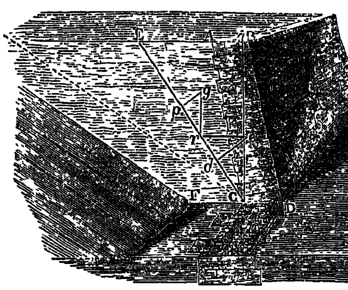

Fig. 8.

separate, if the wall were to yield in a small degree; then AEC will represent the section of the prism of earth, the pressure of which causes the wall to yield.

Put W = the weight of the prism AEC, when its length is unity.
R = the resistance of the wall, when its length is unity.
a = the angle ECa, which the plane of fracture makes with a vertical line.
c = the angle ACa, which the back of the wall makes with a vertical line.
F = the friction of the earth when the pressure is unity.
h = the vertical height of the wall a C in feet.
and S = the weight of a cubic foot of earth, water, or other matter to be supported.

If g be the centre of gravity of the prism of earth, the triangles $r p g$, C a E, being similar, the effort of the prism to slide in the direction EC, reduced for the friction, will be

$$=\frac{W(1-F\tan a)}{\sec a} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18.)$$

This effort is to be opposed by the resistance of the wall, which let us suppose to be collected at c, the centre of pressure, and, reducing to the direction CE, the effect of friction being allowed for, it becomes

$$\frac{R(F+\tan a)}{\sec a} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (19.)$$

Hence, in the case of equilibrium,

$$\frac{W(1-F\tan a)}{\sec a}=\frac{R(F+\tan a)}{\sec a};$$

$$\text{Or, } R=W\left(\frac{1-F\tan a}{F+\tan a}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (20.)$$

57. But, in the case now considered the radius being unity, $W=\frac{h^2S}{2}\left(\tan a-\tan c\right)$ Therefore, R =

$$\frac{h^2S}{2}\left[\frac{(\tan a-\tan c)\times(1-F\tan a)}{F+\tan a}\right] \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (21.)$$

And, from the state of the variable quantities in this equation, it is obvious that it has a maximum value, which determines the angle of fracture. By the principles of maxima and minima, the maximum pressure takes place when

$$\tan a=-F+\left(1+F\tan c+\frac{\tan c}{F}+F^2\right)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (22.)$$

If the angle which the plane of repose (BRIDGE) makes with a vertical plane be denoted by i, then

$$F=\frac{1}{\tan i}\text{; and } \tan a=$$

$$\frac{-1+(\tan c\tan^3 i+\tan^2 i+\tan c\tan i+1)^{\frac{1}{2}}}{\tan i} \quad . \quad . \quad . \quad . \quad . \quad . \quad (23.)$$

If the back of the wall be vertical, $\tan c = o$, and then this equation reduces to the simple form, which Prony obtained, of $\tan a=\tan\frac{1}{2}i$. . . . . (24.)

58. When we substitute in equation (21) the value of the $\tan a$, which has been found in equation (23), it becomes R =

$$\frac{h^2S}{2\tan i}\left\{\tan i+\tan c+\frac{2}{\tan i} - 2\left(\tan c\tan i+\frac{\tan c+1}{\tan i}+1\right)^{\frac{1}{2}}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25.)$$

And when the back of the wall is vertical, it becomes

$$R=\frac{h^2S}{2}(\tan^2\tfrac{1}{2}i). \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26.)$$

The $\tan i$ being the co-tangent of the angle of repose, if the matter to be supported be of so fluid a nature that it naturally assumes a sensibly level surface when at rest, the $\tan\frac{1}{2}i$ becomes equal to unity, and consequently,

$$R=\frac{h^2S}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27.)$$

The same result may be obtained from the common principles of hydrostatics in the case of fluids.

Since the only variable quantity which enters into the calculation of the distance of the centre of pressure is the height h, whatever the nature of the supported material may be; therefore that distance counted from the base will always be $\frac{1}{3}h$, as in the pressure of fluids.

59. TABLE IV.—*Table of Constant Quantities necessary for calculating the Pressure of some Materials.*

Substance.	Angle of Repose.	Weight of a Cubic Foot = S	Value of R in Equation (26).	Value of R in Equa. (25) when $c=10°$.
Water...............	0°	62·5 lb.	$R=31\frac{1}{4}h^2$	$R=31\frac{1}{4}h^2$
Fine dry sand ...	33°	92 „	$R=13{\cdot}8h^2$	$R=4{\cdot}8h^2$
Do. moist	...	119 „	$R=17{\cdot}85h^2$	$R=6{\cdot}2h^2$
Quartz sand (dry)	35°	102 „	$R=13{\cdot}77h^2$	$R=4{\cdot}64h^2$

In sand, clay, and earthy bodies, the natural slopes should be taken when the material is dry, and the clay and earth pulverised. When any of these bodies are in a moist state, the parts cohere, and the angle of repose is greater, though the friction be actually less. The preceding table shows that the pressure of water is greater than that of any of the other kinds of matter, and from the nature of fluids it is evident, that if water be suffered to collect behind a retaining wall, calculated to sustain common earth only, it will

[1] Gauthey, *Construction des Ponts*, tom. i., p. 273.

[2] La charge considérable que cette voûte devait porter à son sommet, a déterminé à choisir pour la courbe de son ceintre *la chainette*. *Traité l'Art de bâtir*, ii. 308.)

Principles of Stability and Strength.

most likely be overturned. Such accidents may be prevented by making proper drains.

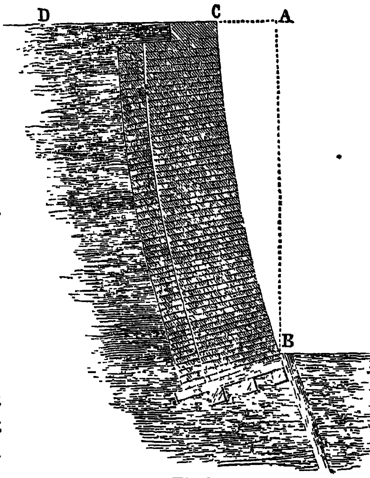

Fig. 9.

60. The preceding analysis will apply, without sensible error to the curved walls which have lately become fashionable. Fig. 9 is a section of one of these walls, as executed from a design by Rennie. The vertical height, AB, 21 feet; the wall of uniform thickness, with counterforts 15 feet apart; and the front of the walls described by a 69 feet radius, with the centre in the horizontal line DA produced. The wall is built of brick, and the uniform part is 4·5 feet thick. The radius is usually thrice the vertical height of the wall; when this proportion is adhered to, the angle c will be ten degrees, for which the value of R is calculated in the table.

Resistance of Walls.

Resistance of walls.

61. In the first place, we propose to investigate the resistance a wall offers to being overturned; and, in so doing, it appears desirable that the resistance of the mortar in the joints should be considered one of the elements of the strength of the wall. Good mortar adds much to the firmness of walls, aud still more to their durability, and, all things considered, its first cost is less than that of bad; besides, the resistance of mortar to compression must be considered, for, in practice, we have no perfectly hard arrises to fulfil the conditions of common mechanical hypotheses.

Put A = the area of the wall.

w = the weight of a cubic foot of masonry.

y = the horizontal distance, $g\,a$, between the vertical passing through the centre of gravity of the wall, and the point where the axis cuts the plane of fracture, the same notation being applied to the other quantities as in the foregoing equations.

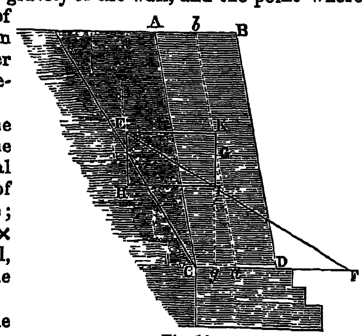

Fig. 10.

Let G, fig. 10, be the centre of gravity of the wall; and on the vertical Gg set off gI, the height of the centre of pressure; also, let IK represent $A \times w$ = the weight of the wall, and HI the force R of the earth.

Then, completing the parallelogram, EI will represent the direction and intensity of the straining force; consequently, $\frac{R}{Aw} = \tan a$ . . . . (28.)

Which determines its direction, and its intensity is

$$W = \frac{Aw}{\cos a} \quad \ldots \ldots \ldots \quad (29.)$$

But, we have found,

$W = \frac{fbd^2}{d\cos a + 6l\sin a + 6y\cos a}$; and as $W = \frac{Aw}{\cos a}$ (equa. (29.)); $\tan a = \frac{R}{Aw}$; equa. (28.); $l = \frac{1}{3}h$, art. 51; and b = unity; the equation reduces to $fd^2 - Adw - 6\,Awy = 2Rh$. . . . . (30.)

If the section of the wall be a parallelogram, then $A = hd$, and $-\frac{1}{2}h\tan c = y$; these values of A and y being substituted in equa. (30), it becomes $-whd^2+fd^2+3h^2wd\tan c = 2Rh$. . . . (31.)

Principles of Stability and Strength.

$$\text{Or, } d = \frac{h^2w}{f-hw}\left(\frac{-3\tan c}{2}+\sqrt{\frac{2R(f-hw)}{h^3w^2}+\frac{9\tan^2 c}{4}}\right) \quad \ldots \quad (32.)$$

When the section of the wall is a rectangle $y = o$, therefore equa. (31) reduces to

$$d = \sqrt{\frac{2Rh}{f-hw}} \quad \ldots \quad (33.)$$

This last equation is also correct for a wall of which the back is vertical, and the front sloping. We suppress the investigation, to afford the young student an opportunity of proving that the diminution of weight is exactly counterbalanced by the alteration of the distance of the centre of gravity from the axis.

The tendency of a wall to slide forward may be easily prevented, by giving an inclination to the joints.

62. To illustrate these rules we shall give two examples, and in these show the construction of a table, which the reader may enlarge at his pleasure.

Example I. Let it be required to determine the thickness of a rectangular wall for supporting the front of a wharf 10 feet in height, the earth being a loose sand, and the wall to be built of brick.

The weight of a cubic foot of brick-work may be estimated at 100 lbs., and the resistance of mortar being valued at 5000 lbs. *per* superficial foot, the experimental value being 7900 lbs., Table III., Experiment 42, and the difference an allowance for any irregularity in building, consequently, $f = 5000$; $w = 100$; and by Table IV., $R = 13{\cdot}8h^2$; hence equa.

(33), $d = \sqrt{\frac{2Rh}{f-hw}} = \sqrt{\frac{2 \times 13{\cdot}8 \times h^3}{5000-100h}} = \sqrt{\frac{h^3}{181-3{\cdot}62h}}$. When $h = 10$ feet, then the thickness of the wall $d = 2\,644$ feet. If h be made successively 10, 20, 30, 40, &c., feet, the numbers under the head of dry sand in the following table will be obtained, observing that they are only calculated to the nearest tenth of a foot.

The proper thickness being found for supporting one kind of material, that for any other may be easily determined; as the thickness varies as the square root of R, equa. (33). Let the thickness for dry sand be d, then

$\sqrt{13{\cdot}8} : \sqrt{31{\cdot}25} :: d : 1{\cdot}5d$ the thickness for supporting water.
$\sqrt{13{\cdot}8} : \sqrt{17{\cdot}85} :: d\ 1{\cdot}14d$ the thickness for supporting moist sand.

In this manner, by means of Table IV. the thicknesses for other kinds are easily calculated.

Example II. If a retaining wall be intended to support a sandy and loose kind of earth, to be constructed of brick, and to be inclined 10 degrees from the vertical, the thickness being uniform; it is required to determine that thickness for any given height.

By equa. (32), $d = \frac{h^2w}{f-hw}\left(-\frac{3\tan c}{2}+\sqrt{\frac{2R(f-hw)}{h^3w^2}+\left(\frac{3\tan c.}{2}\right)^2}\right)$ and as $c = 10°$, $\tan c = {\cdot}18$, hence $\frac{3\tan c.}{2} = {\cdot}27$, and its square $= {\cdot}0729$. Also $f = 5000$, and $w = 100$, consequently, $d = \frac{h^2}{50-h}$

$$\left(-{\cdot}27+\sqrt{\frac{2R({\cdot}5-{\cdot}01h)}{h^3}+{\cdot}0729}\right)$$

For sandy earth $R = 4{\cdot}8h^2$, therefore $d = \frac{h^2}{50-h}$

$\left(-{\cdot}27+\sqrt{\frac{4{\cdot}8}{h}-{\cdot}0113}\right)$; and making h successively 10, 20, &c., feet, the numbers obtained will be the same within one-tenth of a foot, as those in the following Table, column fifth, in which the thickness of leaning and curved walls for supporting dry sand is shown, at an inclination of 10 degrees.

Foundations.

63. TABLE V.—*A Table of the Thicknesses for Retaining Walls, Revetments, Dock-walls, &c.*

Height of Wall.	Thickness of Rectangular Walls to support.			Thickness of Leaning and Curved Walls for supporting Dry Sand, the angle of inclination being 10°.
	Water.	Dry Sand.	Moist Sand.	
10 feet	4·0 feet	2·7 feet	3·1 feet	1·1 feet
20	12·9	8·6	9·8	2·8
30	29·2	19·4	22·2	5·2
40	62·5	41·7	47·5	9·2

Our investigation informs us that the mortar of high walls must be of a superior strength; indeed, we know that when its consolidation takes place, under considerable pressure, it is of much greater strength. According to what function of the pressure the strength increases, we have not experiments to determine, and we therefore point out the circumstance to the notice of experimental inquirers.

Construction of walls.

For further particulars as to construction of walls, particularly of railway embankments, see article CONSTRUCTION.

64. The proper quantity of mortar to be employed in stone-work is another point to which it will be useful to direct the mason's attention. A stone cannot be very firmly bedded upon a very thin layer of mortar; and if the stone be of an absorbent nature, the mortar will dry too rapidly to acquire any tolerable degree of hardness (Vitruvius, lib. ii., cap. viii.), however well it may have been prepared. On the other hand, if the bed of mortar be thicker than is necessary to bed the stone firmly, the work will be a long time in settling, and will never be perfectly stable.

When the internal part of a wall is built with fragments of stone, they should be closely packed together, so as to require as little mortar as possible. Walls are often bulged by the hydrostatic pressure of mortar, when it is too plentifully thrown into the interior, to save the labour of filling the spaces with stones.

The walls of houses are frequently built with hewn stone on the outside, and rubble stone on the inside. The settlement of these two kinds of stone-work during the setting of the mortar are so different, that the walls often separate; or where this separation is prevented by bond stones, the wall bulges outwards, and bears unequally on its base. These evils are best prevented by using as little mortar as possible in the joints of the interior part of the wall, and not raising the wall to a great height at one time.

III.—OF FOUNDATIONS.

On Land.

Foundations.

65. Having considered the nature of the materials to be used, and the scientific principles on which we should proceed in their disposition, we must turn to practical results, and first consider the foundations, or the base, upon which these superstructures are to be placed, so as to stand safely. When a good hard soil is easily accessible, as solid gravel, chalk, or rock, we have nothing to do but to excavate the surface mould to the sound bottom, and to build at once, first putting in the footings, which are one or more courses, forming a sort of steps, each a little wider than the other, and the wall that stands on them (see BUILDING, Pl. 147, fig. 5), according to the judgment of the architect. On hard ground one course of masonry, about half as wide again as the superincumbent wall, is ample. On softer ground it was usual to employ footings at least double the width of the wall, and frequently more; but since the invention, or rather revival, of the use of concrete, this is seldom or never done. In this case, or when the ground is a deep clay, be the material used what it may, it should at least go so deep as not to be affected by change of temperature, or the rising and falling of springs, as the alternate shrinking and swelling of the ground must affect the building. As has been shown (article CLIMATE, p. 768), frost seldom penetrates a foot into the ground in this country; but in clay soils, fissures, the consequences of drought, are found three feet and more in depth. The basis should, therefore, be below this point in such a stratum. If the ground be springy, it should be drained, if possible; if not, a foundation should be made with concrete as low as the lowest level of the water; or if very deep or boggy, piles must be used. The plan of building on sleepers and planking, so common a few years ago, is very bad, as they soon rot, and the building settles in all directions, as the greater weights crush the decayed timbers sooner than the lighter portions of the building. Where ground is alternately wet and dry, the best timber soon decays; even piles should always be wholly below the water.

Footings. Depth of footings.

Definition of concrete.

66. The use of concrete, except in very peculiar occasions, has entirely superseded every other artificial foundation. It may be defined as a sort of rough masonry, composed of broken pieces of stone or gravel, not laid by hand, but thrown at random into the trenches, cemented together with lime prepared in various ways, and thoroughly mixed with it before it is so thrown in. In this country, the lime is generally ground and mixed, when hot, with the stones; in France, the lime is first made into a paste, and the mixture is then called *bêton*, not concrete.

History of concrete.

67. The use of this material is of very remote antiquity. It is no doubt the *signinum opus* of Vitruvius, and is described by Alberti. It is very common in mediæval buildings, walls and even arches frequently being made of it. In Rochester castle the staircases are composed of it; the under sides, or soffites, show to this day the marks of the boards which sustained it till it was set. Smeaton states that he was induced to employ it from the observation of the ruins of Corfe castle. Dance employed a sort of concrete in rebuilding Newgate, 1770-1778. The foundation of part of the new structure was a deep bog, and it was rendered available by shooting a quantity of broken bricks into the holes, mixed with occasional loads of mortar, in the proportions of four to one, and suffering them to find their bed.

Materials of concrete.

68. Any hard substance, broken into small pieces, will make good concrete. That most used is gravel, or ballast. This should not be sifted too fine, as the sand which is left will mix with the lime, and form a sort of mortar, and assist to cement the stones together (see I., sec. 29). If broken stones, or masons' chips, are used, it is well to mix some sharp sand with them. The general rule is, that no piece should exceed a hen's egg in size. In this country the lime is generally ground, and used hot. It is mixed with the ballast by scattering it among the stones, and turning them over with a shovel, water being at the same time thrown upon the mass. It is then immediately filled into the trenches, sometimes by shooting from stages erected for the purpose, six or eight feet above the work. But this process has been very justly censured as uncertain by eminent engineers, who prefer to put it in layers of not more than 1 foot in thickness, and to level each course, and ram it down thoroughly. About one-sixth part of lime is generally used. When too hastily put into the trenches, the lime, which has not had time thoroughly to be slacked, will continue to do so, and the mass will puff or swell, and sometimes cause considerable mischief. The author has seen the wing walls of bridges thrust out by this means. From some experiments made by the Architectural Publication Society, where the materials were carefully mixed, no change took place in the bulk. The lime, if it can be procured, should be hydraulic; and concrete is much improved by the addition of the volcanic sands. The French authors recommend, as good proportions, one-fifth hydraulic lime, one-fourth pozzolano, one-eighth sharp sand, and the rest

Laying concrete. Swelling of concrete.

broken stone or gravel; or 20 per cent. hydraulic lime, the same of terrass, the same of sharp sand, 15 per cent. of gravel, and 25 per cent. of broken stone. Perhaps, after all, the very best concrete is made of a simple mixture of gravel with Portland cement.

Foundations in Water—Ancient Systems.

Loose stones shot in.

69. These are often made by shooting quantities of loose rough stones, &c., into water, at hazard, till the mass finds its own bottom, and becomes solid by degrees. When a sufficient quantity has been shot, so as to appear above the surface, the material is levelled, and the superstructure erected upon it. Most of the *break-waters* (see Art.) have been thus constructed. This method is called by the French, foundations *à pierre perdue* (see BREAKWATER, HARBOUR, &c.) Concrete has been used in the same way with great success. Where it is practicable, it is very desirable first to bring the bottom to a level by *dredging*. (See NAVIGATION, INLAND, p. 68.)

Piling.

70. Another method is to drive a number of piles, side by side, through the mud or other soft soil till they reach a sound bottom, the heads are then cut off to a level, and a platform of timber, or better still, of flat stones, is laid on them, and the superstructure erected. The heads of the piles should always be under water. For small operations they may be driven without dams; but for larger a more elaborate system must be pursued, the most effectual of which are coffer-dams.

Coffer-dams.

71. These are of as great antiquity as the time of Vitruvius, and most probably much older. That author, however (lib. 5, cap. *ult.*), describes the method of forming them, and calls them *arcæ*. Like those of later times, they were composed of two parallel rows of piles driven into the water, and kept together by strong horizontal timbers, and continued around the place where the proposed work is to be erected, so as to form a sort of box or coffer entirely round it. The two rows are kept in their places by other timbers, and the vacant space between such double row stuffed full of clay and weeds, till the whole is quite tight, the water is then pumped out by proper engines till the ground appears, which is then levelled and excavated to a solid stratum, if such is readily accessible. The foundations of the pier, &c., are then laid, and the superstructure carried up to above the water-level, when the dam is removed. If solid ground is not easily accessible, structural piling is resorted to. In large works these are of whole timber, pointed at the end, and shod with iron, to facilitate their penetrating the earth.

Pile-engine.

They are driven by a weight called a monkey, which is raised by a machine called a pile-engine, worked by horse or other power, now frequently by steam. When the monkey is raised to a sufficient height, it is suddenly liberated by a contrivance much like a double pair of scissors, and falls with great impetus on the head of the pile, and of course forces it downward into the bed of the stream. When driven to a proper depth, the heads are cut off to a level line, cross timbers are bolted on these, and the superstructure erected, as shown in BRIDGE (Plate CXLV. fig. 3.) The piles of the dam should not be drawn, as that would allow the water to form holes, and to work under the foundations, but they should be cut off close to the bottom of the stream. Fig. 11 shows a plan of the coffer-dam and pier of a bridge erected by Rennie on the Thames. The outer lines are the parallel piles which keep out the water, and form the coffer; these, as will be seen, are strongly bolted together, both across and lengthwise, and also braced diagonally. The general plan is elliptical, the better to resist the pressure of the water,—a course afterwards adopted in the coffer-dams of London Bridge. The plan of the pier is within this, and is shown in four quarters:—A shows the plan of the great piles, driven down to the solid; B shows the heads of the same piles, when cut off and tied together by strong cross timbers; C shows the planking laid thereon; and D the first courses of the masonry.

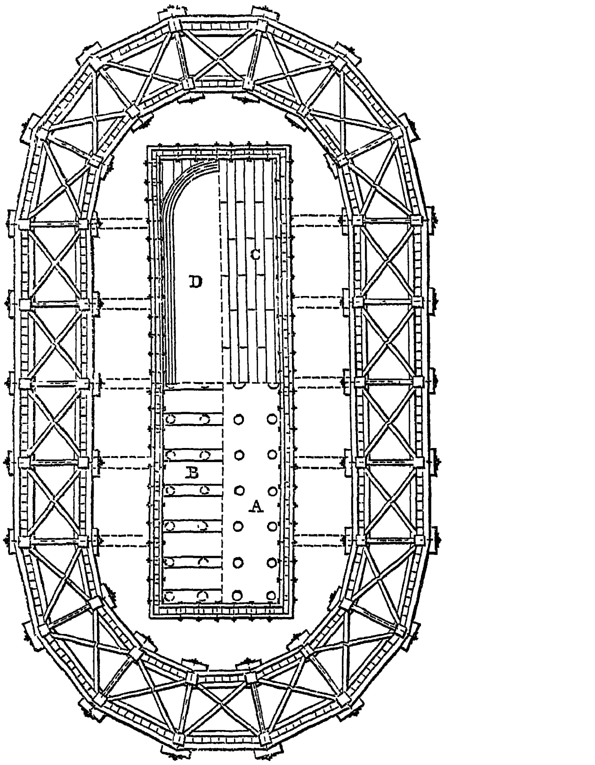

Fig. 11.

Caissons.

72. As the system above described is extremely expensive, especially before the introduction of steam-power for pumping, &c., a very ingenious method was introduced into this country by a Swiss named Labelye, and first used at Westminster Bridge. The bed of the stream was first carefully levelled by dredging. (See NAVIGATION, INLAND, page 68.) Strong frames of timber were then constructed, having upright sides like those of a box, and being about the same area as a coffer-dam. These were floated over the place where the piers were to be built, and the masonry of each pier commenced inside these large cases (the word caisson meaning a large box or *caisse*). It was, in fact, like building in the bottom of a large flat-bottomed barge. Of course, as the weight increased this barge or caisson would gradually sink. The sides were somewhat deeper than the river, and well caulked and pitched to keep the water out and enable the men to work. When the first course of stone was laid and cramped together, the water was let into the caisson by sluices, and the whole sunk to the bottom. It being found this was not sufficiently level, the sluices were closed, the water pumped out, when the whole floated again, and the bottom was again dredged and levelled. This operation was performed three times before the work settled to a level bed. The pier was then built up to a height above water-level, when the sides of the caisson were removed, and used again for the next pier. Blackfriars Bridge was afterwards built on the same plan, but in consequence of the removal of old London Bridge, the scour of the river increased so much as to work under the piers; these directly began to settle in all ways, and the bridges must both be rebuilt. The system of caissons might, perhaps, nevertheless, be used in still waters, but it is manifestly improper for a sharp current, and still worse for a tidal river.

Foundations.

Foundations in Water—Modern Systems.

New systems.

73. The great advance in all objects of engineering, and the desire to avoid expense, has led to some very ingenious and novel systems of laying foundations in water.

Diving-dress.

74. The first of these is chiefly owing to the invention of the diving dress. (See DIVING, vol. viii., Plate CCV.) This has now been brought to such perfection, that excavating, levelling the bottom, setting large blocks of stones, cutting off the heads of piles, in fact, all engineering operations are effected under water almost as easily as on land; the men, in fact, working in a large bag filled with air. The most extraordinary work of this kind is now being carried on at Dover, where a huge mole projects into the ocean, of an extent and construction that exceeds any thing yet achieved. Our limits prevent our giving a full account of this work. It must suffice to say, that the outsides of the pier are composed of two parallel walls, built with large blocks of granite, which are sunk into the solid chalk partly by dredging and partly by excavation. A number of piles[1] are driven into the sea, on the tops of which are strong cross-sleepers, each traversed by a series of iron rails, on which a number of travelling cranes move in all directions. These convey the stones exactly over their intended beds, on to which they are lowered, according to signals given by the divers below, who then cramp them together as well as they can. Between these two outer walls is a filling-in, composed of immense blocks of concrete, made of the ballast from the beach and Portland cement. These blocks are cast, as it were, in wooden boxes, the sides of which are removed when the concrete is set. Pieces of rope or chain are cast within the body of the block, and by them they are raised and lowered just as if they were masses of stone. The pier, therefore, is composed of concrete faced with granite; and the work stands extremely well.

Dover harbour.

Iron piles.

75. The next important change in building in the water is the substitution of iron piles for those of timber. Their success emboldened engineers, and from small piles, driven in the usual way, large cast-iron cylinders came into use. These vary, according to the nature of the work, from 3 or 4, to 6 or 7 feet in diameter. They are first lowered into the water in a vertical position, and driven down as far as they will go without much difficulty. A quantity of clay is then thrown in round the outside of each, to keep the water from coming in under the bottom as little as possible. That inside is then pumped out, and workmen descend and excavate the bottom, sending up the stuff in buckets, just as a well is excavated. The cylinder then sinks partly by its own weight, and partly from weights above, as the earth is excavated beneath to the depths required; each cylinder has a series of flanches, on which another is screwed from time to time as the former sinks into the bottom. When the cylinders are sunk to a proper depth, they are brought to a level at the top, and a platform of girders and planking is fixed for permanent use. In many instances the cylinders have been filled in solid with concrete after they have been thus submerged.

Cylinders.

Rochester new bridge

76. The most extraordinary operation of this kind has, however, just been executed in the piers of the new bridge at Rochester. The ground here was very difficult to work, being composed partly of rag rock and partly of very hard chalk, and it was found almost impracticable to sink the piles in the manner last described, which is successful enough in clay. To overcome this difficulty the following plan was devised:—a proper stage of piles, sleepers, &c., was first erected, and a number of cast-iron cylinders, each 9 feet long and 7 feet in diameter were bolted together in proper lengths. As it was necessary to employ diving-bells to dredge the bottom, it was considered that each cylinder might easily be converted into a sort of bell by putting on it an air-tight cap. This was done, and an ingenious method contrived by which the men could pass in and out of the cylinder without admitting the air. It would exceed our limits to go into all the details of this invention, which was called an air-lock, probably from its permitting or hindering the passage of air, much as the lock-gates on a canal do with that of water. But there was this great difference between the method described in [sec. 75] and this new method. In the former the water was pumped *out* of the cylinder, but in this air was forced *into* the cylinder below the air-tight cap and locks, and the water *driven out* by its pressure. The men then entered through the air-locks, and excavated the ground under the cylinder, which descended by its being heavily weighted above. As each cylinder sunk, the cap was removed and another cylinder screwed on, so that some of the piles (as in fact they may be called), consisted of seven pieces, and measured over 60 feet in length, one half of which was buried in the bed of the river. The girders, tying the heads together on the top, as well as the skew-backs, &c., from whence the arches spring, were then fixed in the usual way. (See IRON BRIDGES.)

Screw-piles.

77. A still more curious method of employing iron piles is the invention of Mr Mitchell, and succeeds admirably in soft ground and even in sands. These are hollow, and of wrought-iron, varying in diameter from 5 or 6 inches to about a foot. They terminate at the end with screws of various shapes (see figs. 12, 13, and 14), and are screwed into the bed of the river or the bottom of the sea, as the case may be, to such a depth as to hold the pile firm, their heads are then connected together with sleepers, &c., and the intended superstructure erected. The lighthouse on the Chapman Sand, in the mouth of the River Thames, is built on piles 7 inches in diameter and about 40 feet long, the screw part is of cast-iron about 4 feet in diameter. They are screwed down till only 2 or 3 feet remain above the sand; on their heads are cast-iron cylinders, braces, &c., which support the lighthouse, which is entirely of wrought-iron. The piles are only seven in number; one driven in the centre, and the others at equal distances around it.

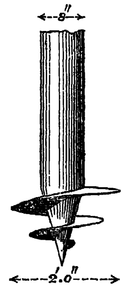

Fig. 12.

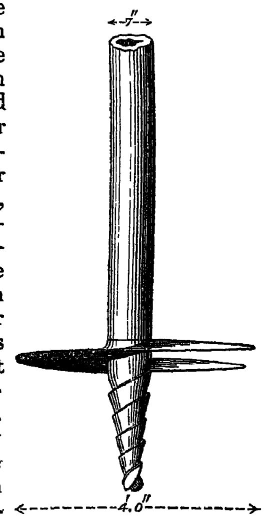

Fig. 13.

Iron coffer-dams.

78. Several very ingenious adaptations of iron for coffer-dams have been tried with success in various places; they are all, however, more or less expensive, not only in construction and removal, but because they entail constant expenses in pumping.

Westminster new bridge.

79. The method lately invented by Mr Page for getting in the piers of the new bridge now in course of erection at Westminster is, however, so novel and so important, we feel our work would not be complete without a short description of it. Figs. 15, 16, and 17 show the plan, the long and cross-sections of half each pier. Rows of

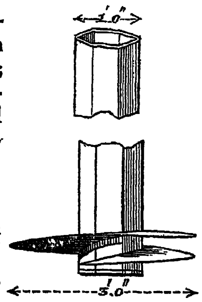

Fig. 14.

[1] These piles form a scaffold, and are removed when the work is done.

Foundations.

strong elm piles, AA,[1] about 30 feet long, are driven into the bed of the river, as shown in the plan, passing first through the gravel, which is about 4 or 5 feet thick, and then going about 20 feet into the London clay. There are about 140 or 150 piles to each pier, ranged alternately in threes and fives, around these a range of cast-iron piles

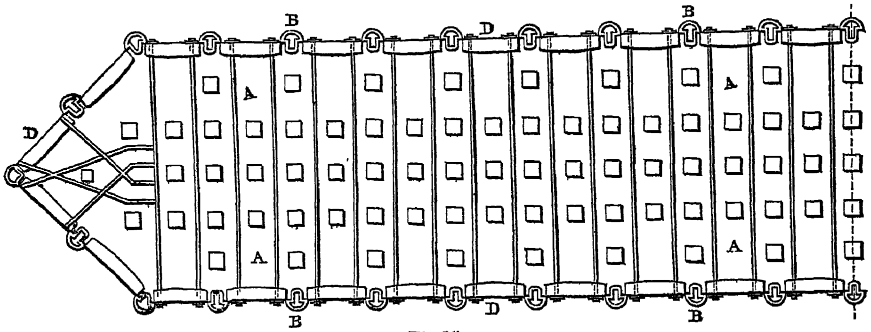

Fig. 15.

BB, are driven about 4 feet apart, as shown in the figure. These are round, 15 inches in diameter, and have strong grooves cast on each side of them. They, however, go into the clay only 10 or 12 feet. Into these grooves large plates of iron, which the engineer calls "plate-piles," are fitted and driven down between the piles, BB. They are marked CC on the cross-section (fig. 16), and, as will be seen, go about 10 feet into the blue clay, and extend to about a

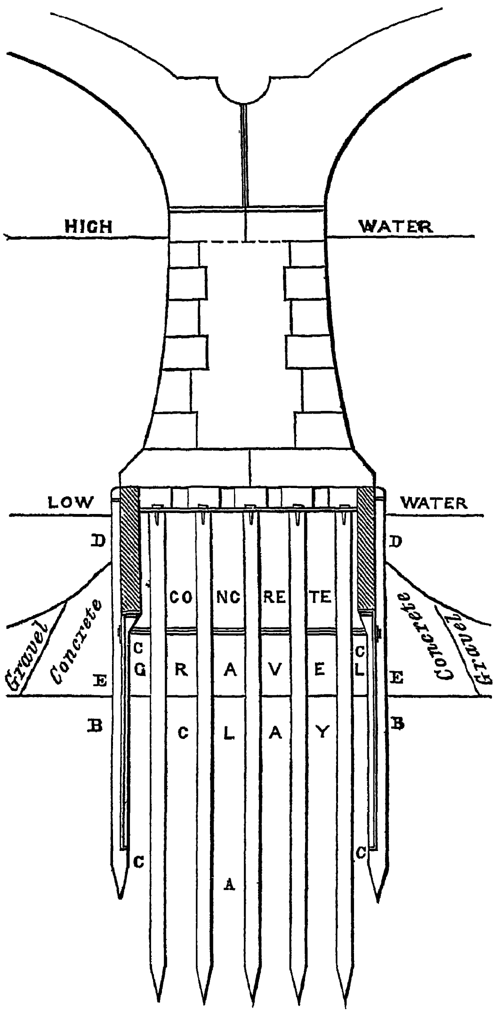

Fig. 16.

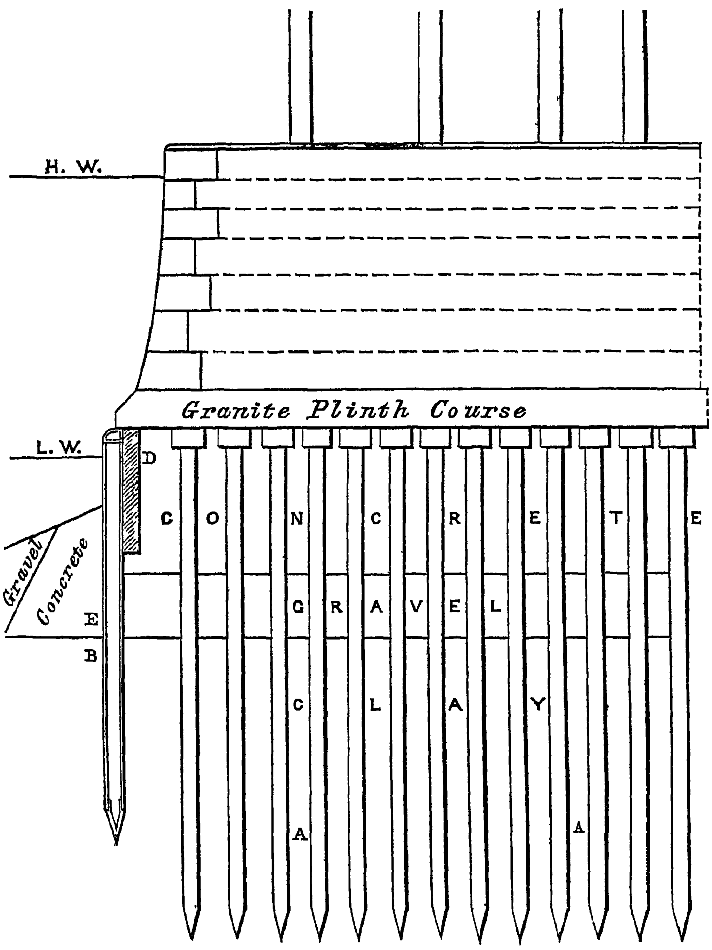

Fig. 17.

foot or two above the natural bed of gravel. Upon these are a series of slabs of granite, DD, placed edgewise, retained in their places thus,—The bottom rests on the "plate-pile," CC, the edges are secured to the round iron-pile A, and the tops to the other masonry. The plate-piles are secured together by two sets of ranges of iron-rods passing through the pier and tying them together. These are all fixed by the divers. It will be seen, therefore, a sort of case or box is made which surrounds the wooden piles AA on all sides. The loose sand and mud

[1] The same letters apply to all three figures.

Stone-Cutting.

is then dredged out, and the case filled up solid with hydraulic concrete, in which, of course, the piles are embedded, and the whole forms one solid mass to about a foot above low water-mark. At this level the tops of the piles are cut off, and on each top a stone 2 feet square and 1·6 thick is bedded, the spaces between which are again filled in solid with concrete. The gravel is then dredged out around the pier on the outside of the case, and the space also filled with concrete, as shown at EE. It has been urged that the steamers will come into collison with the round piles, BB, and break them, so that the granite slabs, DD, will escape, as it were, and fall into the river. This, however, cannot be as long as the concrete E remains in its place, as the top of the slab D is secured by the masonry, and the bottom would not be accessible. It is, however, intended to protect the piles by floating booms, which would prevent the chance of collison, and would act as safeguards for the steamers as well as the bridge.

For the action of waves, running water, &c., on walls, piers, &c., see HARBOUR.

IV.—STONE-CUTTING.

Previous descriptions.

80. The different methods of reducing stones to shape by the axe or scabbling-hammer, the saw, or the tool; of dressing by the chisel or point; the nature and value of plain work, sunk work, moulded work, and beds and joints; the various sorts of bond, and of rubble, coursed, or ashlar, with their proper backings and quoin-stones; the mortar, and such methods of working and setting the beds of stones, that the faces may not chip or flush; the mode of securing and strengthening work, by discharging and relieving arches; by hoop-iron bond, cramps, dowels, joggles, plugs, &c.; the descriptions of copings, cornices, string-courses, blocking-courses, sills, landings, balconies, paving, curbs, steps, hearths, chimney-pieces, &c.; and of columns, with their beds, joggles, flutes, &c.; in short, all that relates to the mechanical part of stone-cutting, has been already given, article BUILDING, pages 737 to 741, to which we refer our readers.

Moulds, and to find the lines for.

81. Before working the various pieces of stone, it is necessary to prepare certain moulds, which are generally of thin metal, wood, mill-board, or some similar substances, of the exact form with which each face of the stone is to be worked; and which are applied to the sides of the stone, and their shapes marked or "scribed" thereon. They serve the double purpose of guiding the workmen, and of enabling him to select pieces of stones of convenient sizes, so that there should be as little waste and labour thereon as may be. We shall now proceed to show how to find these lines, the most important thing a mason can learn.

Making working drawings.

82. The general principles of the making working drawings; the projection of lines, of planes, and of curved surfaces; the finding the angles of planes inclined to one another; the describing mouldings, and the methods of finding the lines where they mitre, on the level or on the rake; in short, all the general principles of projection are given in JOINERY, sect. I., 1 to 20.

Arches, to Describe.

Lines for arches.

83. But as arches form no part of joiners' work, and as our articles ARCH, ARCHITECTURE, BRIDGE, &c., though containing full scientific developments on the subject, necessarily involve the highest branches of pure mathematics, we shall refer the readers of abstract science to these articles, and shall proceed to give a few problems in descriptive geometry for the use of masons, as we have done before for joiners.

84. First, of circular arches. These, if of moderate size, may be set out by a long lath, one brad awl as a centre, and another to trace, or by beam compasses; but if they are flat, the centre is frequently at such a distance as to render this inconvenient, if not impossible. The best way

Circular arches, to draw.

Flat arches.

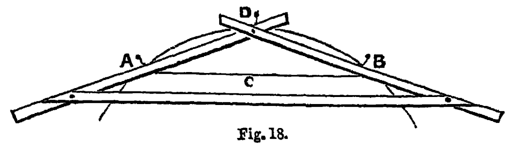

Fig. 18.

to proceed, far better than most of the cyclographs, is thus:—Let AB (fig. 18), be the width of the arch, and CD its height; set out their width and height on a floor, or on some boards joined together for the purpose; drive pins at A and B. Take two straight rods AD, DB, place them so that their sides may touch A and B, and their intersection coincide with D. Tack them together, and also a third lath across, to keep them at the same angle; place a pencil at D, which will trace the curve if the rods are moved to the right and left, and are kept pressed against the pins A and B.

85. Another way (fig. 19), let the letters represent the same): join AD, draw DE parallel to AB, and make DE equal to AD, then cut out a triangle in wood, or form one as above with three laths; put a pin into the board at D, and a pencil at the same point of the triangle, and it will trace half the curve AD; reverse it, and it will trace the other half DB.

Another way.

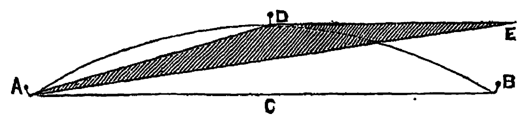

Fig. 19.

86. Next to circular forms, the most common are those from the sections of a cone, of which the most usual is the ellipse; the parabola is sometimes used, and so is the hyperbola, but very seldom. As these forms are necessary in setting out Grecian mouldings, as well as in almost all problems in masonry, it is proposed to treat of all three as shortly as possible.

Arches from conic sections.

87. Let ABC (fig. 20) be the section of a cone, or one cut through its axis downwards to its base, and ABD be half the plan of its base. If the cone be cut by a plane passing through EF, in other words, if it was cut into two parts by

The ellipsis.

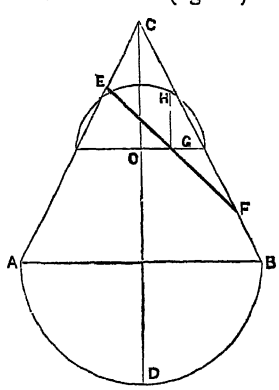

Fig. 20.

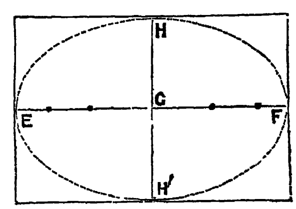

Fig. 21.

a large flat knife passing in that direction, but wholly above the base, its section would be an ellipse. Then EF would be its length, or axis-major. To find its height or axis-minor, bisect EF in G, through G draw a line parallel to AB, touching the sides of the cone; bisect this in O, and on it describe the semicircle as shown; then draw GH parallel to the axis of the cone CD, and this line GH will be the half the height, or the semi axis-minor, and the ellipse will be described within the parallelogram EF, HH' (fig. 21).

Stone-Cutting.

Various ways of describing the ellipsis.

88. This may be done, first, by finding the foci,[1] and describing the ellipsis by a cord or string, thus:—Take the distance FG (fig. 22) in your compasses, and from H as a centre strike the portion of a circle 1, 2, 3, then 1 and 3, where it cuts EF, are the foci. Stick two pins, or brad awls, in their points, and strain a string round H, 1 and 3; place a pencil at H, and move it round, keeping the string tight. The pencil will draw the ellipse, Or it may be done by a trammel. (See vol. viii., Plate CCXXXI. fig. 1; and see article ELLIPTOGRAPH.)

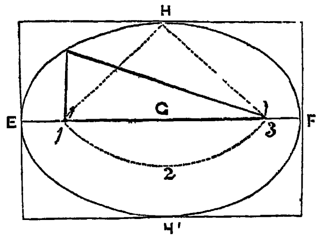

Fig. 22.

To describe an ellipsis by ordinates.

89. Let the parallelogram be, as before (fig. 23). Divide EG, E 4, each into any number of equal parts; here they are divided into 4; from HH' draw lines through 1, 2, 3, as shown, and where they intersect are points in an ellipsis; mark these points, bend a thin lath round them, and strike the curve. The same repeated for the other quarters will complete the ellipse. These methods are mathematically true; but as it is difficult to get laths to bend round a large curve, and very difficult to tie a string exactly to the proper length; and also to prevent its stretching when tied, other means have been taken as approximations.

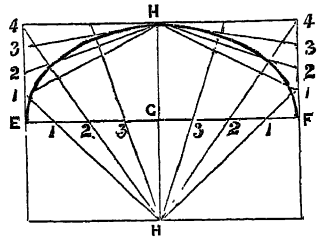

Fig. 23.

To describe an ellipsis by compasses.

90. It is of the utmost importance to the mason, whether in Gothic or other work, to remember, that in all cases where two circles touch each other, the two centres from which they each are struck, and the point in which they touch, must lie in the same straight line; in other words, a line drawn from one centre to the other must pass through the point of contact, a point where they each touch without cutting each other. If this rule be not strictly attended to, any curve coming out of another will not flow freely, but must be crippled. If we attempt to draw an ellipse with the compasses, we must strictly attend to that rule. Now, if we take a diagram similar to fig. 23, but instead of four parts, we suppose the diameter EG and the side E divided into two parts, as fig. 24. Now, joining the lines H 1, H' 1, we get at their intersection, a point K, which, as has been shown before, is a point within the true curve of the ellipse. To prevent the confusion of so many lines, we will now suppose a similar point found in the right hand quarter, and will call it L. Now, we have to draw two portions of circles, one through L and F, the other through LH and K, and they are, of course, to touch each other in L; then this point of contact L and the centres of the circles must be all in the same straight line. To do this we have to join HL by a straight line, and bisect it by a perpendicular line. This is done by taking any convenient opening of the compasses, and from the points H and L cross two small segments, as shown, and draw a line through them on till they meet HG produced to M. Join ML, cutting EF in N. From N as a centre strike the segment of a circle LF; and as LN and M are in the same straight line from the centre M, strike the segment KHL, which will pass through H, and touch LF at L. We have, therefore, a curved line passing through the points KHLF, all of which points are in the curve of a true ellipse, though the curve itself is not so, but parts of circular arcs. Proceed in the same way for the other side of the parallelogram, and the ellipsis is complete. If greater accuracy is required, divide EG, E 2, each into three or four or even more points, instead of two, and proceed on the same principle given above, viz., join the first pair of points so formed (beginning at the top) by a straight line, bisect this by a perpendicular projected till it cuts the line HG, and then join the next pair of points, and bisect again as before.

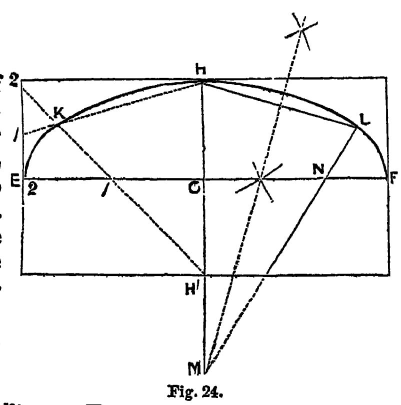

Fig. 24.

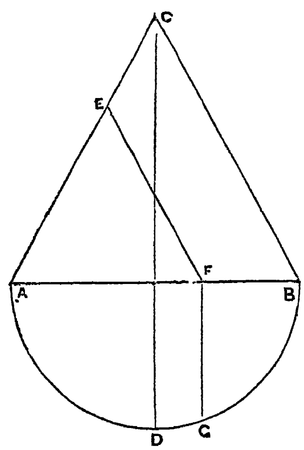
Stone-Cutting.

The parabola.

91. Let ABC (fig. 25) be the section of a cone as before, and ABD half the plan of its base; if the cone be cut through by a flat straight cut or plane in the direction EF, but it always must be parallel to one of the sides (as it is here to the side CB), the section of the cone thus cut will be a parabola, and its height or axis will be EF. From F draw FG at right angles to the base AB, and FG is half the base of the same.

Fig. 25.



To describe the parabola.

92. Draw a parallelogram (fig. 26) of which the height shall be equal to FE, and the base equal to twice FG. Divide the height and each half the base into any number of equal parts (in this case they are divided into 4), draw co-ordinates crossing each other as shown, and *a b c* will be points in the curve; bend a lath round, and strike the curve, which will be a parabola. In a similar way a parabola may be drawn, any height and width being given.

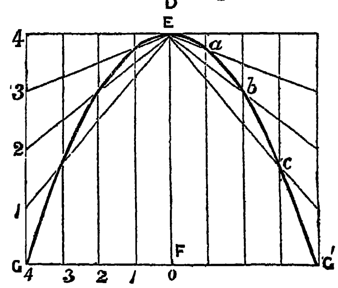


Fig. 26.

The hyperbola.

93. Let ABC, &c. (fig. 27), be the cone and its plan as before, and let it be cut by a plane at EF, falling within the base, but not parallel to the side. The curve of the section is a hyperbola, and FE is its height. From F draw FG at right angles to AB; then twice FG is the base of a parallelogram, within which the hyperbola lies.

To draw the hyperbola.

94. Construct a parallelogram (fig. 28) of the height EF, and width twice FG; then in fig. 27 produce the side AC and the line EF till they meet in H, and make EH (fig. 28) equal EH (fig. 27), divide the sides as shown into any number of equal parts, cross the co-ordinates as before, and through their intersections draw the curve.

The regular solids.

95. It is now necessary to say a few words on the regular solid figures with which the mason has most to do. These are the cone, the cylinder, the globe, and the spheroid. The cone may be considered to be formed

[1] For the definitions of the words *foci, ordinate, axis*, &c., see CONIC SECTIONS, pp. 252, 258, and 269.

Stone-Cutting.

by taking a right angle triangle (ABC, fig. 29), holding it upright, and turning it round as if the perpendicular side AB was an axis. The surface traced by the hypothenuse AC as it turns, would be the surface of a cone, and that

Fig. 27.

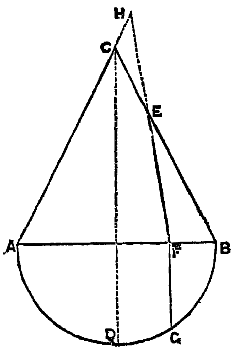

Fig. 29.

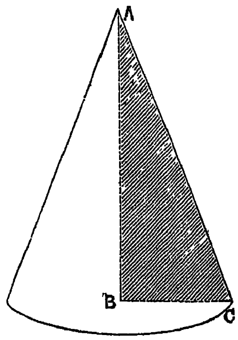

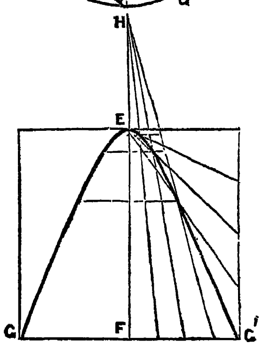

Fig. 28.

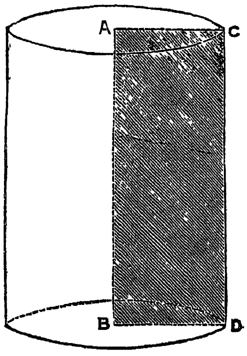

Fig. 30.

by the third side BC the base. In the like manner the parallelogram ABCD (fig. 30), turned round on one of its sides, as AB, would describe a cylinder; a semicircle (ABC, fig. 31) turned on its chord AB, a globe; and a semi-ellipsis, on its axis, a spheroid.

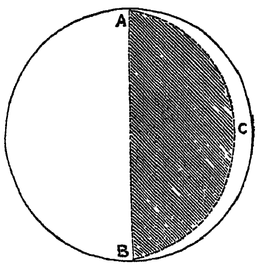

Fig. 31.

Sections of a cone.

96. If a cone be cut by any plane surface passing through its vertex, the section will be a triangle; if cut at right angles to its axis, the section will be a circle; if cut obliquely (as fig. 20), but at so flat an angle that the plane does not cut into the base, the section is an ellipsis; if by a plane parallel to one of its sides (figs. 25 and 26), which, of course, must cut the base, it is a parabola; if of less angle, or perpendicular (figs. 27 and 28) to the axis, it is a hyperbola.

Development of a cone.

97. If a piece of paper could be wrapped round any figure so as to cover its side exactly, and this then be spread out flat, it is called its development. Let ABC (fig. 32) be a right cone, the plan of which is drawn beneath it. Suppose this plan divided into any number of equal parts, as 12,

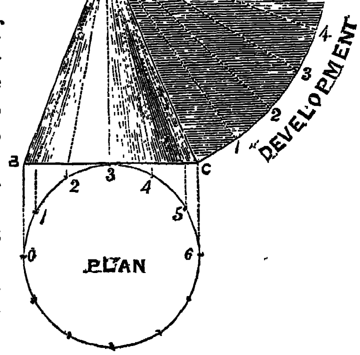

Fig. 32.

and the cone divided in a similar way by lines drawn to the apex A; suppose these lines drawn in wet ink, or paint, and the cone then rolled on its side along a flat surface, A 1, A 2, A 3, &c., would mark the different portions of the cone; and C 1 2 3–6 will be the stretch out of half its base, and AC 6 the development of half its surface. The other half will be merely a continuation of the same. To draw this development from the centre A with the radius AC, describe the segment of a circle, and set off upon it the openings 0, 1–6, equal to the circumference of the half-circle 0–6 on the plan, and join A 1, &c. Each division will be the development of a portion of the cone—thus, AC 3 will be a quarter of the cone, AC 4 one third, &c.

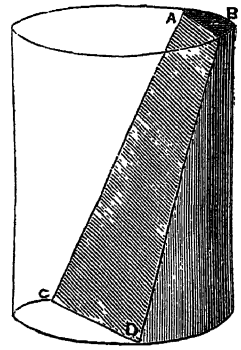

Fig. 33.

Sections of a cylinder.

98. If a cylinder be cut parallel to its axis, the section is a parallelogram; if the plane be inclined from the axis so as not to pass outside the ends or bases (fig. 33), a trapezium, ABCD; if at right angles to the axis, a circle; and if cut obliquely to its axis, the plane not cutting into the ends, the section is an ellipsis (fig. 34), of which AB is the larger and CD the lesser axis.

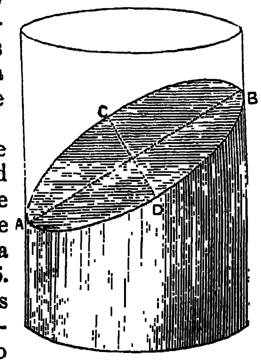

Fig. 34.

Development of a right cylinder.

99. Let ABCD (fig. 35) be the elevation of a cylinder, and its plan be below it; and suppose it divided as directed for the cone, and then rolled along a plain surface from E o to F 6. 0–6 is the stretch out of half its base, and E o–F 6 is the development of half its surface. To draw this proceed as directed for the cone.

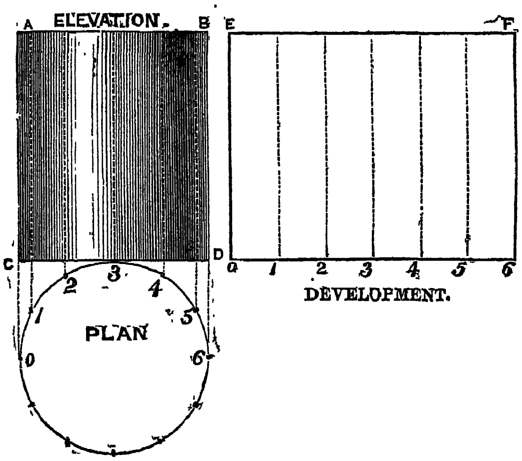

Fig. 35.

100. Let ABCD (fig. 36) be a cylinder cut square at the base BC (of which the plan is below), but obliquely at the top, as AD.

Development of an oblique cylinder.

The upper section (sec. 98), will be an ellipse, of which AD will be the length, and the radius of the circle (on the plan) equal to half the height EF. This may be described by any of the foregoing methods. Divide the circle at the base as before, and draw lines on to the surface of the cylinder; set out the stretch out from 0 to 6 as before directed, and draw the perpendiculars—as 0 0′, 1 1′, 2 2′,

Stone-Cutting.

&c. Again, draw perpendiculars from 0 1 2, &c., on the stretch out, and cross them by horizontal lines drawn from

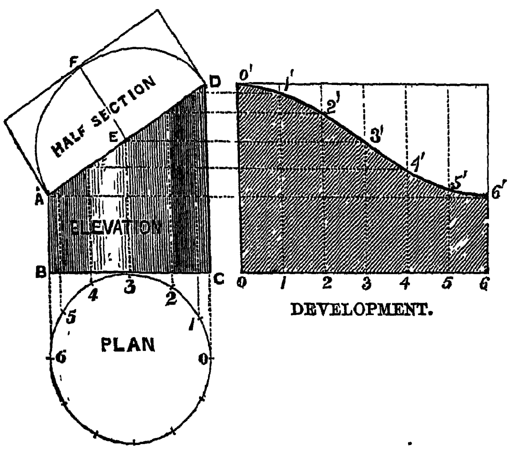

Fig. 36.

similar points in the elevation, cutting the lines on the development at 1′ 2′ 3′, &c., the surface between the curved and the straight line is its development. In like manner the other half may be drawn.

Sections of a globe.

101. If a globe be cut through by any plane, the section is a circle. If the plane passes through the centre of the globe it is called a great circle, being the largest that can be cut out of that solid. For the development of a globe see 117, 118.

Sections of a spheroid.

102. If a spheroid be cut by a plane at right angles to its larger axis, the section is a circle; all other sections are oval, of which all parallel sections are similar.

These foregoing problems are indispensable to a mason, and should be carefully studied and gone over till they are thoroughly understood. Several other mathematical curves have been used for arches, as cycloidal, catenary, cassinoidal, &c.; but the trouble of setting them out, and the difficulty and confusion the workmen often get into has led engineers and architects to the use of circular and elliptical arches almost exclusively. Indeed, in many cases where the latter were formerly used, it has been found better and cheaper practically to substitute segments of circles.

To find the Joints of Arches.

Circular arches.

103. In all cases the joints of all arches should be at right angles to the tangents of the curve. For this reason those of circular arches should simply be drawn to the centre of the circle of which they form a part. If that be very distant, as is frequently the case with very flat arches (fig. 37), divide the arc into as many equal parts as may be

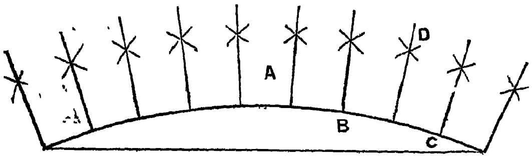

Fig. 37.

convenient, having relation to the size of the arch-stones or voussoirs, and taking care that the middle of the key-stone A shall be exactly in the centre of the curve. Then, from every alternate centre as B and C, with any convenient opening of the compasses, strike two small arcs, as at D, crossing each other; these will give the angles for the joints. In fact, this way is very nearly true for all flat arches, whether circular or elliptical.

Stone-Cutting.

Joints of elliptical arches.

104. Let EHF be an ellipse, and a the point from which the arch-joint should be struck; find the foci 1 3 (sec. 88, fig. 22), and draw lines from each through the point a, as shown towards b and c. Bisect the angle $b\,a\,c$, by the segments as shown; draw $b\,a$, which is the arch-joint. In cases of arches drawn by segments of circles, as fig. 39, the arch-joints are simply parts of radii from the respective centres ABC. This figure

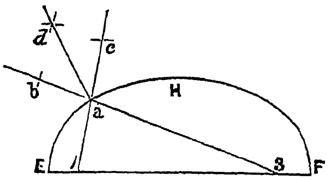

Fig. 38.

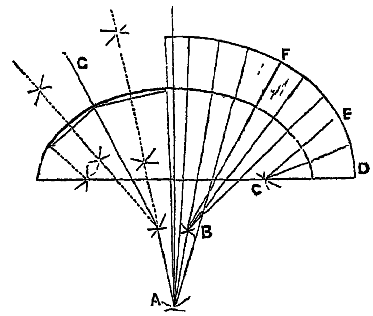

Fig. 39.

shows the case of an arch drawn from three centres in each quadrant instead of two. The arch-joints from D to E are to be ruled from C, from E to F they are to be drawn from B, and F to G from A. The method of finding these points is shown on the other half of the diagram. (See also sec. 90.)

Joints to parabolic arches.

105. The same rule holds good with parabolic arches as with others, that the arch-joint shall be at right angles to a tangent, passing through the point whence it rises. Then let ABC be a parabola, drawn as shown, sec. 92, figs. 25 and 26. It is required to find the arch-joint at D, draw DE

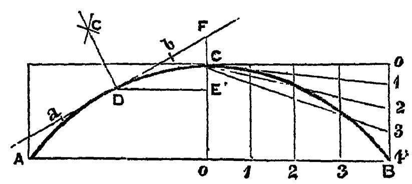

Fig. 40.

parallel to AB, and make CF equal to CE; through D, draw FD a as shown; take a, b equal distances from D, and raise the perpendicular D e, which is the arch-joint.

To find the Arch-Stones or Voussoirs.

Voussoirs of right arches.

106. Let fig. 41 be the elevation of the arch, below which is its plan. Then, as the stones are generally longer than they are high, the workman will take a block of about the size required, and will work any long side, say the bed $a\,b\,e\,f$ (see plan). He will then work the ends square, and of course they will be parallel with the face of the wall; he will then, by means of bevels, set off the angles $a\,b\,c$, $b\,a\,d$, $b\,c\,d$, and work these sides; he will then apply a mould the exact shape of the arch-stone, as shown by the shaded lines, to each end of the stone he is working, and describe its exact shape, taking care to keep the moulds out of winding, and work off the waste between the dotted lines $a\,d$, $b\,c$, reducing them to the curve shewn by the mould, and the work is complete.

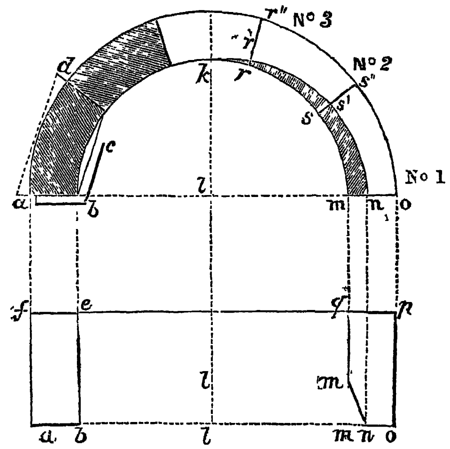
107. If the arch be splayed inside, as on the right hand

Stone-Cutting.

Arches splayed inside.

side of the plan, fig. 41, and lm be the half of the width of the square part, and ln that of the splayed, then the

ELEVATION.

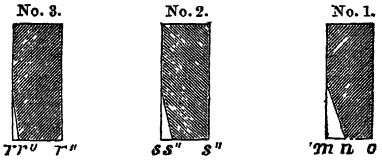


PLAN.

Fig. 41.

line marked r', s', n', is an ellipsis. Draw this by any of the methods given above, taking ln as the length and lk as the height. Then the plan of the bed (No. 1) at the springing will be $mnopq$ (see plan, fig. 41). The next bed $ss's''$, fig. 42, No. 2; the third, r, r_1, r_2, &c., &c.—the

No. 3. No. 2. No. 1.



PLANS OF BEDS OF ARCH-JOINTS.

Fig. 42.

depth of the square part, and the entire thickness of the arch being always the same.

Arches in oblique walls.

108. Let AB represent the plan of an opening (as a door or window) which cuts obliquely into a wall. If the

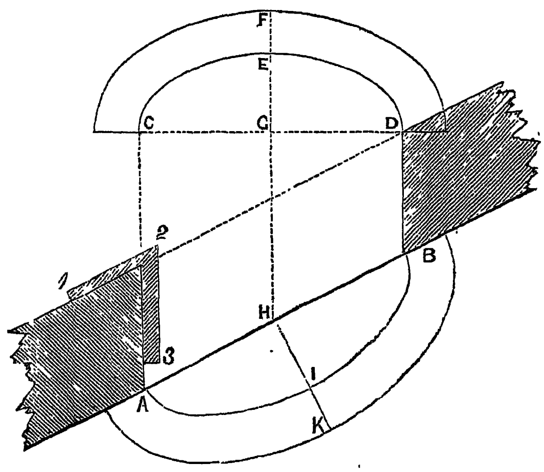


Fig. 43.

face of the arch be a circle, proceed as in 41; but instead of working the stones square at the end, they must be worked according to the bevel 1 2 3. The face bevels are obtained as shown before. But if the section of the arch be an ellipse, as CED (fig. 43), and the depth of the voussoir EF, the delineation of the face will be found by drawing HI at right angles to and bisecting AB, and making HI equal to GE as the height, and AB the length, and describing an ellipse; also make IK equal to EF, and describe a second ellipse through K as shown; AKB will be the face of the arch. If these arches are of great length, or very oblique, another method has been lately used, which is given in the separate article SKEW ARCHES.

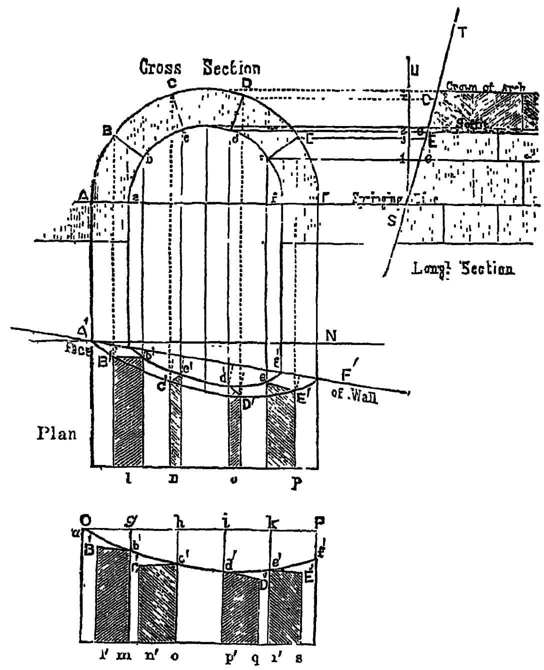
Skew arches.

To find the soffits.

109. The soffit of an arch may always be found by considering it to touch a cylinder placed as a centre under it, and by finding the development of such cylinder by the methods given in JOINERY, and in the sections 99, 100.

Arches in oblique walls, which also batter.

110. Let ABC . . F, abc,f (fig. 44) be the section of the arch of a tunnel, or of one in a terrace wall, the face of



Development.

Fig. 44.

which is not square with the section, but inclined on the plan at the angle NAF′, and which also batters or falls back out of the perpendicular at the angle UST on the longitudinal section, SU being perpendicular to the springing line. From the intrados def, &c., draw the faint lines to ST, as 1e, 2d, &c., and from the extrados draw the dotted lines 3E, 4D, &c.; also let fall the perpendicular bb', cc', dd, on A′F′. Then take the several divisions intercepted between ST and the perpendicular US, and transfer them to the line A′F′, and set them off at right angles to it as shown; then $a'b'c' \,.\,.\, f'$, will be the line of the intrados on plan, and A′, B′ . . F′, that of the extrados; and the portion between those lines will represent the battering face of the arch. From B′b', C′c', &c., let fall perpendiculars as shown, and the shaded portions will represent the places of the arch-joints on the plan.

The moulds for the soffits and arch-joints.

111. Take any line OP equal to the stretch out of the inner circle of the arch $ab \,.\,.\, f$, and divide it into as many parts as there are arch-stones. Draw perpendiculars from these points as shown in the figure, and set out on them gb', hc', &c., equal to the same on the plan. Then $a'b'$, c', &c., is the development of the line of the intrados; and each portion, as $c'd'op$, $d'pre'$, is the mould for the soffit of each respective stone. Next make lm, no, &c., equal to Aa, or Dd, in the section which will represent the depth of each arch-joint, and make B′l', C′n, &c., in the development equal to B′l, &c., on the plan. B′blm,

Stone-Cutting.

$d'D'pq$, &c., are the moulds for the arch-joints, as shown by the shaded surfaces.

Arches in circular walls.

112. Let $Aabc$, &c. (fig. 45), be a circular-headed arch

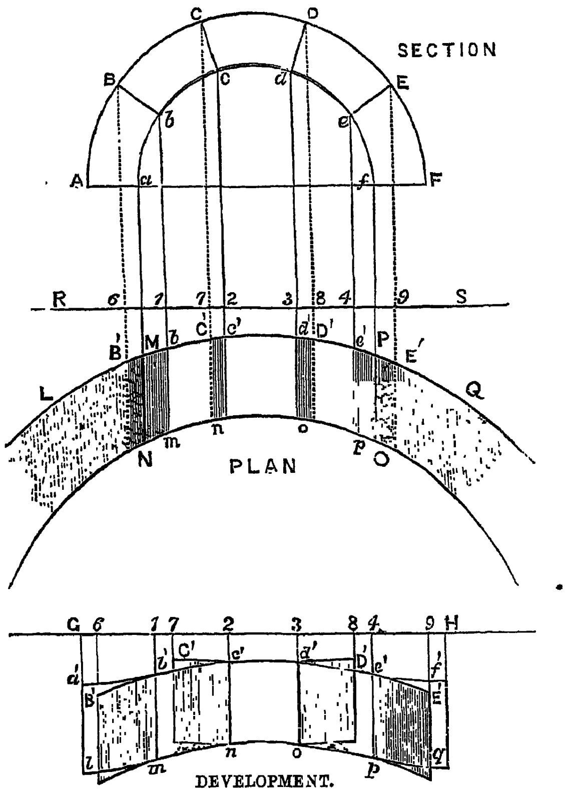


Fig. 45.

over a door or window, in the wall of a circular bow or tower; the plan of which is LMNOPQ. Draw the arch-joints bB, cC, &c., in the section, and let them fall on the plan in b'B′, c'C′, then the shaded part will represent the lines of the arch-joints on the plan.

To find the moulds for the soffits.

113. Draw any line in the plan RS perpendicular to the lines let fall. Also draw GH in the development, and make it equal to the stretch out $ab\,..f$, and divide it into as many parts as there are arch-stones at 1, 2, 3, &c.; draw the perpendiculars, and set down 1, b', 2, c', on the development equal to 1b', 2c', &c., on the plan. Do the same with 1m, 2n, 3o, &c., and the line $a'\,b'\,c'$, &c., is the front line of the soffit, and $l\,m$, q, the inner line of the same; also $c'd'\,n\,o$, $b'c'\,m\,n$, will represent the soffit of each arch-stone.

To find the arch-joints.

114. From the lines $b'm$, $c'n$, &c., set out the depth of the arch-stone equal to Bb, &c., on the cross section, and on the line GH set down 6B′, 7C′, &c., equal to the same on the plan. The shaded portions will then be the moulds for the arch-joints.

General remarks.

115. The above problem may be used for any sort of arch, or any form of wall, whether cylindrical or conical, care being taken that all section lines be first carefully transferred to the plan and then to the development. Perhaps the method of finding the arch-joints will be better understood if the reader will suppose the stones of an arch to be transparent or made of glass; and the joints or surfaces where they touch to be blackened. If the eye were placed exactly above such an arch, it would present the appearance as shown in our plans.

Spherical Vaults, Domes, Niche Heads, &c.

116. Spheres or globes may be developed in two ways,—*first*, in horizontal sections or zones; and, *second*, in vertical sections or gores.

Stone-Cutting.

To develop a sphere.

117. Let Ao, 1, 4 (fig. 46) be the section of a dome, and 1, 2, 3, 4 the places of the arch-joints; AB 4, the springing line; B, o, the line through the vertex; produce this line towards C, and through 2 1, 3 2, 4 3; draw chords to the vertical line, cutting it in a, b, C. Then o is the centre of the eye of the globe, or the key-stone of the dome; a the centre of the development of the first zone, 1, 2; b, the centre of the second 2, 3, C, of the third 3, 4; and so on for as many divisions as you may think proper to divide the globe into.

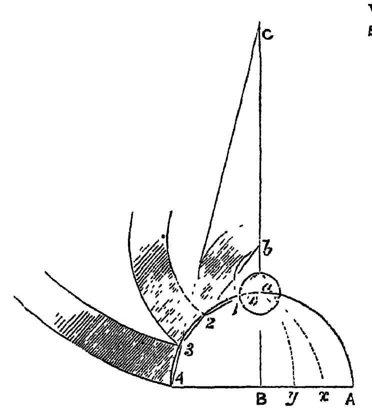

Fig. 46.

The same vertically or in gores.

118. Let xy, in fig. 46, be a gore or section of globe, made by two vertical planes passing through its centre. Then those planes are portions of great circles 101, and their sections are quadrants. Let ADB (fig. 47) be one of these quadrants, draw DC parallel to AB, and make it equal to half the gore required. Draw CF parallel to DB; produce AB to F, and CF to E, and join DF. Divide AD into any number of parts, as 0, 1, 2, 3, &c., and draw ordinates parallel to AB, cutting DF and CF. On CE set out 0, 1, 2, &c., so that CE will be the stretch out of AD. Draw ordinates through these points, and make 1, a; 2, b; &c., in CE, equal to the same lines intercepted between DF and CF. The curved line which passes through Dabc, &c., will be the development of half the gore. Transfer these points to the other side, and the whole is completed.

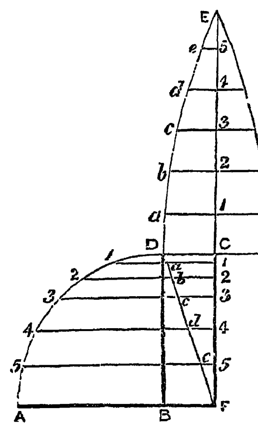

Fig. 47.

By these two methods any portion of the surface of a globe may be drawn, and if cut out of any thin material will form a mould for any of the curved surfaces.

To find the joints of a dome.

119. Let fig. 48 be the section, and fig. 49 the plan of a semi-circular dome, or a niche head. For greater clearness this is drawn with only two ranges of arch-stones besides the key, but the theory is the same for any number. Then $a\,b\,c\,d$ upon the plan will be the bed; $a\,b\,e\,f$ on section, the end mould of the first voussoir; the face moulds will be found by the preceding problems. It remains to find the upper bed at $e\,f$. With the radius Of strike part of a circle (fig. 50), and set out on it the line $f\,p\,g$, equal to $f\,g$ stretched out on the plan. If the thickness of the dome be parallel, as on the left side of the diagram, set out such thickness $e\,f$ (fig. 48), and then describe the circle $e\,h$, and $e\,f\,g\,h$ is the mould. The bevels can easily be set from the plan and section. If the arch-stones are intended to bond in with the level masonry, as shown on the right side of the section (fig. 48), make $p\,q$ (fig. 50), equal to $p\,q$ in the section, and proceed as before. In this latter case it will be better to work the arch-stones thus: from the point 1 on section let fall (through p) the perpendicular 1 p 2, and draw 4, 3, parallel thereto; then 2, r, 3, 5, 6, on the plan

Stone-Cutting.

(fig. 49), will be the mould of the bed: 1, 4, 2, 3, on the section, fig. 50, of the end: and the plane 1, 2, 3, a square angle

SECTION.

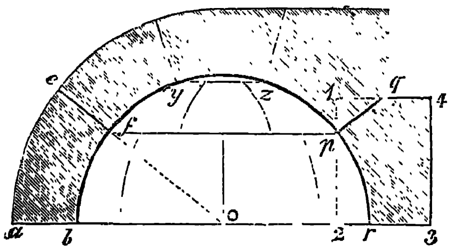

Fig. 48.

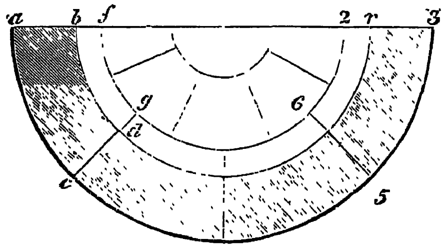

Fig. 49.

PLAN.

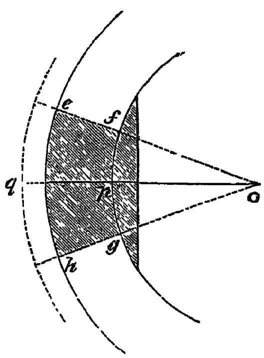

Fig. 50.

with the plan. The block will be the portion of an upright cylinder shown by 1, 2, 3, 4, 5, 6, 7, fig. 51. Then make q 4, 2 r, 2 p, &c., equal to the same on the section, and work off the waste as shown. As the radii of a globe are all equal, the curve is alike in all parts. A radius rule is therefore very convenient, this is found (fig. 50) by simply making $f g$ a chord to the curve, and the section included by the lines forms the rule. The key is simply part of a cone, the widest diameter of which is w x, and narrowest y z.

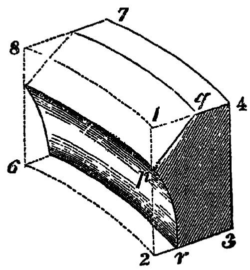

Fig. 51.

Arched Vaults which intersect each other or Groins.

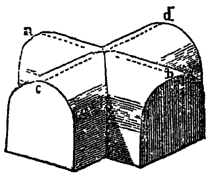
Cylindrical vaults with equal apertures.

120. Almost all groins (except the mediæval) are either circular or elliptical, and their crowns a b, c d (fig. 52), form straight lines. If the openings and heights be equal, the two sections (Nos. 1 and 2, fig. 52), will be alike, and the centers will intersect on the groin lines. Then (99) the intersection of two cylinders will be an ellipse of the length a b on the plan, fig. 53, and of the height of c d equal to that of either of the sections. Having thus the width and height, the ellipse may be drawn by any of the methods given above.

Unequal apertures, but equal heights.

121. If arches are of equal height, and level both at crown and springing, but of unequal widths, one arch at least must be the portion of an ellipse, and the intersection an ellipse more or less regular. Let the main arch, No. 1, be semi-circular ABC (fig. 54), and the cross arch, No. 2, of the width DE, but of the same height OC as No. 1. Join AB on plan No. 3, and draw OC perpendicular to AB, and equal to OC, Nos. 1 and 2. Then the

Fig. 52.



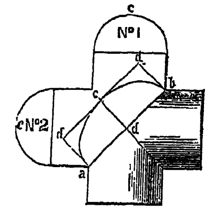


Fig. 53.

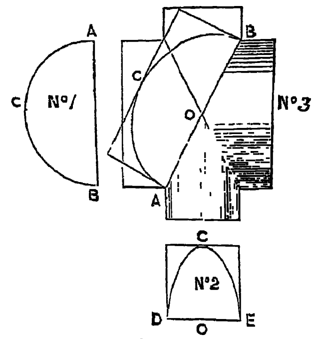

Fig. 54.

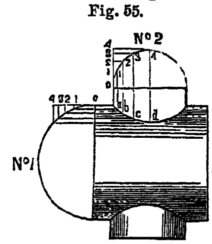
line of intersection will be an ellipse, the length of which is AB, and the height OC. The section, No. 2, will be an upright ellipse, the greater axis of which is OC and the less DE, all which may be drawn as before. If the cross vault be a semicircle, the main vault will be a flat ellipse, and the groins found as before.

Arches of different heights, but same springing.

122. These are either from the same springing, in which case the crowns of the intersecting arches are not level; or the crowns are level, in which case the springing of the lesser arch is higher than that of the greater. In fig. 55, No. 1 is the section of the main arch, No. 2 of the cross arch, No. 3 is the plan of a groin in which both arches are semicircular, but No. 2 is less than No. 1, and of course of different heights. In the smaller arch, No. 2, take any number of points, 0, 1, 2, 3, 4, and draw horizontal lines from them to the perpendicular 0, 1, 2, 3, transfer them to No. 1, return them to the curve, and draw co-ordinates from these points, meeting in the line a b c d, which is the curve of intersection. These are called under-pitch groins, and sometimes Welsh arches. In the same way the lines may be formed where one arch intersects another obliquely (fig. 56), where the respective numbers and letters refer to the same things.

Fig. 55.



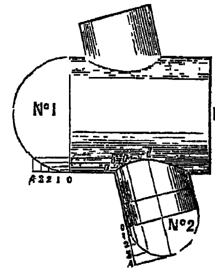


Fig. 56.

Arches of different heights, but level at the crown.

123. In this case the springing of the smaller arch must be higher than the other. This often occurs in Roman work, and almost always in Norman groining. No. 2 (fig. 57) is the smaller semicircle, the springing line of which is AB. Make OC in No. 2 equal to OC in No. 1, which is the height from the crown to the springing of the main arch. Take any points in the curve 0, 1, 2, 2, 3, &c., of No. 2, draw them to the perpendicular A 4, and transfer them to No. 1, and cross the co-ordinates as before, and the line of intersection will be found. But it must be noticed this is a curved line, and not a straight groin point, as will be the case in the next problem.

To find the lines when a cylinder is intersected by a portion of a cone.

124. This is often the case at the end of a building with a canted bow, or a church that ends with a hexagonal apsis. Let ABCD (fig. 58, No. 3), be the plan of cylindrical vault, the section of which is DEF, No. 1, and let it be pierced by the portion of a conical vault GHIK. Produce

Stone-Cutting.

GH, IK, O, till they meet in O the vertex of the cone, and till de in No. 2 is made equal to DE in No. 1,—de, of course, being parallel to GI. Draw the semicircle def in No. 2 equal to DEF in No. 1, and divide each into the

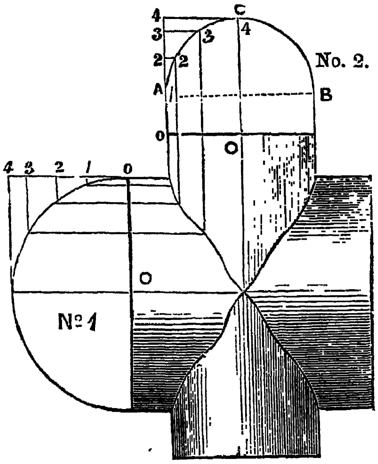

Fig. 57.

same number of equal parts. In No. 2, draw ordinates, first perpendicular to de, and thence radiating to the point

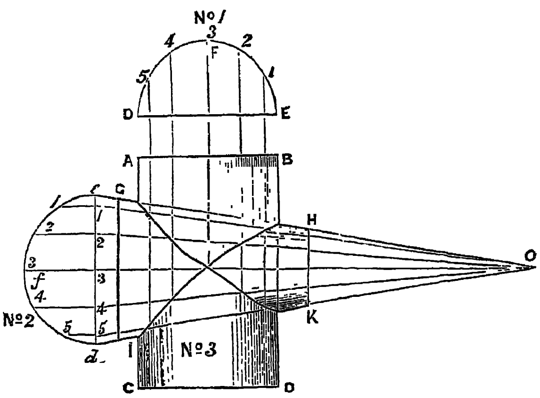

Fig. 58.

O; cross these by the co-ordinates from No. 1, all as shown in the diagram, and the curved lines GK, IH, will show the intersections.

Descending vaults. 125. The lines for these may be formed on exactly the same principles, viz., from a plan, two sections, and a double set of ordinates. In descending vaults, however, we have to remark, if it is intended the cross arches should be cylindrical, the groined points will be curved, as in 123 and 124. If it be intended that the groined points shall be straight, and should intersect in the middle of each bay, then the section of the cross arch will be an oblique oval.

If a mason will carefully master these problems, he will find very little difficulty in any methods of stone-cutting.

The same problems give the lines for centering, the practical method of executing which is found in CARPENTRY, CENTERING, &c., &c.

Mouldings.

Greek and Roman mouldings. 126. All the sections for Roman mouldings are given in JOINERY, p. 807, but as those used in stone work, particularly in Grecian architecture, are parts of Conic Sections, and not struck by compasses, we give a short problem by which they may all be easily set out.

127. Let (fig. 59) the moulding required, be an ovolo, the height of which (to the point where the moulding curves backward) is AC or BD, and the greatest projection AB or CD; and let CE be a tangent line, or line which the curve must touch but not cut. Produce CA to F, and make AF equal to AC, and AG to ED. Divide GB BE each into the same number of equal parts as 5. Draw the co-ordinates from F and C to the respective numbers, their intersections will trace the curve. If BE be more than

To draw a Grecian moulding, having its height, its greatest projection, and a tangent to the curve.

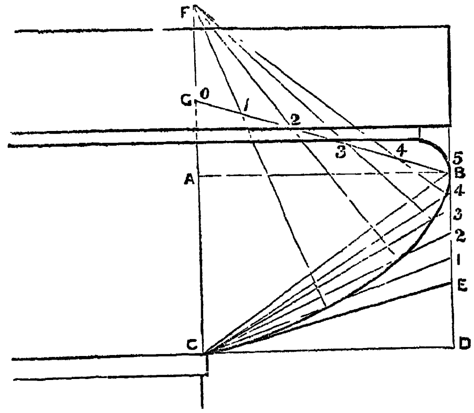

Fig. 59.

half the whole height, the curve is an ellipsis; if exactly half the height, it is a parabola; and if BE be less than half BD, the curve will be a hyperbola. All other moulding can be drawn by this method, remembering that cymas, ogees, and all reflex curves, must be divided and drawn in two separate portions.

Staircases.

128. The general principle of designing staircases, as regards the rise and tread of steps, setting out curves, curtails, landings, &c., are given in the article JOINERY (35, &c.) The chief difference between these and other staircases consists in the fixing, the one being framed with wooden strings, while the other have no strings, but are supported entirely by the walls. If there be a wall at each end, they are simply built in at the time the work goes up; but if they are supported at one end only, they are called geometrical stairs, and depend entirely on their being securely wedged into the wall; on which, and on the support each derives at one edge from the step below, they wholly rely. If they are square in section, they are called solid steps; but as the under side or soffit, then, is irregular, it is usual to make the steps of somewhat a triangular shape, so as to present a regular soffit. In this case they are called arris, or feather edge steps. Care should be taken that there are no sudden or irregular changes in the curves. These may be easily avoided by the method shown for the easing of the curves and ramps in handrails. (See JOINERY.) Stairs. Solid steps. Arris steps.

129. Landings should also be very carefully pinned into the walls. Fig. 60 will show the danger, should they not be so, through the full length of their insertion. If the front edge be pinned up, as at A, but a vacancy be left, as at B, the point C will become the fulcrum of a lever, and the landing have a tendency to turn at that point, and to break at the edge C. Every step and landing should have 8 inches hold in a brick wall. Landings.

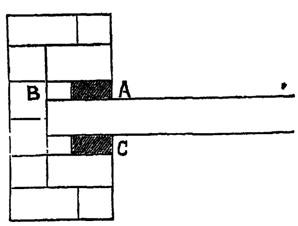

Fig. 60.

(130.) All landings should be well joggled; the joint Joggles

made as at *a* (fig. 61) is called by workmen a he, and that at *b* a she, joggle. The late accident at the Polytechnic Institution in London arose no doubt from the carelessness of the workmen, who put two landings together, on which two she joggles were worked (fig. 62), and filled the open space with plaster. There happened to be a large fossil in the stone close to the wall in the landing *b*, which having no support from the other landing *a*, gave way, and caused the destruction of the staircase below, upon which it fell.

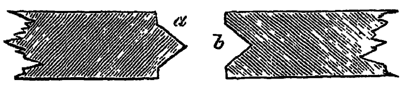

Fig. 61.

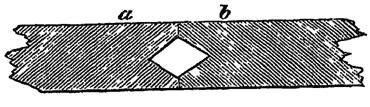

Fig. 62.

V.—STONE-MASONRY—MEDIÆVAL.

Materials.

131. It has already been stated (secs. 67, 68) that many of the early buildings of the middle ages were entirely constructed of masses of concrete, often faced with a species of rough cast. The early masonry seems to have been for the most part worked with the axe and not with the chisel. A very excellent example of the contrast between the earlier and later Norman masonry may be seen in the choir of Canterbury cathedral. In those times the groining was frequently filled-in with a light tufa stone, said by some to have been brought from Italy, but more probably from the Rhine. The Normans imported a great quantity of stone from Caen, it being easily worked, and particularly fit for carving. The freestones of England were also much used; and in the first pointed period, Purbeck and Bethersden marbles were employed for column shafts, &c. As time went on the art of masonry advanced with us, till in point of execution it at length rivaled that of any country. The methods of working and setting stone were much the same as at present, except that, as the roads were then in a very bad state, and in many places the only means of conveyance was by pack-horses, the stones were used in much smaller sizes than at present. The methods of setting out work were, however, different from those of other styles, as might be expected from the difference of forms.

Arches.

132. The earliest arches were circular (see ARCHITECTURE, page 480, and figs. 1 to 9, Plate LXVII.), and of course easily set out. But as the pointed styles came in, several methods were used for describing them. Pointed arches may be classed as—1st, lancet; 2d, equilateral; 3d, depressed; and 4th, four-centred or Tudor.

Lancet arches.

In the first the centres (1, 2, fig. 63) are without the arch *a b*. At Westminster Abbey the arches of the choir are so acutely pointed, that the distance from 1 *a*–2 *b* is nearly two-thirds of the entire opening *a b*. In the nave at York the points are without the arch at a distance of about one-fifth the opening *a b*.

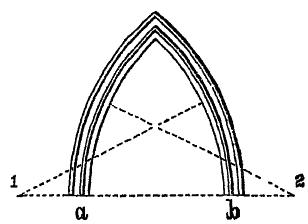

Fig. 63.

Equilateral arches.

In equilateral arches the centres are exactly on the points *a b* (fig. 64), so that the apex *c*, joined to *a* and *b*, will form an equilateral triangle. The nave arches at Wells are of this description, and also those at Lincoln (Plate LXIX., fig. 1).

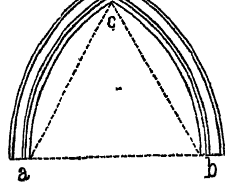

Fig. 64.

Depressed arches.

In later times the arches were of lower pitch, and then of course the centres 1, 2 (fig. 65), were within the arch *a b*. At Salisbury Cathedral (Plate LXVII., fig. 14), the distance *a* 1 is one-sixth of *a b*, while in the choir at Lincoln (fig. 2, Plate LXIX.) it is as much as two-fifths.

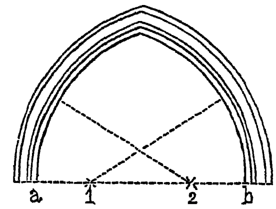

Fig. 65.

To describe similar arches.

133. To describe arches which shall be similar to one another throughout a building, however the openings may differ, this principle must always be borne in mind: that the centres shall always be distant from the points *a b* by some aliquot portion of the whole opening. This is the more important, as the lines of tracery will not fall into their proper places except the arches are set out upon some regular principle (sec. 136). If the arches are not equilateral, some distance from each point, *a b* should be first determined on (say one-third the opening *a b*), and after this, whatever the span of the other arches may be, one-third its own opening is to be taken from the points *a b*, as the centres from which to strike its curves. The only exception is, that in mediæval buildings, the arches to the doorways are frequently somewhat flatter than those of the windows.

To describe four-centred arches.

134. In the Tudor period the arches are very frequently drawn from four centres instead of two. It must be remembered that it has already been stated (sec. 90) the point where two circles touch each other must always be in the same straight line that is drawn through both their centres. As there has been great misapprehension as to four-centred arches, some persons treating them as parts of conic sections, whereas they are really parts of segments of circles, it is thought well to give two methods of describing these arches. First, when the width AB, and the apex height OC, are given, and a tangent to the upper circle CD. In this case draw AD perpendicular to AB, and set out A 1 equal to AD; draw C 3 perpendicular to CD, and make CE equal to AD or A 1; join 1 E and bisect the same as shown by a perpendicular meeting CE produced in 3; join 3 1 and produce towards F, then 1 and 3 will be the centres for half the arch; and, transferring the points across, 2 and 4 will be the centres for the other half. In the second case, when the width AB and the height OC, and the centres of the small circles 1, 2, are given. Make AD equal to A 1, join CD (which will be a tangent to the upper curve), draw C 3 at right angles thereto, make CE

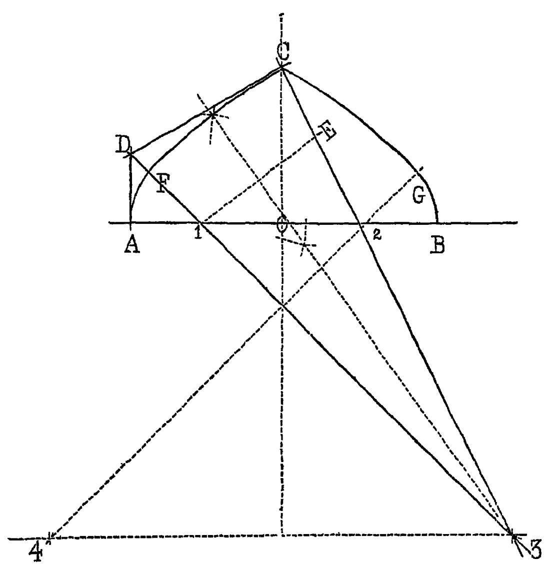

Fig. 66.

equal to A 1, join 1 E, bisect the same, and proceed as before. The points FG, as has before been explained, are the points where the circles will touch each other. The joints to these arches will all radiate to their respective centres, as has been before explained in secs. 103, 104.

Archjoints.

Mouldings.

135. The mouldings of mediæval architecture are almost infinite in variety, and even a short description of those used in each style would exceed our limits. They are sometimes set out with the compasses, and many often appear to have been drawn by eye. We must refer our readers to the works of Willis, Paley, and particularly of J. H. Parker, for their description. A very curious treatise was published by the former gentleman called the *Architectural Nomenclature of the Middle Ages*, which goes at great length into the subject. A bead or astragal seems to have been called a bowtelle; a torus, a grete bowtelle; a hollow or scotia, a casement; an ogee, a ressaunte, &c., &c.; but the subject is too long to be discussed in our pages.

Nomenclature of.

Window tracery.

136. The various sorts of tracery which adorn the windows of the mediæval periods, and are in fact their greatest glory, are treated of in the art. ARCHITECTURE, and specimens given in the different plates, particularly Plate LXVIII., figs. 4 to 8. The designs for these are almost infinite, and the various methods of setting them out would fill a volume. But although they display such ingenuity and fancy that one would think the design to be quite arbitrary, it is a curious fact they are all, or very nearly all, set out on the principle of geometrical intersections. An example, therefore, is given (fig. 67) to show the principles on which the mediæval architects proceeded to describe the tracery, and also the method of finding the joints of the various pieces of stone. Let *a b* be the opening of the arch; as there are to be two mullions, divide the same into three equal parts, as *a c*, *c d*, *d b*; then determine the points from which to strike the arch. In this instance, for the sake of simplicity, we make it equilateral (sec. 132 and fig. 64); *a* and *b* then are the centres for striking the main arch *a e g*, *b f g*, and the height *o g* is that of an equilateral triangle. Produce the springing line, and the same opening of the compasses through *c*, and *d* will give the principal inner branches of the tracery *c e*, *d f*. From the centre *o*, with an opening extending to the middle of the lights *a c*, *d b*, strike a semicircle, raise perpendiculars from *c* and *d* to 1 and 2; draw a line through 1 and 2; on this and the springing line will be found the centres of the

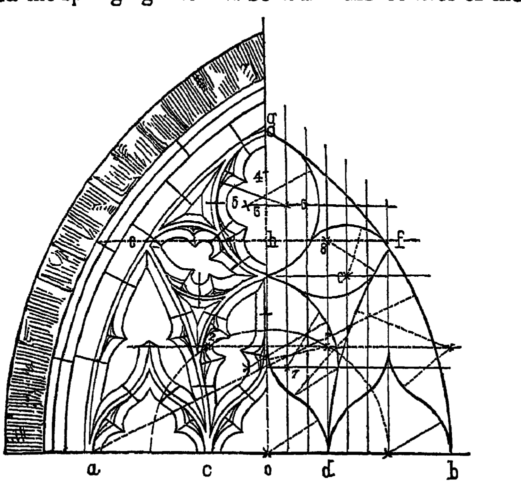

Fig. 67.

lower ogees; bisect the line from the intersection 1, 2, in *h*, which is in fact the same thing as dividing the whole height *o g* into three; divide *h g* into three parts, as 3, 4; through 3 draw a horizontal line, and set off from 3 equal to one-third of the width *o d*, or draw the perpendicular lines as shown, which is better; then 5, 6, will be the centres of the upper quatre-foil. From the line 1, 2, on the same perpendicular as last, set down similar points as at 7. These will be the centres for the lower sub-division as shown. Next draw *e h f* and sub-divide by similar perpendiculars, and where the lines intersect, as at 8, 9, will be the centres for the upper sub-divisions. The lines thus drawn will form a species of skeleton diagram, as shown on the right side of fig. 67, which is called the *element of the tracery*, and is in fact the centre line of the mullion, as shown by *a*, fig. 68. On each side of this, using always the same centres for the same branches, draw lines, showing the face (or what the workmen call the *nose*) of the mullion, and answering to *b c*; and then others answering to the sides of the mullion as *d e*. Any other mouldings upon their sides or faces may be drawn in like manner. Put in the cuspings as shown, and the tracery is complete. The practical stone-mason will take care never to make a joint where there is an angle of any sort, as the point of a cusp. In all cases the joints must tend to the centres of the circles from which they are struck, and where the lines branch off in two directions, the joints must not be in one line, but must tend in two, or as many directions as there are branches, and each to the centres of such respective branch. When the lines are perpendicular, as at *c d*, and at the joint below *h*, the joints are horizontal. A close inspection of fig. 67, where they are carefully drawn, will elucidate the matter more than any number of words can do. Our readers would scarcely believe that the elaborate west window at York is entirely set out on this principle; and so is the still more remarkable instance, the eastern window at Carlisle, which is composed of 86 pieces of stone, and the design for which is drawn from 263 centres. On no account should iron be used as cramps or dowels in Gothic work, as it rusts and breaks pieces out of the stone. The best material is slate run with the Portland cement. Lead is often used; but any metal will expand and contract with heat and cold, and its use is much better avoided altogether. All the upper construction of windows and doors, and of aisle arches, should be protected from superincumbent pressure by strong relieving arches above the labels (see fig. 67), which should be worked in with the ordinary masonry of the walls, and so set that the weight above should not press on the fair work, in which case the joints of the tracery, &c., will sometimes flush or break out.

Element of tracery.

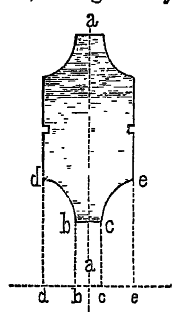

Fig. 68.

Joints of tracery.

Cramps, dowels, &c.

Relieving arches.

Vaulting.

137. Mediæval vaults differ much from those before described, principally that the crowns *ab*, *cd*, are not level, as shown in fig. 52, but all have a slight curve or spring, and the filling-in between them also is slightly curved, so as to partake in some degree of the character of the dome as well as of the groined arch. Bearing this carefully in mind, and setting the lines out thus on the sections, the rules we have given for finding the various lines for groins (120–125) will apply as well to Gothic groins as to those of ordinary character; the principle of working from plan, section, and stretch-out being the same, though for the most part the ribs in early vaulting are not true segments of ellipses, but approximations drawn by the compasses. The triumph of mediæval stone-masonry, however, is that species of

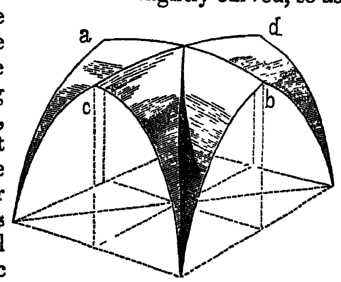

Fig. 69.

Artificial Stones.

groin known as fan vaulting. This is unlike that of any other age or time. The roofs of King's College Chapel, Cambridge, and of Henry VII.'s Chapel at Westminster, are eminent examples. It is impossible in our limited space to give demonstrations of them, and we must refer our readers to the admirable treatises on the subject by Professor Willis, published in the first volume of the *Transactions of the Institute of British Architects.* The filling-in between the ribs of mediæval groins is generally of clunch or some soft stone, over which some concrete is placed in such manner as to bind all together, and to resist the thrust.

Fan vaulting.

Spires.

138. The bold and beautiful termination to mediæval towers, which the French call flêches and we call spires, is another proof of the skill of the mediæval masons. These are generally octagonal, and rise partly from the walls of the tower and partly from arches thrown anglewise from wall to wall, to cut off the corners, as it were, and afford a springing to the spire. The wonder of these constructions is their extreme thinness and lightness. The top of the spire at Salisbury is 411 feet from the ground, of which 207 is taken up by the tower, leaving, of course, 204 feet for the height of the spire itself; this is only 9 inches thick at the bottom, diminishing to 7 inches, or on an average only about the three-hundredth part of its height. It has been attempted to show mathematically that the joints of a spire would be stronger if at right angles to its face; but they would then slope inwards and hold the wet, which in sudden frosts would do most serious injury; practically, therefore, it is found best to lay the courses on a level bed. They should, however, be frequently dowelled and cramped together, but not with metal, as above stated.

VI.—ON ARTIFICIAL STONES, AND ON THE INDURATION OF SOFT STONES.

Cements and terra cottas.

139. The great expense of obtaining and working Portland has driven our masons into the use of the softer freestones. These (as has before been described, sec. 19, &c.), are liable to rapid decay from the action of frost and wet, and in towns from the action of the sulphurous acid in the coal-smoke. To avoid these inconveniences several contrivances have been resorted to within the last century to obtain a cheap and durable material in which to execute external architectural ornament; or to invent some process by which soft stones may be so protected by an outer coat of impervious matter as to throw off the wet; or may be so indurated as to resist the ordinary wear to which Portland or the harder stones may be subjected. The earliest attempts were to manufacture a hard hydraulic cement, which might be modelled with the tool, or cast into moulds. The earliest use of this is said to have been by the Adam's, it suiting very well with the low relief of their style of ornamentation. (For an account of cements, see this article, sec. 22, *ut supra.*) Another method, which has been frequently tried with success, but seems too expensive to come into general use, was to model the ornaments in good plastic clay, as colourless as possible, and burn them in kilns. The best known of these systems was that called Coade's artificial stone, the manufactory of which, however, is now discontinued. (For an account of this species of manufacture, see POTTERY, TERRA COTTA, &c.) A method, however, which seems to bid fair to excel them all in beauty, cheapness, and durability is that patented by Mr Ransome of Ipswich. It appears, the idea suggested itself to him as long back as 1844, that if he could mix sand, or pounded flint with anything that would make a sort of fluid glass, and stick it together, as it were, in a pasty state, it might be pressed into moulds, and when dry it would form a sort of strong glass. After a variety of experiments, and trying to accomplish his object through a number of changing theories, he at length succeeded in the following process. He first obtains a strong caustic alkali, which is purified by a most ingenious process. This is made, by the assistance of steam and heat, to act upon some broken flints, which it does, and the alkaline solution is then drawn off and evaporated till it becomes the thickness of treacle. One part of this is mixed with ten parts of sand, one of flint, and one of clay. The whole is kneaded up till like putty, so as to be readily pressed into moulds, and so as to take the sharpest forms. Our space will not permit us to give the full details; but it may suffice to say that the objects, after being dried in close stoves, are then submitted to a strong red-heat in a kiln like that of a potter, which drives off all the alkaline and other chemical agents in the process, and leaves the granules of the sand and flint enveloped in, and, as it were, stuck together by a sort of glass. Time alone, however, can only ultimately show the results. At present the material seems of beautiful colour, texture, and sharpness; and unless some unknown or unforeseen chemical agent should act upon it, Ransome's stone appears to be indestructible.

Coade's artificial stone.

Ransome's.

Induration of stone.

140. The rendering soft stones hard, and the protecting the surfaces from the weather when worked and set, has been the subject of great investigation lately. The idea of the latter seems to have originated with the late well-known John Sylvester, who tried the method of washing over the faces of stone walls with first a solution of soap and then of alum. Another method was that of washing with what was called water-glass, or silicate of potash, both of which are said to have failed. The next idea was to soak the stone, or in some way to cause the surface to imbibe a quantity of oily or fatty matters to throw off the wet, as well as to harden the stone itself. The first patent was taken out by Mr Hutchison, at Tunbridge Wells, in 1847, and was applied to the new sandstone there. The stones, when worked, were boiled in a solution of resin, turpentine, wax, oil, &c., and sometimes, we believe, pitch, till they were impregnated a sufficient depth from the surface. In 1851 Mr Barrett took out a patent something like the preceding, but far more elaborate; in fact, too long to be described in our pages. The main elements, however, were resins, fats, and tallows, some of which were mixed with gutta-percha, unslacked lime, copperas, and a number of other ingredients. In April 1856 Mr Daines took out a patent, not so much to indurate stone, but to preserve stone, or cement walls from damp and efflorescence. His process was to apply, first, a solution of sulphate of zinc, or solution of alum, to the wall, and then a composition of sulphur dissolved in oil. In the same year, and in the next month, Mr Page took out a patent for a similar purpose; his material was wax dissolved in coal-tar, naphtha, or, for more delicate work, in camphine. We are informed the manufacture of the first of these patents is discontinued, but not from any failure of process. Of the others it is impossible to say much, as so little time has elapsed since they commenced, and as early experiments in all manufactures often fail; judging, however, on the grounds expressed as to mastic (37, *supra*), we should fear they would fail from a like cause, especially as such very volatile media as naphtha, camphine, &c., are used. Mr Ransome's, however, seems to promise better. His is deduced from his experiments on the artificial stone. It consists of treating the surface of the stone first with a solution of silicate of potash or soda, and then with a solution of the chloride of barium, or chloride of calcium, by which means an insoluble silicate, either of barium or lime, is deposited in the pores of the stone. The most extraordinary results, however, are promised by Mr Szerelmey's process. The author of this article has been informed by that gentleman that it will not only entirely protect the surface of stone or brick, or cement, but of iron; as a proof, he states that an anchor coated with it was sunk in the sea many months, and raised

again without trace of oxidation. As his process is a profound secret, and his experiments are now in progress, it is impossible to pronounce an opinion on the subject.

The principal works on Stone-Masonry are as follows:—

Foreign.—Jousse de la Flêche, *Secrets d'Architecture*, fol. 1642. Bosse, *La Pratiquè du Trait pour la Coupe des Pierres*, fol. 1643. Francois Derrand, *Des Traits et Coupe des Voutes*, fol. 1643. De la Rue, *Traité de la Coupe des Pierres*, fol. 1728. Frézier, *Traité de Stéreotomie*, 4to, 1737–57; *Elements de Stéreotomie*, 1759. Simonin et Delagardette, *Traité de la Coupe des Pierres*, 4to, 1792. Douliot, *Traité Speciale du Coupe des Pierres*, 4to, 1825. *Vorlegeblatter, per Maurer*, fol. 1835. Adhémar, *Traité de la Coupe des Pierres*, fol. 1836–40. Normand, *Epures d'Escaliers en Pierre*, 4to, 1838. Le Roy, *Traité de Géometrie Descriptive*, 4to, 1850. Claudel et Laroque, *Maçonnerie Pratique*, 8vo, no date. Besides these see the article Maçonnerie in the various Encyclopédiès, and the famous general treatise by Rondelet, *L'Art de Bien Bâtir*, and the older work of De L'Orme, fol. 1643.

In English.—Moxon, *Mechanick Exercises*, 4to, 1677–93, 1700. Batty Langley, *Ancient Masonry*, fol. 1736. Nicholson, *Practical Builder*, 4to, 1823, &c.; *Practical Treatise on Masonry*, 8vo, 1828; *Guide to Railway Masonry*, 8vo, 1839–46. *Practical Masonry, Bricklaying*, &c., 4to, 1830. Dobson, *Rudimentary Treatise on Masonry*, 4to, 1849–56. Besides the valuable articles in Gwilt's well-known *Dictionary of Architecture*, and Cresy's on *Engineering*. (A. A.)

STORACE, Stefano, a very popular English composer in the latter part of the 18th century, was born at London in 1763. His father, a Neapolitan, performed for many years as a contrabassist at the King's Theatre in London, and married a Miss Trusler of Bath. The family name is said to have been really Sorace, and not Storace. Stephen, under his father's instructions, acquired considerable command of the violin when only ten years old. His father then sent him to study the violin, the harpsichord, and counterpoint, in the conservatory of Sant' Onofrio, at Naples. On leaving the conservatory, he visited different Italian cities, and then proceeded to Vienna. His sister, Anna Selina Storace, a pupil of Sacchini, travelled with him. She had become one of the best singers of the day, and had been received with great applause at several theatres in Italy. In 1784, the Emperor of Germany engaged her for the Imperial Italian Theatre, at L.500 for the season. Storace composed an opera, *Gli Equivoci*, for that theatre. He and his sister returned to England in March 1787, and Signora Storace was instantly engaged for the King's Theatre, where she appeared on the 24th of that month as *Gelinda*, in Paisiello's opera, *Gli Schiavi per Amore*. Her brother becoming disgusted with the intrigues of the theatre, retired to Bath, and devoted himself to drawing, in which he had considerable skill. Returning to London in 1788, he brought out, at Drury Lane, Dittersdorf's music to *The Doctor and Apothecary*, an opera, translated and adapted by Mr John Cobb. On 24th November, 1789, he produced his first English opera, *The Haunted Tower*, written by Mr Cobb. This had a run of fifty nights the first season, and for many years remained a favourite opera. In 1790, Storace produced *No Song no Supper*, written by Prince Hoare, which also had great success. On 1st January 1791, the Spanish composer Martin's celebrated opera *La Cosa Rara*, altered by Mr Cobb, was brought out by Storace (who added to it some music of his own), under the name of *The Siege of Belgrade*. It had a run of sixty nights the first season. In the same year, *The Cave of Trophonius*, translated by Prince Hoare, with music selected by Storace from Salieri's opera, did not succeed. On 26th November 1792, the opera of *The Pirates*, composed by Storace, and the scenery from drawings made by him at Naples, was performed with great success. His next operas were—*Dido; The Prize; The Glorious First of June; The Cherokee; Lodoiska*, the music from Kreutzer and Cherubini; *The Three and the Deuce; My Grandmother; The Iron Chest;* and the opera of *Mahmoud*, unfinished at the time of his death, on 19th March 1796. This last opera was completed by Michael Kelly and Signora Storace, and performed on 30th March 1796, for the benefit of Storace's widow and child. Storace married a daughter of Mr Hall, the engraver. His sister died in 1814. Among Storace's contemporaries, who distinguished themselves as composers of English operas, were Shield, Arnold, Hook, Dibdin, Mazzinghi, and Thomas and William Linley. (G. F. G.)

STORNOWAY. See Lewis.

STORY, Joseph, an eminent American judge, professor of law, and jurist, was born 18th September 1779, at Marblehead, a small fishing town in the county of Essex and state of Massachusetts. His father had been a surgeon in the army, and had served with General Washington, but had afterwards retired, and was in good practice in Marblehead and the adjacent towns. As a boy, he was remarkably intelligent and studious, and his precocious talents were developed by his becoming early a favourite of the village barber, and being permitted to frequent the shop, and listen to the interesting miscellaneous talk of the host and his customers, thereby receiving impressions which continued through life. At the age of fifteen, Joseph, after showing unusual firmness and determination in preparing himself for matriculation, was entered at Harvard College, where he was a fellow-pupil with the Rev. Dr Channing, the distinguished divine and philanthropist, and his immediate chum was the Rev. Dr Tuckerman. Though he had been brought up as a Calvinist, he became, during his college career, a Unitarian, a faith which he continued throughout his life to hold; while, at the same time, the prevailing temper of his mind was a settled tolerance of every other creed. He was not only in youth, but throughout his life, more or less inclined to poetry, and wrote many verses; but these seldom, if ever, attained mediocrity; and it does not appear that he gave way to this habit, except at leisure hours, and as a variety to graver studies. His career at college was very distinguished. The constitution of his mind, which was eminently legal, no doubt insensibly impelled him towards the law. On leaving college, he entered the office of Mr Sawell, then a distinguished advocate at the Essex bar, and a member of Congress. Though at first somewhat repelled by the dryness of legal authors, which presented so great a contrast to the more elegant and various studies of his youth, he soon conceived a great love for its principles and a settled desire to master its details.

At the age of 22, Joseph Story was admitted to the Essex bar, and opened his office at Salem. His progress was not rapid, but sufficiently encouraging to admit of his falling in love and soon marrying his first wife, whose early death threw a gloom over this period of his life, which was, however, dissipated by time, and, in 1808, he married again. During his early career at the bar, he devoted much time to the study of composition, and to poetry and declamation, the practice of delivering annual orations, commemorative of the Independence and other great events, offering attractive opportunities to young American lawyers. He also mixed in politics, and, in 1805, he became member for Salem in the legislature of Massachusetts. Here he developed his talent as a debater, and gained so great distinction in the House that he was elected a member of Congress. Having declined a re-election to Congress, in consequence of an early disgust at the meanness and petty intrigues of public life, and its incompatibility with success at the bar, he returned to the Massachusetts legislature, and was elected speaker of the House of Representatives. At this period, his reputation for ability, and for frankness of character, had gradually increased. During the same year, a vacancy having occurred in the Supreme Court, the appointment,

after two successive refusals from other persons, was unexpectedly offered to him. At this period, his age was only 32; he was then making an income of upwards of L.1000 a year, and the salary of associate justice was under L.800 a year. He fully considered the subject, and after balancing the advantages and disadvantages, he preferred the serenity and dignity of the judicial office, to the rough and ready warfare of the bar, and accepted the appointment.

Shortly before Mr Story's appointment to the office of associate justice of the Supreme Court, he had edited three English law books, in general request in America, viz., Chitty on *Bills of Exchange*, Abbot on *Shipping*, and Lawes on *Assumpsit*. He had not, however, as yet shown that eminence as a scientific lawyer which he afterwards attained. His cotemporaries no doubt gradually arrived at the conclusion that he was peculiarly fitted for the office of a judge. They observed, in all his judgments, a philosophical mind, well equipped with all the learning of his profession, stored with details, as well as anxiously careful of first principles. His acuteness was more than equalled by his singular fertility in illustrations; and his judicial eloquence, readiness, and urbanity of manner, soon led him to be marked out as the most able and popular judge of his day. He was, however, no popularity-hunter, in the vulgar sense of the word, but seemed always to be actuated by a strong sense of duty, and was zealously attached to the great principles of the American constitution. Marshall was then the chief justice of the court—a thoroughly able and upright judge—and it was often said, that the same relations existed between him and Justice Story as existed between Lord Mansfield and Mr Justice Buller. Story was distinguished above all his contemporaries for the extent of his reading and his familiarity with the English reports, and indeed his interest in everything English extended far beyond his own profession; for he devoured, with unceasing interest, throughout his life, the English newspapers, and was always well versed in their minutest details.

In 1829, eighteen years after Mr Justice Story's appointment as a judge, Mr Dane, who had long meditated the foundation and endowment of a law professorship at Harvard University, and had long had in his eye the preeminent qualifications of Mr Justice Story for such an office, at last matured his plan, and offered him the appointment. Though the salary was only about L.150, the duties were not incompatible with the office of a judge, and Justice Story readily accepted the office, having always felt a peculiar pleasure in imparting his own ample stores of information to others, especially to the young. He gradually increased his pupils from six to upwards of a hundred. It was part of the conditions annexed to the office, that the professor should write some legal works in four or five volumes, on subjects which were left to some extent to his own selection. These terms were probably in his eyes one of the greatest attractions of the office, and he at once applied himself to the preparation of his first work, which was entitled, *Commentaries on the Law of Bailments.* The subject was one which had not hitherto been fully developed by any legal writer, Sir William Jones's work, though elegant and able, being somewhat slight in its treatment. It also admitted of appropriate references to the civil law. His great judicial experience was also greatly in his favour. The work, when completed, displayed an elegance, ability, and copiousness of illustration, till then unknown in America, and, with the exception of Blackstone's *Commentaries*, little known in England. All his contemporaries were struck with its great merits, and these were also acknowledged in England. In a year and a half afterwards, viz., in 1833, his *Commentaries on the Constitution of the United States*, in three volumes, were published. This work, though, from its subject, not so familiar to English lawyers, was conspicuous for the same merits as the preceding. He immediately afterwards commenced his *Conflict of Laws*, one of the works by which he is best known to English lawyers. The subject had not been touched upon by any writer on the law of England, which had, indeed, always treated with contempt all other systems of jurisprudence; and it was scarcely to be wondered that a work which discussed in a liberal spirit, and with copious illustrations from the continental jurists and American reports, till then unknown even by name, was welcomed by all English lawyers. The next works followed in rapid succession, all equally able and replete with learning; his treatises on Equity Jurisprudence, on Equity Pleadings, on Principal and Agent, on Partnership, and on Bills of Exchange. While some of the latter works were in preparation, successive editions of the prior works, with large additions and improvements, were published. The rapidity with which these works were produced, while his duties, as a judge and a professor of law, were at the same time conscientiously performed, was the wonder of his contemporaries. At last, under his untiring labours, his health broke down in 1842. His physician recommended a visit to England, where his great reputation as a jurist had now made his name familiar to all the leading lawyers, and where he had acquired many friends. Lord Brougham having heard of his probable visit, had assembled the Lord Chancellor and many of the leading judges to welcome his arrival; but, in the meantime, his health had rallied, and the visit was postponed, never to be resumed. He had, however, since the time of his becoming an author, corresponded with many of the English judges, particularly Lord Stowell. It was a subject of regret that Mr Justice Story had not been appointed chief of his court on the death of Chief-Justice Marshall, a station to which his merits entitled him: his claims were ignored owing to his constitutional views being opposed to that of the then President of the United States. He died somewhat suddenly on the 10th of September 1845, at the age of sixty-six.

Justice Story has rendered a great service to the law of England, by introducing into the text-books a more philosophical spirit, and also by liberalising the minds of his readers with ample references to the foreign jurists. He was the means, also, of introducing to English lawyers what little they knew of Scotch law by his frequent references to Bell and Erskine. His treatises are now accepted as standard authorities, and stand side by side with, and in some cases superior to, the best English works. It is impossible to look upon his life without admiration for his indefatigable industry, united, as it was, with great acuteness and elegance of mind. He was universally beloved in private life, and his death left a blank in American society. He was eminent as a conversationalist; his appearance was prepossessing, intelligence and refinement being at once conspicuous in his countenance; yet withal he was mild and unassuming in manners. In every respect he is entitled to be regarded as one of the worthies of America. (J. P—N.)

STOTHARD, CHARLES ALFRED, an ingenious antiquarian draughtsman, son of Thomas Stothard the painter, noticed in the next article, was born in London on the 5th of July 1786. After studying successively at the Royal Academy, the Life Academy, and at the British Institution, Pall Mall, he began, in 1810, his first historical piece, "The Death of Richard II. in Pomfret Castle." Having taken a strong interest from an early period in the costumes of different ages and nations, he was induced to publish the first part of a valuable work on the *The Monumental Effigies of Great Britain* in 1811. It is of great value to the historical painter, as well as to the player, and the work met with entire success. He was appointed historical draughtsman to the Society of Antiquaries, and was deputed by that body to commence his visits to Bayeaux, to make drawings of the fine old remains of ancient tapestry

which had been preserved there. Stothard was made a Fellow of the Society of Antiquaries in 1819. He subsequently engaged in numerous journeyings, with the view of illustrating the works of D. Lysons. When at Beer-Ferrers, Stothard, while engaged in tracing a portrait from one of the windows of the church, fell from a height of 10 feet, and was killed on the spot. This occurred on the 27th of May 1821. Stothard's widow and her brother completed his *Monumental Effigies*, which was left unfinished at the time of his death. His biography has since been written by his widow, now Mrs Bray, known as a popular writer of novels and books of travel.

STOTHARD, *Thomas*, an English painter, was born in London on the 17th of August 1755. He was originally apprenticed to a pattern drawer of brocaded silk, but subsequently took to painting, and gained high repute by his compositions for Bell's *British Poets* and the *Novelist's Magazine*. He was made a Royal Academician in 1794; and became librarian to the Royal Academy in 1812. His more important works were his "Canterbury Pilgrims," his "Flitch of Bacon," his "Fête Champetre," and his "Wellington Shield." He besides illustrated Boydell's *Shakspeare*, Roger's *Poems* and *Italy*, and the *Complete Angler* of Isaac Walton; as well as having designed part of the ceiling of the Signet Library in Edinburgh. His compositions number in all upwards of 5000, some 3000 of which have been engraved. He followed Mortimer somewhat slavishly at the outset of his career, but when he came to his maturity as a painter he displayed simplicity and grace in a high degree. He died in London on the 27th of April 1834. His life was written in 1851 by his daughter-in-law. He had a numerous family, of whom the most noted was Charles Alfred, noticed in the previous article.

STOURBRIDGE, a market-town of England, Worcestershire, on the left bank of the Stour, 23 miles N. by E. of Worcester, and 122 N.W. by W. of London. It is pleasantly situated on the slope of a hill; and as it consists, for the most part, of well-built houses, and is somewhat irregularly laid out, it has a picturesque appearance. The river, which here divides Worcestershire from Staffordshire, is crossed by a stone-bridge, from which the town derives its name. Stourbridge contains a large market-house, of modern erection, a neat brick parish church, and several dissenting places of worship. The Free Grammar School, founded here by Edward VI. in 1551, contained 44 scholars in 1854. This is one of the schools to which Dr Johnson was sent in his youth. Stourbridge has also an endowed national school and an infant school, a theatre, and an extensive public library. Races are held here annually. The clay of this town is much esteemed for its excellence in resisting the action of fire; it is made into crucibles, glass-house pots, and fire-bricks, and is exported in large quantities. Glass, earthenware, and hardware, are the principal manufactures of the town. A considerable trade is carried on, and is facilitated by the Staffordshire and Worcestershire Canal, which has a branch to Stourbridge, and by the railways which connect this town with all the other parts of the kingdom. Pop. 7847.

STOURPORT, a market-town of England, in the county and 10 miles N. by W. of Worcester, at the confluence of the Stour and the Severn; the latter river being here crossed by an iron bridge of one arch. It is quite a modern town, and is, for the most part, well built of brick. It has several churches and schools, a savings bank, and several benevolent institutions. Carpets and leather are made here, and there are an iron-foundry and a wool-spinning mill. A considerable trade is carried on in hops, corn, apples, coal, &c. Pop. 2993.

STOVE (Saxon, *Stofa*), a mechanical contrivance for heating public buildings, private apartments, green-houses, hot-houses, fruit-walls, &c. Under HEAT, the communication and radiation have been fully explained. By the former, the caloric is given from one object to another, and communicated from particle to particle of the same object *by contact;* by the latter, it emanates in straight lines, through the air, from substance to substance, the emanations being absorbed by some bodies, and reflected by others.

The power which objects possess of receiving and communicating heat by the former of these modes, is termed their *conducting power;* by the latter, their *radiating,* their *absorbing,* and *reflecting* power. Those which receive it quickly by the former, also give it off quickly in the same way; and those which radiate powerfully also absorb powerfully; of course they reflect little: accordingly the radiating and reflecting powers are opposed to each other. Metals are good conductors; stones, bricks, and porous bodies of a similar nature, are bad conductors. The radiating, reflecting, and absorbing powers depend not so much on the nature of the substance, as on the surface. Highly polished surfaces radiate and absorb little, while dark and rough ones radiate and absorb powerfully; of course, resplendent surfaces are good reflectors.

When fuel is consumed with the view of heating apartments, the communication of heat depends entirely on the manner in which it is consumed. In an open fire-place or common grate, the heat thrown into the apartment is chiefly that emitted by radiation and reflection; the former coming directly from the fuel, and from the parts of the fire-place warmed by it; the latter being the radiated heat reflected by the polished parts of the grate. The rays thus thrown off, being absorbed by the objects in the room, then communicate warmth to the atmosphere which it contains. But part of the warmth must also be received by communication; for the walls adjoining the fire-place being heated by *contact,* will likewise communicate caloric to the air brought in contact with them; and as it is expanded it will ascend, and allow other particles to flow in, also to receive their supply. This however is small in comparison to that given to the apartment by radiation and reflection.

Much of the heat thus thrown into the room is carried off, indeed may be said to be lost; for, owing to the manner in which the fuel is consumed, a large supply of air is necessary for the combustion, which, rushing in upon the fuel, is itself, after acting on it, carried up the vent. Hence, to warm apartments in this way, a great deal of fuel is required. The quantity must depend very much on the form of the fire-place, and on the materials of which it is constructed.

The principle on which stoves operate is different. A stove, however modified in form, is merely a fire-place enclosed on all sides; the air necessary for the combustion entering from below, and carried off, as in a common grate, by a vent. Now, in this way of consuming fuel, the radiation is trifling in comparison to the communication by contact. Of course much must depend on the kind of stove employed; but it is allowed, that by far the greater part of the heat which the atmosphere of the room receives is that given directly by communication; for the air in contact with the sides of the stove is heated, is expanded, and carried upwards; and thus, by the constant flow of cool air on the stove, the whole of that in the room is warmed. No doubt, the stove being itself warm, must give off heat, not only by contact, but also by radiation; and the proportion thus emitted must depend on the temperature and surface, as already explained. But though heat is thus distributed, yet it must be borne in mind, that it is chiefly by contact that the atmosphere of the room is warmed; and as the air is thus easily heated, much less fuel is required than when it is burned in an open fire-place. The necessary supply of air is therefore not so great; and it is this which principally causes the difference in our feelings when in a room warm-

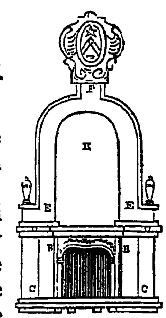
ed by a stove, and by a grate; for in the latter instance, not only have we the exhilarating influence excited by the blaze of the fuel, but there is a more rapid renewal of air through the apartment, and accordingly the atmosphere has not the close unpleasant feeling which it has when warmed by a stove.

The warming by stoves must therefore be conducted on principles different from those adopted in the employment of open fire-places. The general principle is, 1st, to employ the fuel in the most effectual manner for heating the external part of the stove, which is immediately efficient in warming the contiguous air, chiefly by contact; and, 2d, to keep within the room the air thus warmed, at least as much as is consistent with wholesomeness and cleanliness. It would occupy a volume to describe the immense variety of stoves which ingenuity has constructed. We shall content ourselves with giving a specimen of the two chief classes into which they may be distinguished.

The air of a room may be equally warmed by applying it either to the surface of a small stove made very hot, or to the surface of a much larger stove more moderately heated. The first kind is chiefly used in Holland, Flanders, and the milder climates of Germany and Poland. The last are used in the frozen climates of Russia and Sweden. The first are generally made of cast-iron, the last partly of iron and partly of brick-work.

Fig. 1 represents a small German stove, fully sufficient for warming a room of 24 feet by 18. The base is about three feet broad and fourteen inches deep, that is, from back to front, and six or seven feet high. The decoration is in the fashion of that country; but the operative structure of it will admit of any style of ornament. A is the fire-place, and the wood or charred coal is laid on the bottom, which has no bars. Bars would admit the air too freely among the fuel, and would both consume it too fast and raise too great a heat. That no heat may be uselessly expended, the sole of the fire-place and the whole bottom of the stove is raised an inch or two above the floor of the room, and the air is therefore warmed by it in succession, and rises upwards. For the same reason, the back of the stove is not in contact with the wall of the room, or of the niche in which it is placed. The fire-place is shut up by a door which fits closely to its case, and has a small wicket at the bottom, whose aperture is regulated by a sliding plate, so as to admit no more air than what suffices for slowly consuming the fuel. The flame and heated air rise to the top of the fire-place, three or four inches above the arch or mantle-piece, and get out laterally by two narrow passages B, B, immediately below the top-plate of the base. The current bends downward on each side, passes at C, C, under the partition-plates which divide the two side-chambers, and then rises upwards through the outer division of each, and passes through narrow slits D, D, in the top-plate, and from thence along the two hollow piers, E, E. The two lateral currents unite at the top of the arch, and go through the single passage F into the larger hollow behind the escutcheon G. From this place it either goes straight upwards into the vent in the wall by a pipe on the top of the stove, or it goes into the wall behind by a pipe inserted in the back of the stove. The propriety of this construction is very obvious. The current of hot air is applied to the exterior of the stove everywhere except in the two side-chambers of the base, where the partition-plates form one side of the canal. Even this might be avoided by making each of these side-chambers a detached hollow pillar. But this would greatly increase the trouble of construction and joining together, and is by no means necessary. The arch H has a graceful appearance, and affords a very warm situation for any thing that requires it, such as a drink in a sick person's bed-chamber, &c. Persons of a certain class use this place for keeping a dish warm; nay, the lower part of the arch is frequently occupied by an enclosed chamber, where the heat rises high enough even for dressing victuals, as will be easily imagined when we reflect that the sole of it is the roof of the fire-place.

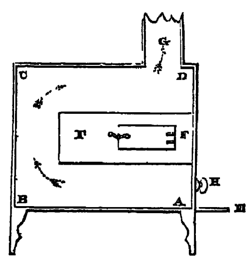
Fig. 1.



The stove now described is supplied with fuel and with air by the front door opening into the room. That there may be space for fuel, this middle part projects a few inches before the two side-chambers. These last, with the whole upper part of the stove, are not more than ten inches deep. The passages therefore from the fire-place are towards the back of it; so that if we have a mind to see the fire, which is always cheerful, the door may be thrown open, and there is no danger of the smoke coming out after the current has once warmed the upper part of the stove. When the stove is of such dimensions that the base is about two feet and a half or three feet high, the fire-place may be furnished with a small grate in the British style. If the door is so hung that it can not only be thrown back, but lifted off its hinges, we have a stove-grate of the completest kind, fully adequate, in our mild climate, to warm a handsome apartment, even with an open fire; and when we hang on the door, and shut up the fire-place, a stove of the dimensions already given is almost too much for a large drawing-room.

A very simple form of stove is that represented in the annexed cut. It consists of a square box of iron, A B C D, resting on feet, and having a projecting hearth-plate at E. FF is an inner box projecting into the outer one. G is the chimney. The fuel is burned at A; and the flame passes to the chimney around the inner box, which may be used as an oven for cooking. At H there is a large door for the introduction of the fuel, in which there is also a smaller door. Both of these are generally kept shut when the furnace is in use; but when a greater heat is required, the smaller door is opened.

Fig. 2.



The effect of stoves as now described may be greatly increased, as is frequently done, by having the mouth communicating with or joined to an opening of the same dimensions, formed in the wall; and the door is in this case on the other side of the wall, in an antechamber or lobby. In some places the apartments are disposed round a spacious lobby, in which the doors of all the stoves are situated, and through which the fuel and air necessary for the combustion are supplied. But this method, though it warms the apartment, is very unfavourable to health and cheerfulness; for the same air confined and repeatedly breathed, and adulterated with the volatile emanations of the room, loses the refreshing quality which is so desirable, and even so necessary for health.

Something of this kind, it has been already mentioned, is unavoidable in all rooms warmed by stoves; and the hotter the surface of the stove, the more and more unpleasant does the air in it become; because, in addition to the slight renewal of air consequent on their use, when the surface becomes very hot, the impurities constantly floating in the atmosphere are decomposed, and emit offensive effluvia. The stove already described is almost always made of metal, and this objection applies particularly to it; hence the necessity of being attentive when cleaning it outside, to avoid the contact of greasy or oleaginous matter, which is so easily decomposed by heat, and gives off offensive and deleterious vapours.

The objections stated to the stoves as now described, have given rise to the use of those constructed of brick-work, or other materials of a similar nature. These are much used in Flanders, Holland, and Germany, where they are made of the most elegant forms, and finely decorated; but it is evident that they cannot be so effectual, nor equally warm a room with the same expense of fuel; earthen ware being inferior to metal in its conducting power. In addition to this, they are liable to a very great objection, the difficulty of preventing their cracking when heated; for different parts of the stove being of different heats, they expand unequally; and no cement can be expected to withstand this, especially when we recollect, that the heat which causes the baked earthen ware to expand, causes a contraction of the clay or cement with which the parts of the stove are joined together. Accordingly stoves of this kind do not stand long without cracking, even when strengthened by iron hoops and cramps judiciously disposed within them; nor does hooping them externally prevent it. When a crack is thus occasioned, it is not only unsightly, but may be dangerous, from its allowing the vitiated air to escape into the apartment.

For these and other reasons, we can scarcely hope to make stoves of brick-work or pottery which shall bear the necessary heat without cracking; and their use must therefore be confined to cases where very moderate heat is sufficient. We need not describe their construction. It is evident that it should be more simple than that of iron stoves; and we imagine, that in the very few cases in which they are likely to be employed in this country, a single fire-place, and an arch over it, divided by a partition or two of thin tile to lengthen the flue, will be quite enough. If the stove is made in whole or in part of potter's ware, a base for the fire-place, with an urn, column, obelisk, or pyramid above it, for increasing the surface, will also be sufficient. The failure commonly happens at the joinings, where the different pieces of a different heat, and perhaps of a different baking, are apt to expand unequally, and by their working on each other, one of them must give way. Instead of making the joints close and using any cement, the upper piece should therefore stand in a groove formed in the undermost, having a little powdered chalk or clay sprinkled over it, which will effectually prevent the passage of any air; and room being thus given for the unequal expansion, the joint remains entire. This may be considered as a general direction for all furnace-work, where it is in vain to attempt to hinder the mutual working of the parts. When fitted up with these precautions, the brick or pottery stoves are incomparably more sweet and pleasant than the iron ones.

But in the intense colds of Russia and Sweden, or even for very large rooms in this kingdom, stoves of these small dimensions are not sufficiently powerful; and we must follow the practice of those countries where they are made of great size, and very moderately heated. It is needless to describe their external form, which may be varied at pleasure. We shall only enlarge a little on the peculiarities connected with the general principle of their construction.

The stove is intended as a sort of magazine, in which a great quantity of heat may be quickly accumulated, to be afterwards slowly communicated to the apartment. The stove is therefore built extremely massive, and is found to be more powerful when coated with clay as wet as can be made to hang together. We imagine the reason of this to be, that very wet clay, and more particularly stucco, must become exceedingly porous when dry, and therefore a very slow conductor of heat. Instead of sticking on the glazed tiles with no more clay or stucco than is sufficient to attach them, each tile has at its back a sort of box, baked in one piece, about two or three inches deep. It is represented in fig. 3. This is filled with mortar, and then stuck on the brick-work of the stove, which has a great number of iron pins or hooks driven into the joints, which may sink into this clay and keep it firmly attached when dry. This coating, with the massive brick-work, forms a great mass of matter to be heated by the fuel. The lowest chamber, which is the fire-place, is somewhat wider, and considerably thicker than the stories above, which are merely flues. When the fire-place is finished, and about to be arched over, a flat iron bar of small thickness is laid along the top of the side-wall on both sides, a set of finishing bricks being moulded on purpose, with a notch to receive the iron bar. Cross bars are laid over these, one at each end and one or two between, having a bit turned down at the ends, which takes hold of the longitudinal bars, and keeps them from being thrust outwards either by the pressure of the arch or by the swelling in consequence of the heat. In fig. 4, A is the cross section of one of the long bars, and BC is part of one of the cross bars, and CD is the clench which confines the bar A. This precaution is chiefly necessary, because the contraction of the stove upwards obliges the walls of the other stories to bear a little on the arch of the fire-place. The building above is kept together in like manner by other courses of iron bars at every second return of the flue. The top of the stove is finished by a pretty thick covering of brick-work. The last passage for the air has a ring lining its upper extremity, and projecting an inch or two above it. The flat round it is covered with sand. When we would stop this passage, a cover shaped like a basin or cover for dishes at table is whelmed over it. The rim of this, resting on the sand, effectually prevents all air from coming through and getting up the vent. Access is had to this damper by a door which can be shut tight enough to prevent the heated air of the room from wasting itself up the vent. When the room is too warm, it may be very rapidly cooled by opening this door. The warm air rushes up with great rapidity, and is replaced by cool air from without.

Fig. 3.

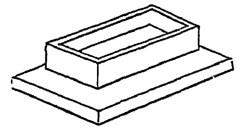


Fig. 4.

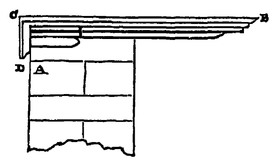


In a stove of this kind the fire is kindled early in the morning, after which the stove-door is shut, and the air-aperture below left open for some time to blow it up; but in the course of a short time, to prevent the too rapid consumption of the fuel, the fire-door is opened, by which the draught is checked. In this way the combustion is allowed to go on, and the materials of the stove become warmed, after which the air-passages are shut, so as to prevent any abstraction of heat by the current that would otherwise be occasioned. The stove thus becomes a great mass of heated matter, which is gradually pouring warmth into the apartment during the whole of the day; and as the temperature of the surface never becomes very high, the impurities in the atmosphere are not decomposed, and consequently it is free from those offensive effluvia unavoidable when metal stoves are used. One precaution, however, is necessary in the management of these stoves, which does not apply to the metal ones; we must take care that when the air-apertures are closed, there is no back-draught to carry the products of combustion into the apartment, which might be attended with fatal consequences. These being almost free from smoke, give little or no warning of their presence, and when inhaled for some time, produce giddiness and lassitude, and in some cases a dangerous state of insensibility. Hence the necessity of allowing the fire to be burned down, or nearly so, before closing the air-aper-

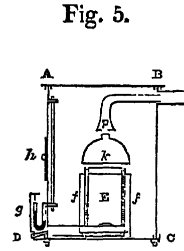
tures. Should the escape of the noxious gases into the room be suspected, the furnace-door and air-apertures must be opened, and a draught established through the stove, by kindling some wood shavings in it, the door and windows of the room being at the same time thrown open. This attention to back-draught is of course more necessary when charcoal or coke is used instead of coal, the products of combustion being then entirely free from smoke. When coal is used in stoves, the vent-tubes are apt to become choked with soot; but this may in a great measure be prevented by giving for a short time every day a brisk draught, by which the soot will be burned.

To prevent the injurious or disagreeable effects of the first kind of stoves, and at the same time to secure their advantages, numerous modifications have been proposed, not only with the view of preventing the too great heat of the external surface, but also of avoiding unnecessary expenditure of fuel. Perhaps the most important of these is *Arnott's stove;* the principle of which consists in allowing the fuel to burn very slowly, the admission of air for the combustion being regulated by an adjustment connected with the stove, and influenced by the degree of heat produced. Numerous forms and modifications of this stove are now in use, but in their general structure they are the same. The stove consists of a square or cylindrical box of iron, generally lined inside with a thick layer of fire-clay, and having a grating near the bottom, on which the fuel is burned; or the fuel may be contained in a small fire-box within the stove. Sometimes the fuel is burned within a hollow cylinder of fire-clay, in which case the stove is not lined with it. There is an ash-pit below for the reception of the ashes, and the products of the combustion are, as usual, carried off by a vent.

The principal feature of this stove is the contrivance by which the air is admitted for the combustion. When the stove-door or ash-pit door is open, the combustion is lively, and the fuel is soon consumed; but when these are shut, and they ought to be so made as to shut quite close, then air must be admitted otherwise, and this is done by the air-tube, furnished, as already stated, with a regulator.

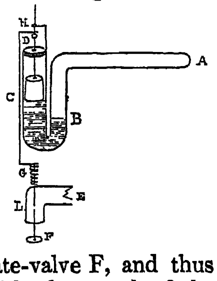
The annexed figure represents the stove of its simplest form. ABCD is the outer casing of iron, in which there is the fire-box E, with its grating. Over the fire-box there is a dome, *k*, with a funnel to carry the products of combustion into the chimney; *h* is the stove-door, and *g* is the *thermometer regulator*, or adjustment by which the air is admitted for combustion. A great variety of these regulators has been described. Perhaps the best of these is represented by the annexed cut.

Fig. 5.



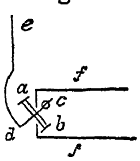
ABC is a glass tube, shut at A, containing air from A to B, and filled with mercury from B to C. On the mercury at C is placed a float, from which there proceeds an upright rod D, kept steady by passing through a support at H. From this upright wire there descends another, FGH, terminated by the plate-valve F. LE is the air-tube of the stove. When the heat within is great, the air in the shut limb of the regulator at A is expanded, and forces up the mercury at C, raising the rods and plate-valve F, and thus bringing it near to, or in contact with, the mouth of the tube, by which more or less air is admitted to the stove, according to the heat within. If the combustion is proceeding too slowly, then the air in the tube A is not much expanded, consequently air is allowed to enter the stove more freely; but when, owing to this, the combustion becomes lively, and the temperature too high, then, by the elevation of the plate-valve, air enters in smaller quantity, and the temperature is moderated. Instead of the flat plate a conical valve is sometimes used, which, passing more or less into the mouth of the tube, allows the passage of less or more air; and sometimes this contrivance is resorted to.

Fig. 6



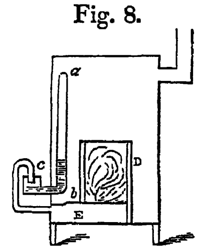
ed is the wire raised by the movement of the mercury; *ab* is a plate hung on an axis within the air-tube, and acting like a throttle-valve. When the edge of the plate is turned to the current, air is admitted freely; but when the heat becomes high, then the mercury rises and makes the plate revolve, by which more and more of the area of the tube is shut, and consequently less and less air is admitted.

Fig. 7.



Perhaps the simplest of these regulators is that here represented. *abc* is a bent tube shut at *a*, where it contains air, and open at *c*, where it is cup-shaped. The bent part at *b* is occupied by mercury. From *c* there proceeds a bent tube to supply air to the stove. When the heat within is great, the air in *a* is expanded, and forces the mercury up in *c*, and thus, bringing it in contact with the mouth, prevents the free admission of air to the stove. Numerous other contrivances of a similar nature have been recommended, all acting in the same way. Instead of these, the admission of air is sometimes regulated by a semicircular slide over the mouth of the air-tube, which may be placed so as to admit to the stove a greater or smaller quantity, as occasion requires.

Fig. 8.



The principle on which this stove operates, whatever modification of it may be used, is merely the slow combustion of the fuel, by which the stove itself is warmed; and there is thus a reservoir of heat to be communicated to the air in the apartment. As the quantity of fuel consumed is small, there is no necessity for frequent supply. When one of the ordinary dimensions for a room is in use, it will require to be supplied morning and evening, supposing that it is kept constantly burning, and the ashes removed once a day. These, instead of falling into the ash-pit, may be received in a box placed there for the purpose, which is taken out and emptied, so as to avoid dust in the apartment.

The quantity of fuel consumed must of course depend on circumstances. During the severe winter of 1836–37, Dr Arnott kept his library at a temperature varying from 60° to 63° of Fahrenheit, by about six pounds of coal a day; which, supposing the coal to be twenty shillings per ton, is at the daily expense of less than a penny.

Though the Arnott stove answers well the purpose for which it is intended, that is, economy of fuel, for most undoubtedly a room may be kept warm at a very moderate expense, yet it is liable to the objection already stated with regard to the unpleasant feeling consequent on the use of all stoves of the kind, and indeed with it more than others; for, owing to the very slight expenditure of fuel, there is little or no change in the atmosphere. It is generally allowed that a pound of coal on an average requires about 150 cubic feet of air for combustion; but as part of the air passes off without being acted on, 200 may be allowed, and this is a large allowance where the combustion is going on so slowly as in the stove. Now suppose the apartment in which the stove is placed to be fifteen feet long by twelve wide and eleven in height, its cubic contents are 1980 feet; and suppose six pounds of coal per day to be the consumption, each pound requiring about 200, that is in all 1200 feet of air for combustion. This quantity must pass through the stove and be carried off by the vent, so

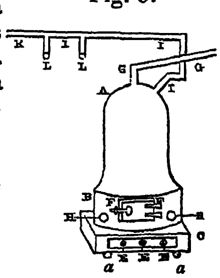
that in the course of twenty-four hours the atmosphere of the apartment is not once completely changed, and consequently renewed, by the direct influence of the fire. Hence it is that the apartment is so easily warmed; but it is this which necessarily renders it so unpleasant.

These stoves, however, fell out of use on account of another circumstance. Our readers will see the whole of the action of the self-regulator was due to the expansion and contraction of the mercury in the tube ABC, fig. 6; but mercury is a very volatile substance, and the constant heat of the stoves caused a daily loss of mercury, and consequent imperfection in the action of the regulators. This was attempted to be remedied by tightening the collar at D; but the resistance thus offered to the use of the float by the expansion of the volume of the mercury frequently caused the tube to burst, and scattered its contents about the room. The most valuable feature of the Arnott stove, the making the fire-box itself of fire-clay, however, is still in frequent use in the modern German stoves.

The stoves now described answer for small apartments. When the place to be heated is large, or when several apartments in the same building are to be warmed, a different kind is used. The heat in these cases is in general not communicated to the apartment or apartments by the direct influence of the stove, but by air heated by its external surface (of course not brought into contact with the fuel), and then conveyed by tubes or otherwise to the places to be warmed, on the principle already illustrated, that when heated it expands and ascends, and consequently rushes along the tubes, the supply being kept up by the constant flow of cold air upon the hot sides of the stove. Stoves for this purpose are made of iron or of brick-work, and sometimes of both. Fig. 9 represents a cast-metal stove of this kind. It may be considered as a double stove; an outer case, and a furnace or inner stove. The fuel is burned in the inner stove, and the smoke produced during the process of combustion is carried off by a chimney, which passes through the top of the outer stove, and is conveyed to the outside of the building. The outer case includes not only the furnace or inner stove, but also a considerable space, occupied by the air of the atmosphere, which is freely admitted through a number of openings placed around it; and when any current of air is produced, it passes off from the space between the outer case and inner stove, and is conveyed by tubes through the body of the apartment. But we shall first describe the different parts of which the stove is composed, after which we shall be better able to understand its mode of operation.

Fig. 9 exhibits a perspective view of this stove. AB is the body, which is about three feet high, and of a circular form. C is a square pedestal, on which the stove is placed, and which contains the ash-pit. The height of the pedestal is about a foot, and it is nearly insulated by resting on the spherical supports *a a*, also of cast-iron. EEE are openings in front of the ash-pit, through which the air enters to support the combustion. These openings can be enlarged or diminished, or opened and shut at pleasure. FF is the door of the furnace, through which the fuel is introduced. This door is attached to the inner furnace, and is double. It is one foot broad, and eleven inches high. GG is the chimney, which passes from the furnace within, through the outer case, and conveys the smoke out of the building. HH are openings in the outer case, and are eight in number, through which the air enters, and being heated, is greatly rarified, and passes off through the funnel or pipe III. This pipe communicates only with the outer stove, and being shut at

Fig. 9.



the end K, the air rushes out from the small tubes LL, inserted into the side of the pipe III, and thus mixes with the cold air of the apartment. The diameter of the outer case at the bottom is about two feet, and the diameter of the furnace within is about sixteen inches.

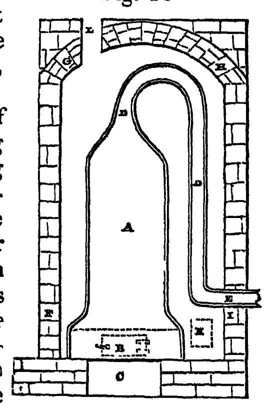
The length of the body of a church in which two stoves of the form and dimensions now described are erected, is about sixty feet, and the breadth is about forty-five feet. The tubes III are conveyed along the lower edge of the gallery, about half the length of the church. The fires are lighted about four or five o'clock on the Sunday morning during the earlier part of the cold season; but as the season advances it is usual to light them earlier. From this time till the congregation assembles for the afternoon service, the furnaces are constantly supplied with fuel. By this management the air in the church is kept comfortably warm during the coldest season of the year.

When only one apartment is to be heated by a stove of this kind, the stove ought to be placed in the apartment, because then it is supplied with air from it, which has been previously heated; whereas, when it is placed in another situation, the supply of heated air thrown into the apartment being derived from without, that within must be forced out to make way for it, and subsequently at a great expenditure of fuel. When several apartments are to be warmed, suppose those of a dwelling-house, the stove ought to be situated in some part of the lobby, from which the tubes proceed to the rooms. Of course the size of the stove, and the distribution and size of the tubes, must depend on the supply of heat required.

There is one very great objection to the stove as now described. It has been already stated, that when air is projected against a red-hot surface, the impurities constantly floating in it are burned, and emit offensive effluvia; and this is generally the case with metallic hot-air stoves. Hence the necessity of having them so placed that they shall be supplied with air as free as possible from impurities. Instead of having the whole of the stove made of metal, the inner part is sometimes metal and the outer covering brick-work; in which case the chamber between them is generally larger than in the others, consequently the temperature does not become so high, and the objection urged against the metal stoves is in a great measure removed.

The annexed figure represents a vertical section of a stove of this kind. A is the stove of metal, with the door at B and ash-pit at C. DD is the vent, making a turn downwards, and carried into the chimney at E. FGHI is the outer casing of brick-work, completely enclosing the stove, and also the descending part of the vent; K is the opening for the admission of air to the hot chamber. L is the tube for carrying off the warm air, and from this it is conveyed by other tubes to the rooms to be heated. The stove from which this figure is taken is two feet and a quarter in width, six feet in height, and the sides three-fourths of an inch in thickness. The brick casing is at the distance of six inches from the metal, and the descending vent within is six inches in diameter. It is used for warming a lecture-room thirty-five feet long, twenty-seven feet broad, and twenty high, also a large apartment thirty feet long, twenty-seven broad, and eighteen high, besides two smaller rooms and a staircase. The fire is kindled during winter at seven in the morning, and kept burning till four in the afternoon, when it is allowed to go out. The

Fig. 10



quantity of coal amounts daily, on an average, to rather less than half a hundredweight. The temperature of the air from the tubes varies from 120° to 180°, according to the state of the fire. The temperature of the different apartments is kept at about 60°. When first erected, the supply of air for the hot chamber was brought from without; but now the air for the fuel and for the hot chamber are both taken from the apartment in which the stove is placed, which is generally at the temperature of 70°.

When the place to be heated is spacious, or when there are several apartments, it is customary to have the part of the stove immediately exposed to the fire lined with fire-brick, in order to prevent the direct action of the fuel on the metal; for in these instances the stove is much larger than that described, and consequently the fire more powerful. Its size must depend on the size and number of the apartments. In its general construction it resembles the other, consisting of the inner part for the fuel, with its grating, ash-pit, and vent, and of the outer casing, with the aperture for the supply of air to the chamber, and the tube or tubes for its transmission to the apartments.

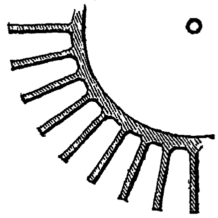
The great advantage attending the use of stoves of this kind is, that they do not become so warm as to decompose the impurities in the air flowing into the hot chamber, and consequently there are no offensive effluvia generated. As the temperature is not so high as that of metal stoves, more of the warm air is requisite, by which there is a frequent renewal of that in the apartment, and the temperature throughout is more uniform than when a smaller quantity of hotter air is admitted. It has already been mentioned that the temperature of the air from the hot chamber of the stove described is from 120° to 180°. Perhaps this is higher than it ought to be. Many prefer having the stove so constructed that the temperature of the air which it throws into the apartment shall not exceed 70°. Of course, in this case, a much larger quantity of it is necessary. By throwing in a sufficient supply, that of the apartments may be maintained at about 60°. The mouths of the hot air-tubes are made to terminate as near the floor as possible, that the air may rise, and gradually mix with the atmosphere of the apartment.

In erecting stoves for the supply of hot air in this way, there are many circumstances to be considered, to which it would here be useless to allude. Much must depend on local situation, the size and number of the apartments, and the draught through them. These considerations must be left to the skill and ingenuity of the workman, who must be guided by keeping in view the general principles which determine the supply of air to the furnace, the ascensional force of the column of warm air to be conveyed through the tubes, the manner in which the apartments to be warmed are disposed, &c.

In heating buildings by these stoves when they are not in constant use, as is the case in churches, the time for keeping them going must also depend on circumstances. If the object is merely to throw in a supply of warm air, then the stove must be kindled a few hours before the apartment is to be occupied, especially if it is not expected that there shall be much change in its atmosphere; but if the object is to keep the place warm, then the stove ought to be kept in constant use, so as to be constantly throwing in warm air. During night the fire can be banked up, and it is again made brisk when required. This is much better than allowing the fire to go out, because in again heating the stove to the requisite temperature, there must be a considerable waste of fuel. After the fire is in good condition, and the stove well heated, the combustion should be allowed to proceed slowly, which is accomplished by the proper regulation of the draught.

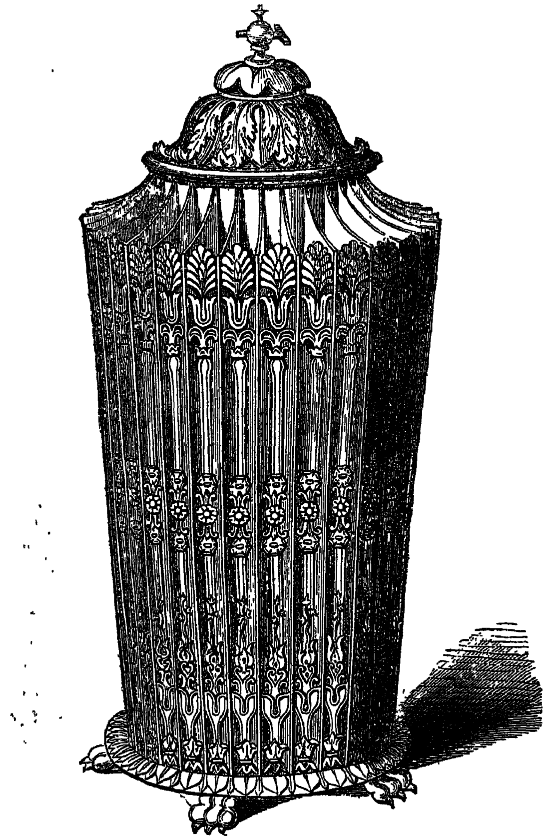
One of the most ingenious adaptations of iron, for the purposes of heating rooms, is that of the late Mr John Sylvester, although the medium conveying the heat is water. It is generally in the form of a cylinder, or part of a cone (fig. 11), from which cone radiate a number of plates (see the plan of one quarter of the stove, fig. 11), which resemble the gills of a fish, from which circumstance it is generally called the "gill stove." The whole is of iron, cast in one piece. The hot water circulates inside the cylinder. The use of the gills is to afford as large a radiating surface as possible, and to diffuse heat as soon as it is communicated, in the smallest degree, to such surface. The consequence is, the air in contact with the iron is only warmed, and never burned. Although this stove has hitherto been used with water, it seems very probable that it would succeed with coal or coke, if it had an internal fire-box of burned coke, and proper doors, vents, &c.

Fig. 11.



There can be no question, as before stated, that there is nothing so comfortable or so healthy as an ordinary open fire-place; and it is to be doubted, after all, whether by attention and management of the supply of fuel, and judicious stirring, there is such extra expense about them. But open fires require proper chimney places and flues, and will only consume fuel of good quality, while stoves will burn almost any thing. If, however, we construct our stoves so as almost to make them furnaces, we lose from two causes—the too rapid consumption of fuel, and the rapid draught of air, which carries a great quantity of heat up the chimney.

Fig. 12.



One of the best adaptations of these principles, however, is to be found in the stoves invented by Messrs Featham of Clifford Street, London. These are in the form of an ordinary register stove, with the usual grate, fire-bars,

&c., but the back and cheeks are of fire-clay. In the front of the stove there is a sort of iron shutter, sliding in a groove like a sash window, which can be drawn quite down to the front of the fire, and cause an action of the draught like that of a furnace, or it may be thrown quite up, in which case the action is that of a simple register stove. For recent continental improvements, the reader is referred to Peclet's *Traité de la Chaleur*.

STOW, JOHN, an industrious historian, son of Thomas Stow, merchant-tailor, of St Michael's, Cornhill, in London, was born about the year 1525. Of the early part of his life we know very little, except that he was bred to his father's business, which, in the year 1560, he relinquished, devoting himself entirely to the study of our ancient historians, chronicles, annals, charters, registers, and records. Of these he made a considerable collection. But this profession of an antiquary being attended with no present emolument, he was obliged for subsistence to return to his trade. It happened, however, that his talents and necessities were made known to Dr Parker, archbishop of Canterbury, who, being himself an antiquary, encouraged and enabled Stow to prosecute his darling study. In those times of persecution, though Elizabeth was then upon the throne, John Stow did not escape danger. His collection of popish records was deemed a cause of suspicion. His younger brother Thomas preferred no less than 140 articles against him before the ecclesiastical commission; but the proof being insufficient, he was acquitted. In 1565 he first published his *Summary of the Chronicles of England*. About the year 1584, he began his *Survey of London*. In 1585 he was one of the two collectors for a great muster of Limestreet ward. During the same year he petitioned the corporation of London to bestow on him the benefit of two freemen, to enable him to publish his *Survey;* and in 1589 he again petitioned for a pension. Whether he succeeded is not known. He was principally concerned in the second edition of Holinshed's *Chronicle*, published in 1587. He also corrected and twice augmented Chaucer's *Works*, published in 1561 and in 1597. His *Survey of London* was first published in 1598. To these laborious works he would have added his large Chronicle, or History of England; but he lived only to publish an abstract of it, under the title of *Flores Historiarum, or Annals of this Kingdom, from the time of the Ancient Britons to his Own.* This work was printed in 1600. The folio volume, which was printed after his death, with the title of Stow's *Chronicle*, was taken from his papers by Edmund Howes. Having thus spent his life and fortune in these laborious pursuits, he was at last obliged to solicit the charitable and well-disposed for relief. For this purpose King James I. granted him, in 1603, a brief, which was renewed in 1604, authorising him to collect in churches the benefactions of his fellow-citizens. He died in April 1605, aged eighty; and was buried in his parish church of St Andrew Undershaft, where his widow erected a monument to his memory. John Stow was a most indefatigable antiquary, a faithful historian, and an honest man.

STOWMARKET, a market-town of England, in the county of Suffolk, in a valley on the Gipping, 12 miles N.N.W. of Ipswich, and 75 N.E. of London. It has one main street, and many substantially built houses. The parish church is a fine old building of the thirteenth century, partly in the early English, and partly in the decorated style; the spire, 120 feet high, is modern. The Baptists, Methodists, and Independents have places of worship here; and education is provided for by national and other schools. Stowmarket has a handsome court-house, a large corn-exchange, a news-room, and a mechanics' institute. It is an active, bustling place, and has some important manufactories, including several malt-houses, an iron-foundry, and a rope-work. In the immediate neighbourhood there are hop-grounds and brick-fields. The river is navigable up to the town; and by its means timber, coal, and slate are conveyed up from Ipswich. The markets, which are held weekly, are well supplied with corn, cattle, and other goods; and there are at Stowmarket three annual fairs. Pop. 3161.

STRABANE, a market-town of Ireland, in the county of Tyrone, on the Mourne, 20 miles N.N.W. of Armagh, and 130 N.N.W. of Dublin. It is very irregularly built on the right side of the river; and the older part of the town consists for the most part of very mean and wretched houses; but there have been formed some new and much better streets, lined with good houses and shops. The parish church is a fine cruciform edifice in the Grecian style. Besides this, there are places of worship for Presbyterians and Methodists, several schools, a court-house, jail, dispensary, hospital, and workhouse. The manufacture of linen is carried on to a considerable extent here; and in former times Strabane was one of the chief seats of this branch of industry. There is also a large brewery, and a considerable trade is carried on in grain and provisions. A canal from Strabane to the Foyle facilitates the commercial intercourse between this town and Londonderry. Pop. 4925.

STRABO, an illustrious geographer, was born at Amasia, a city of Capadocia. The time of his birth cannot be ascertained, but he is known to have flourished during the age of Augustus and Tiberius. Some writers have fixed his birth about 66 B.C., and Clinton makes it occur not later than B.C. 54. He studied grammar and rhetoric under Aristodemus, at Nysa, in Caria; philosophy under Xenarchus, a peripatetic; and he took lessons from Tyrannis of Amisus. Influenced by the authority, probably, of Boethus of Sidon, who had been his preceptor, he adopted the tenets of the Stoics. He obtained the friendship of Cornelius Gallus, governor of Egypt. Strabo composed a history in 43 books which, unfortunately, is now lost. In order to collect materials for his great work, he travelled in many different regions, and after much toil and research completed his *Geography*, which is justly regarded as a very precious relic of antiquity. It consists of seventeen books, all of which are not, however, entire. The first two books are employed in showing that the study of geography is not only worthy of, but even necessary to, a philosopher; the third describes Spain; the fourth, Gaul and the Britannic Isles; the fifth and sixth, Italy and the adjacent isles; the seventh, which is imperfect at the end, Germany, the countries of the Getæ and Illyrii, Taurica Chersonesus, and Epirus; the eighth, ninth, and tenth, Greece with the neighbouring isles; the four following, Asia within Mount Taurus; the fifteenth and sixteenth, Asia without Taurus, India, Persia, Syria, Arabia; and the seventeenth, Egypt, Ethiopia, Carthage, and other countries of Africa. Groskurd fixes his death to the year A.D. 24.

Strabo's *Geography* first appeared in a Latin version, executed by Phavorinus and Tifernas, and printed at Rome by Sweynheym and Pannartz. It is an ample folio volume, without date, but is supposed to have been printed in or about the year 1469. The earliest edition with a date is that of Venice, 1472, fol. The *editio princeps* of the Greek text proceeded from the press of Aldus, Venet., 1516, folio. This edition, which is not distinguished by its accuracy, was succeeded by that of Hopper and Heresbach, Basil., 1549, fol. An edition, containing an elegant version, with notes and castigations, was next produced by Xylander, Basil., 1571, fol. The next edition was by Casaubon, Genev., 1597, fol. By the aid of four MSS. and of his own critical sagacity, he greatly improved the Greek text. He retained the version of Xylander. He afterwards augmented and improved his annotations, and the work was reprinted at Paris in 1620, after the death of the learned editor. This second edition of Casaubon, together with the notes of various other critics, was repub-

lished by T. Janson van Almeloveen, Amst., 1707, fol. He has subjoined the *Chrestomathiæ*, or epitome of Strabo, which, according to Dodwell, was compiled by some unknown writer, between the years 976 and 996 A.D. It had been found of some use, not only in contributing to the correction of the text, but likewise in supplying to a certain extent the defect of the seventh book. An elaborate and valuable edition of Strabo was commenced by Siebenkees, and completed by Tzschucke, Lipsiæ, 1796-1819, 7 tom. 8vo. Much was expected from the edition of Falconer, Oxon., 1807, 2 tom. fol. It was one defect of the editor that he was not sufficiently acquainted with the labours of the continental critics. Nor must we overlook an edition of the text, illustrated with Greek notes by Coraÿ, Paris, 1815, 4 tom. 8vo. Strabo was translated into German by Penzel, 4 vols. 1775. A French translation was undertaken by command of the emperor, and was executed by De la Porte du Theil, Coraÿ, and Letronne. The introduction, and the notes distinguished by the letter G, were contributed by Gosselin, Paris, 1805-19, 5 tom. 4to. Kramer has also published an edition of the *Geography* of Strabo, in three vols. 1844-52, with notes by Meineke, 3 vols., Leipsic, 1852. An excellent German translation of it is by Groskurd, 4 vols., Berlin, 1831-34. A recent English translation of the work is by Falconer and Hamilton, in 3 vols., 1854-57.

STRADA, Famiano, an ingenious and learned Jesuit, was born at Rome in the year 1572, and there taught rhetoric for fifteen years. He wrote several pieces upon the art of oratory, and published some orations with the view of illustrating by example what he had inculcated by precept. But his *Prolusiones Academicæ* and his *Historia de Bello Belgico* are the works which raised his reputation and have preserved his memory. His *History of the War of Flanders* was published at Rome, the first decade in 1640, the second in 1647, the whole extending from the death of Charles V., which happened in 1558, to the year 1590. His *Prolusiones Academicæ* show great ingenuity, and a masterly skill in classical literature; that prolusion especially in which he introduces Lucan, Lucretius, Claudian, Ovid, Statius, and Virgil, each of them versifying according to his own strain. This work has often been printed. Strada died at Rome in the Jesuits' College in the year 1649.

STRADBALLY, a market-town of Ireland, Queen's county, 44 miles S.S.W. of Dublin. It contains a handsome parish church, places of worship for Roman Catholics, Wesleyan, and Primitive Methodists, several schools, a court-house, and a dispensary. Pop. 1326.

STRAFFORD, Earl of. See Wentworth, *Thomas*.

STRAHAN, William, an eminent printer, was born at Edinburgh in the year 1715. After having passed through the tuition of a grammar-school, he served an apprenticeship to a printer, and when a very young man removed to a wider sphere in that line of business, and went to follow his trade in London. His abilities in his profession, accompanied with perfect integrity and unabating diligence, enabled him, after the first difficulties were overcome, to advance with rapid success. And he was one of the most flourishing men of the trade, when, in the year 1740, he purchased a share of the patent for king's printer, of Eyre, with whom he maintained the most cordial intimacy during the rest of his life. Never had such rewards been given to the labours of literary men as were received from him and his associates in their purchases of copyrights. Having now attained the first great object of business, wealth, Strahan looked with a very allowable ambition on the stations of political rank and eminence. Politics had long occupied his active mind, and he had for many years pursued them as his favourite amusement, by corresponding on that subject with some of the first men of the age. Strahan's queries to Dr Franklin in the year 1769, respecting the discontents of the Americans, published in the *London Chronicle* of 28th July 1778, show the just conception which he entertained of the important consequences of that dispute, and his anxiety to investigate, at that early period, the proper means by which their grievances might be removed, and a permanent harmony restored between the two countries. In the year 1775 he was elected a member of parliament for the burgh of Malmesbury, in Wiltshire, with a very illustrious colleague, Mr Fox; and in the succeeding parliament, for Wooton Basset, in the same county. In this station, applying himself with that industry which was natural to him, he was a useful member, and attended the house with a scrupulous punctuality. When parliament was dissolved in 1784, Strahan was not again returned for the borough he had previously represented, and his declining health induced him to retire from political life. He died on the 9th of July 1785, in the seventy-first year of his age.

STRAIT, a narrow passage or channel connecting two larger portions of water together.

STRALSUND, a fortified town of the Prussian monarchy, in the province of Pomerania, capital of a government of the same name, formerly of the whole of Swedish Pomerania, on the strait between the island of Rügen and the mainland, 120 miles north by west of Berlin. It is entirely surrounded by water, and only approached by three bridges, which connect it with as many suburbs on the mainland opposite to the town. It is an old-fashioned town, and somewhat gloomy in its appearance; the streets are very narrow and irregular, but for the most part clean and well paved. The principal buildings are the town-hall, a fine old building with seven pinnacles; and the churches of St Nicholas and St Mary, the former of the thirteenth and the latter of the fourteenth century, and both fine specimens of the pointed style of architecture, similar to the churches of Lübeck. Near one of the city-gates there is a stone built into the wall which marks the place where Charles XII. of Sweden used to spend the night when defending Stralsund against the kings of Prussia, Poland, and Denmark, in 1715. Besides the two already mentioned, Stralsund contains four other churches, one of which has two celebrated paintings by Tischbein. There is also a government-house, a town-hall containing a public library, a gymnasium with a museum and library, a school of navigation, a lunatic asylum, orphan hospital, and workhouse. The manufactures of the town are numerous, including ship-building, and the making of woollen and linen cloth, starch, sugar, tobacco, soap, candles, leather, &c. An active trade is carried on; and the harbour, which is good, though somewhat encumbered with shoals, is much frequented by vessels. Wheat, malt, timber, wool, and linen are the chief articles of export. Stralsund was founded in 1209 by Jaromar I., Prince of Rügen, and it soon rose to a high degree of prosperity, as a free imperial town and a member of the Hanseatic League. In the Thirty Years' War it successfully resisted the arms of Wallenstein, who besieged it in 1628, determined, as he expressed it, to take the place "though it were bound to heaven with chains." The brave defence of the citizens, supported by the Danes and Swedes, compelled the Imperial general to raise the siege, after a loss of 12,000 men. In 1678 Frederick William of Brandenburg bombarded and took the town from the Swedes, who had gained possession of it by the peace of Westphalia in 1648. It was, however, restored to Sweden in 1679. In 1715 Stralsund was besieged by the Prussian, Danish, and Saxon forces, and was compelled to surrender. Again, however, in 1720 it was given back to Sweden. In 1807 it was surrendered to the French, who destroyed its fortifications. It was in Stralsund that Schill, a German who attempted to deliver his country from the French, lost

his life in 1808. The place where he fell is still marked in one of the streets, and his body lies in one of the churchyards, without the head, which is now at Brunswick. In 1810 Stralsund was ceded to Denmark, and in 1815 to Prussia. The fortifications have been since restored. Pop. 20,333.

STRANGE, Sir Robert, an eminent line-engraver, was descended from the family of Strange or Strang, of Balcasky, in Fife, and was born in the island of Pomona, in Orkney, on the 14th of July 1721. Having early displayed a taste for drawing, he was apprenticed to Richard Cooper of Edinburgh, where he gave great satisfaction to his employer, and awakened in his friends the highest expectations of his future success.

In the year 1747 he married Isabella, only daughter of William Lumsden, son of Bishop Lumsden; and soon after his marriage he went to France, where with the most ardent application he prosecuted his studies, chiefly at Paris, under the direction of the celebrated Le Bas, who engraved many excellent prints from the Dutch painters. It was from Le Bas that he had the first hint of the use of the instrument commonly called the *dry needle*, but which he afterwards greatly improved by his own genius, and which has added such superior beauties to his engravings. In the year 1751 Strange removed with his family from Edinburgh and settled in London, where he engraved several fine historical prints. He set out for Italy in 1760. He there made many admirable drawings, several of which he afterwards engraved. He was chosen a member of the academies of Rome, Florence, and Bologna, and professor in the Royal Academy at Parma. The ceiling of the room of the Vatican library at Rome, in which the collection of engravings is kept, represents the progress of engraving; and the portraits of the most eminent artists in that line are there introduced, among which is that of Strange. Under his arm he holds a portfolio, on which his name is inscribed. In France, where he resided many years at different periods his talents were likewise appreciated. He was chosen a member of the Royal Academy of Painting at Paris. He settled in London in 1751, and soon became the first historical engraver in England. He received the honour of knighthood on the 5th of January 1787.

Such was Sir Robert Strange as an artist; nor was he less distinguished by his truly amiable moral qualities, which endeared him to all who had the happiness to know him. With regard to his works, he left fifty capital plates, which have been carefully preserved in his family. They are engraved from pictures by the most celebrated painters of the Roman, Florentine, Lombard, Venetian, and other schools. They are historical, both sacred and profane. Sir Robert carefully preserved about eighty copies of the finest and most choice impressions of each plate he engraved; which, from length of time, have acquired a great beauty, mellowness, and brilliancy. He did this with a view of presenting them to the public at a period when age should disable him from adding to their number. These he collected into as many volumes, and arranged them in the order in which they were engraved. To each volume he prefixed two portraits of himself, on the same plate, the one an etching, the other a finished proof, from a drawing by John Baptiste Greuse. This is the last plate which he engraved, and is a proof that neither his eyes nor hand were impaired by age. It likewise shows the use he made both of aquafortis and the graver. Each volume, besides a dedication to the king, contains an introduction on the progress of engraving, and critical remarks on the pictures from which his engravings are taken. These volumes were ready to be given to the public, when Sir Robert's death delayed this magnificent publication. He died at London 5th July 1792.

The following is an authentic catalogue of his works:—"Two Heads of the Author," one an etching, the other a finished proof, from a drawing by John Baptiste Greuse; "The Return from Market," by Wouvermans; "Cupid," by Vanloo; "Mary Magdalen," by Guido; "Cleopatra," by the same; "The Madonna," by the same; "The Angel Gabriel," by the same; "The Virgin holding in her hand a book, and attended by angels," by Carlo Maratt; "The Virgin with the Child asleep," by the same; "Liberality and Modesty," by Guido; "Apollo rewarding Merit and Punishing Arrogance," by Andrea Sacchi; "The finding of Romulus and Remus," by Pietro da Cortona; "Cæsar repudiating Pompeia," by the same; "Three Children of King Charles I.," by Vandyke; "Belisarius," by Salvator Rosa; "St Agnes," by Dominichino; "The Judgment of Hercules," by Nicolas Poussin; "Venus attired by the Graces," by Guido; "Justice and Meekness," by Raffaello; "The Offspring of Love," by Guido; "Cupid Sleeping," by the same; "Abraham giving up the handmaid Hagar," by Guercino; "Esther a Suppliant before Ahasuerus," by the same; "Joseph and Potiphar's Wife," by Guido; "Venus blinding Cupid," by Titian; "Venus," by the same; "Danae," by the same; "Portrait of King Charles I.," by Vandyke; "The Madonna," by Correggio; "St Cæcilia," by Raffaello; "Mary Magdalen," by Guido; "Our Saviour appearing to his Mother after his Resurrection," by Guercino; "A Mother and Child," by Parmegiano; "Cupid Meditating," by Schidoni; "Laomedon, King of Troy, detected by Neptune and Apollo," by Salvator Rosa; "The Death of Dido," by Guercino; "Venus and Adonis," by Titian; "Fortune," by Guido; Cleopatra," by the same; "Two Children at School," by Schidoni; "Mary Magdalen," by Correggio; "Portrait of King Charles I. attended by the Marquis of Hamilton," by Vandyke; "Queen Henrietta, attended by the Prince of Wales, and holding in her arms the Duke of York," by the same; "Apotheosis of the Royal Children," by West; "The Annunciation," by Guido; "Portrait of Raffaello Sancio d'Urbino," by himself; "Sappho," by Carlo Dolci; "Our Saviour asleep," by Vandyke; "St John in the Desert," by Murrillo.

STRANGFORD, a small seaport and market-town of Ireland, in the county of Down, on the south side of the mouth of Lough Strangford, 6 miles N.E. of Downpatrick. It has a chapel of ease and places of worship for Roman Catholics and Wesleyans. The people are mostly employed in fishing. There belonged to the town in 1857, 57 vessels, tonnage 3871; and there entered the port 526 vessels, tonnage 25,680; cleared, 172 vessels, tonnage 7595. Pop. 620.

STRANRAER, a royal parliamentary and municipal burgh and seaport-town of Wigtonshire, on the S. shore of Loch Ryan, 8 miles N.E. of Portpatrick, and 50 S. of Ayr. It consists principally of three main streets running parallel to the shore, and connected by several cross streets. Among the principal public buildings are an elegant parish church, a town-hall, and a jail, which was formerly one of the residences of the noble family of Stair. Besides the parish church there are a *quoad sacra* church, two Free churches, three United Presbyterian, an Original Secession, a Reformed Presbyterian church, and a Roman Catholic chapel. There is likewise a poorhouse for the Rhynns of Galloway situated here. There are also an academy and several schools, some of which are endowed. Stranraer is a thriving place, and forms the emporium for the Rhynns or western district of Wigtonshire. The number of registered shipping belonging to the port at 31st December 1858 was 30, tonnage 1196. The number of vessels that entered the port during that year was 503, tonnage 35,644; left, 368, tonnage 31,564. The harbour is protected by a high-water stone-pier, with a wooden continuation, which is at present (1860) undergoing extensive improvements. Stranraer is on the line of the Castle-Douglas and Portpatrick Railway, now approaching completion. It has a weekly market and several annual fairs. It unites with Wigton, Whithorn, and New Galloway in sending a member to Parliament. Pop. (1851) of royal burgh, 3877; of parliamentary burgh, (5738).

STRASBURG (Fr. *Strasbourg*, Germ. *Strassburg*, anc. *Argentoratum*), a fortified town in France, capital of the department of Bas-Rhin, on the Ill, an affluent of the Rhine, about a mile from its confluence with that river, 250 miles E. by S. of Paris. It stands on a flat piece of ground, and is of an irregular but somewhat triangular form, 5 or 6

miles in circuit. The defences consist of a wall with bastions, ditches, and outworks, and a citadel at the eastern extremity with five bastions, whose outworks stretch down to the Rhine. A bridge of boats leads across the river to the fortress of Kehl in Baden. Strasburg is entered by seven gates. The Ill flows through the town from south-west to north-east; at its entrance there is a sluice by means of which the surrounding country can be laid under water. Immediately below this it divides into five branches, four of which re-unite a short way further down, and form the principal channel, flowing first east and then north, and receiving the canal of the Rhine from the right. The other branch, which is much smaller, flows first north and then east, and unites with the former just before leaving the town. Strasburg is thus divided into three parts, which are joined by numerous wooden bridges. The town is very irregularly laid out; the principal streets are broad, and some of the squares spacious and regular; but in general, the streets are narrow and winding. The houses are all substantially built of stone, they rise to a great height, and have steep roofs, with two or three tiers of windows. Although Strasburg has now for a long time belonged to the French, the character of the town, and the language, manners, and customs of its inhabitants are still entirely German. The chief public squares are that of Kleber, a native of Strasburg, containing a statue in his honour; that of Gutenberg, likewise containing a statue of the inventor of printing, who carried out his first experiments here; that of Austerlitz near the gate of the same name; and that of Broglio, formerly the horse-market, one of the most busy in the town. Among the public buildings, the largest and most interesting is the Cathedral, one of the finest Gothic buildings in Europe, with the loftiest spire in the world. It is said to have been originally founded in 504; but this earlier edifice was almost entirely destroyed by lightning in 1007. The present building was begun in 1015, but not finished till 1439. Erwin of Steinbach, the architect of the tower, died in 1318, when his work was incomplete, but it was carried on by his son, and afterwards by his daughter. It stands at the northern side of the west front; and according to the original design, there should have been a similar tower to the south of this, but it has only been raised to a much lower height. This west front is exceedingly fine; it has three large portals, a rose window 48 feet in diameter, and three equestrian statues of Clovis, Dagobert, and Rudolph of Hapsburg. The height of the tower is 466 feet, 18 feet higher than St Peter's at Rome, and 16 above the great pyramid as it is at present; though the latter, in its original state, was probably considerably higher than the spire. The interior of the church consists of a nave and aisles, transepts and choir; and its principal dimensions are as follows:—entire length, 357 feet; height of the nave, 79 feet; length of the transepts, 140 feet; breadth of the nave, 35 feet; of the choir which has no aisles, 67 feet. The most remarkable objects in the interior are the rich painted glass in the windows, the carved stone pulpit, the font, and the celebrated clock, recently repaired, a most elaborate piece of machinery, indicating in addition to the hours the phenomena of the heavens. Some of the other churches in Strasburg are interesting and remarkable, such as that of St Stephen, the oldest in the town; that of St Thomas, which belongs to the Lutherans, containing a splendid monument by Pegalle to Marshal Saxe; the *Temple Neuf*, also a Lutheran church, and *St Pierre le jeune*, which is partly Roman Catholic and partly Lutheran. The Jews have also a splendid synagogue here. The whole number of churches in the town is 15. The other principal buildings are the royal palace, Episcopal palace, prefects' office, town-hall, custom-house, court-house, public library of 130,000 volumes, the Royal Academy, which was originally a Protestant school, afterwards a university, but degraded from the latter rank at the French Revolution; the Theatre with an Ionic portico; and the Picture Gallery. There are many and extensive military establishments here; including an arsenal, artillery school, cannon foundry, barracks, and military hospital. The manufactures of Strasburg are very numerous. Woollen, linen, and cotton goods, sailcloth, jewellery, metal buttons, clocks and watches, cutlery, cast-iron goods, china, porcelain, earthenware, soap, leather, straw-hats, hosiery, paper, playing-cards, &c. There are also large bleachfields, dye-works, sugar refineries, breweries, printing-offices, and other manufactories. The town is celebrated for its goose-liver pies (*pâtés de fores gras*). An extensive trade is carried on with other parts of France, as well as with Holland, Germany, Switzerland, and Italy, and it is greatly facilitated by the advantageous position of the town so near the Rhine. Strasburg is the seat of a bishop, of a prefect, of a court of law, chamber of commerce, theological, legal, and medical faculties, numerous academies and schools, hospitals, &c. It occupies the site of the ancient Argentoratum, which probably existed before the Roman conquest, but was made by them a fortress against the incursions of the Germans, who obtained possession of it at a subsequent period, but were driven back by Clovis. About the sixth century the ancient name began to be superseded by that of *Strateburguen*, whence has come its present appellation. During the middle ages it was subject to the German emperors, and was the capital of Alsace, but along with that province it was ceded to Louis XIV. in 1681. Since then its defences have been greatly improved under the direction of Vauban, so that it is now one of the strongest fortresses in Europe. Pop. (1851) 75,565, of whom 35,000 are Protestants.

STRATFORD, Stony, a market-town of England, in the county and 7 miles N.E. of Buckingham, on the Ouse, which is here crossed by a bridge. It is generally well built of freestone, and contains a parish church with an ancient tower, Wesleyan, Independent, and Baptist chapels, a national school, and several charitable institutions. Many of the people are employed in lace-making. Pop. 1757.

STRATFORD-UPON-AVON, a municipal borough and market-town of England, in Warwickshire, on the Avon, 9 miles S.W. of Warwick, and 96 N.W. of London. Its situation is very fine, on a gentle slope above the river, which has here a considerable breadth, and is crossed by an old bridge of fourteen pointed arches. The older parts of the town are irregularly laid out, and but indifferently built; but many improvements have been made of late, and new streets, with large and good houses, have been constructed. Close to the river, at the south-east corner of the town, stands the church, a fine cruciform building, illustrious as the burial-place of Shakspeare. The remains of the poet lie on the north side of the chancel, and on the wall is his monument, partly of marble, with a half-length bust, and two inscriptions, one Latin and the other English. The church, which was completely restored in 1840, is distinguished also for its architecture, and has some ancient stone seats and two modern carved pulpits. Stratford has also a chapel of ease and places of worship, belonging to Methodists, Independents, Baptists, and Roman Catholics; national and British schools, a free grammar school, and several charities. There are a theatre and a town-hall, the latter having a statue of Shakspeare on the outside, and a portrait in the interior. The house in which he was born is still preserved, but that in which he spent the later years of his life has been pulled down. The inhabitants of Stratford are chiefly employed in agriculture. Numerous fairs are held here, and an active trade is carried on. Pop. 3372.

STRATHMIGLO, a burgh of barony and parish of Scotland, Fifeshire, 10 miles W.S.W. of Cupar, on the left bank of the Miglo. It has a town-hall, a parish church,

Strato || Strength of Materials.

and others belonging to the Free Church, the United Presbyterians, and the Reformed Presbyterians, as well as several schools. The people are chiefly employed in weaving; and there are here also a bleachfield, corn-mills, malt-houses, and breweries. Pop. 1304.

STRATO, a Greek philosopher who flourished in the third century B.C., was the son of Arcesilaus, of Lampsacus. He belonged to the Aristotelian school, and in 286 B.C. was appointed by Theophrastus, the immediate successor of Aristotle, to succeed him as head of the Lyceum. This position he held for eighteen years; and he is also said to have instructed Ptolemy Philadelphus in philosophy. Strato devoted his attention chiefly to physical science, and on that account was known by the surname of Physicus, or the naturalist. A list of his works given by Diogenes shows that only a few of them were devoted to any other than physical subjects. No authentic fragments of his writings have been preserved, and we can only form some imperfect idea of his teaching from incidental notices in other authors. He seems to have introduced some modifications of the peripatetic philosophy, which were afterwards more fully developed in the epicurean system. In psychology he carried to a greater length the tendency which had been previously begun by Theophrastus; to represent the purely intellectual acts of the mind as much more closely allied to sensation than Aristotle had admitted. The mind, according to him, in pure thought no less than in sensation, makes use of the material organism; and these two operations, though distinct from each other, can never be carried on separately. Consequently, if Strato adhered to Aristotle's view as to the perishable nature of the lower or sensational part of the soul, he could not have held in any sense its immortality. The metaphysical opinions of Strato are not so certainly known as his psychological views, and they have given rise to considerable discussion in modern times. The peculiarity of his doctrine was, that the self-moving power of nature is, as it were, dormant, until it is called into action by something from without. Cudworth, Leibnitz, Bayle, and others have accused Strato of atheism; but he has not been without defenders from this charge. The few and brief notices we have on this subject from ancient writers do not perhaps warrant us in coming to any decided conclusion.

Straubing || Strength of Materials

STRAUBING, a town of Bavaria, on the right bank of the Danube, 25 miles S.E. of Regensburg. It is walled, and has a castle, a number of churches and convents, a gymnasium, Latin school, and normal seminary, an orphan and other hospitals. Brewing and weaving are extensively carried on; there are large powder and corn magazines, and an important trade in corn and horses. The castle was the residence in the fifteenth century of Albert III. of Bavaria, with his wife, Agnes Bernauer, the beautiful daughter of a citizen of Augsburg. Albert's father, the reigning duke, being displeased with his son's marriage, ordered the lady during his absence to be drowned in the river. She is now buried in the church of St Peter, where a marble tablet records her tragic fate. Pop. 9300.

STREHLEN, a town of Prussia, in the province of Silesia, government and 23 miles S. of Breslau, on the left bank of the Ohlau. It is surrounded by walls, and entered by three gates; has an old castle, a court-house, a Roman Catholic and several Protestant churches, and an hospital. Woollen and linen cloth, leather, and tobacco are manufactured here. Pop. 5114.

STRENGTH OF MATERIALS,

Importance of the subject.

In *Mechanics*, is a subject of so much importance, that in a nation so eminent as this for invention and ingenuity in every species of manufacture, and in particular so distinguished for its improvements in machinery of every kind, it is somewhat singular that no writer has treated it in the detail which its importance and difficulty demand. The man of science who visits our great manufactories is delighted with the ingenuity which he observes in every part, the innumerable inventions which come even from individual artisans, and the determined purpose of improvement and refinement which he sees in every workshop. Every cotton-mill appears an academy of mechanical science; and mechanical invention is spreading from these fountains over the whole kingdom. But the philosopher is mortified to see this ardent spirit cramped by ignorance of principle, and many of those original and brilliant thoughts obscured and clogged with needless and even hurtful additions, and a complication of machinery which checks improvement even by its appearance of ingenuity. There is nothing in which this want of scientific education, this ignorance of principle, is so frequently observed, as in the injudicious proportion of the parts of machines and other mechanical structures; proportions and forms of parts in which the strength and position are nowise regulated by the strains to which they are exposed, and where repeated failures have been the only lessons.

Strength of materials arises from cohesion.

The strength of materials arises immediately or ultimately from the cohesion of the parts of bodies. Our examination of this property of tangible matter has as yet been very partial and imperfect, and by no means enables us to apply mathematical calculations with precision and success. The various modifications of cohesion, in its different appearances of perfect softness, plasticity, ductility, elasticity, hardness, have a mighty influence on the strength of bodies, but are hardly susceptible of measurement. Their texture, whether uniform like glass and ductile metals, crystallized or granulated like other metals and freestone, or fibrous like timber, is a circumstance no less important; yet even here, although we derive some advantage from remarking to which of these forms of aggregation a substance belongs, the aid is but small. All we can do in this want of general principles is, to make experiments on every class of bodies. Accordingly philosophers have endeavoured to instruct the public in this particular. The Royal Society of London, at its very first institution, made many experiments at their meetings, as may be seen in the first registers of the society; and since then a vast multitude of experiments have been made by public bodies and private individuals. The best of these, perhaps, up to the date of the present edition, are those of Mr Barlow.

Experiments to ascertain it.

Rendered useful by generalization.

But to make use of any experiments, there must be employed some general principle by which we can generalize their results. They will otherwise be only narrations of detached facts. We must have some notion of that intermedium, by the intervention of which an external force applied to one part of a lever, joist, or pillar, occasions a strain on a distant part. This can be nothing but the cohesion between the parts. It is this connecting force which is brought into action, or, as we more shortly express it, excited. This action is modified in every part by the laws of mechanics. It is this action which we call the *strength* of that part, and its effect is the strain on the adjoining parts; and thus it is the same force, differently viewed, that constitutes both the strain and the strength. When we consider it in the light of a resistance to fracture, we call it *strength*.

Strength defined.

Causes known only from their effects.

We call every thing a *force* which we observe ever to be accompanied by a change of motion; or, more strictly speaking, we infer the presence and agency of a force wherever we observe the state of things in respect of motion different from what we know to be the result of the action of all the forces which we know to act on the body. Thus when we observe a rope prevent a body from falling, we infer a moving force inherent in the rope, with as much confidence as when we observe it drag the body along the ground. The *immediate action* of this force is undoubtedly exerted between the immediately adjoining parts of the rope. The immediate effect is the keeping the particles of the rope together. They ought to separate by any external force drawing the ends of the rope contrariwise; and we ascribe their not doing so to a mechanical force really opposing this external force. When desired to give it a name, we name it from what we conceive to be its effect, and therefore its characteristic, and we call it *cohesion*. This is merely a name for the fact; but it is the same thing in all our denominations. We know nothing of the causes but in the effects; and our name for the cause is in fact the name of the effect, which is *cohesion*. We mean nothing else by gravitation or magnetism. What do we mean when we say that Newton understood thoroughly the nature of gravitation, of the force of gravitation; or that Franklin understood the nature of the electric force? Nothing but this: Newton considered with patient sagacity the general facts of gravitation, and has described and classed them with the utmost precision. In like manner, we shall understand the nature of cohesion when we have discovered with equal generality the laws of cohesion, or general facts which are observed in the appearances, and when we have described and classed them with equal accuracy.

Let us therefore attend to the more simple and obvious phenomena of cohesion, and mark with care every circumstance of resemblance by which they may be classed. Let us receive these as the laws of cohesion, characteristic of its supposed cause, the force of cohesion. We cannot pretend to enter on this vast research. The modifications are innumerable; and it would require the penetration of more than Newton to detect the circumstance of similarity amidst millions of discriminating circumstances. Yet this is the only way of discovering which are the primary facts characteristic of the force, and which are the modifications. The study is immense, but it is by no means desperate; and we entertain great hopes that it will ere long be successfully prosecuted; but, in our particular predicament, we must content ourselves with selecting such general laws as seem to give us the most immediate information of the circumstances that must be attended to by the mechanician in his constructions, that he may unite strength with simplicity, economy, and energy.

All bodies elastic.

1. Then, it is a matter of fact that all bodies are in a certain degree perfectly elastic; that is, when their form or bulk is changed by certain moderate compressions or distractions, it requires the continuance of the changing force to continue the body in this new state; and when the force is removed, the body recovers its original form. We limit the assertion to *certain moderate* changes. For instance, take a lead wire of one fifteenth of an inch in diameter and ten feet long; fix one end firmly to the ceiling, and let the wire hang perpendicular; affix to the lower end an index like the hand of a watch; on some stand immediately below let there be a circle divided into degrees, with its centre corresponding to the lower point of the wire; now turn this index twice round, and thus twist the wire. When the index is let go, it will turn backwards again, by the wire untwisting itself, and make almost four revolutions before it stops; after which it twists and untwists many times, the index going backwards and forwards round the circle, diminishing, however, its arch of twist each time, till at last it settles precisely in its original position. This may be repeated for ever. Now, in this motion, every part of the wire partakes equally of the twist. The particles are stretched, require force to keep them in their state of extension, and recover completely their relative positions. These are all the characters of what the mechanician calls *perfect* elasticity. This is a quality quite familiar in many cases, as in glass, tempered steel, &c., but was thought incompetent to lead, which is generally considered as having little or no elasticity. But we make the assertion in the most general terms, with the limitation to moderate derangement of form. We have made the same experiment on a thread of pipe-clay, made by forcing soft clay through the small hole of a syringe by means of a screw, and we found it more elastic than the lead wire; for a thread of one twentieth of an inch diameter and seven feet long allowed the index to make two turns, and yet completely recovered its first position.

2. But if we turn the index of the lead wire four times round, and let it go again, it untwists again in the same manner, but it makes little more than four turns back again; and after many oscillations it finally stops in a position almost two revolutions removed from its original position. It has now acquired a new arrangement of parts, and this new arrangement is permanent like the former; and, what is of particular moment, it is perfectly elastic. This change is familiarly known by the denomination of a *set*. The wire is said to have *taken a set*. When we attend minutely to the procedure of nature in this phenomenon, we find that the particles have, as it were, slid on each other, still cohering, and have taken a new position, in which their connecting forces are in equilibrio; and in this change of relative situation, it appears that the connecting forces which maintained the particles in their first situation were not in equilibrio in some position intermediate between that of the first and that of the last form. The force required for changing this first form augmented with the change, but only to a certain degree; and during this process the connecting forces always tended to the recovery of this first form. But after the change of mutual position has passed a certain magnitude, the union has been partly destroyed, and the particles have been brought into new situations; such, that the forces which now connect each with its neighbour tend, not to the recovery of the first arrangement, but to push them farther from it, into a new situation, to which they now verge, and require force to prevent them from acquiring. The wire is now in fact again perfectly elastic; that is, the forces which now connect the particles with their neighbours, augment to a certain degree as the derangement from this new position augments. This is not reasoning from any theory. It is narrating facts, on which a theory is to be founded. What we have been just now saying, is evidently a description of that sensible form of tangible matter which we call *ductility*. It has every gradation of variety, from the softness of butter to the firmness of gold. All these bodies have some elasticity; but we say they are not perfectly elastic, because they do not completely recover their original form when it has been greatly damaged. The whole gradation may be most distinctly observed in a piece of glass or hard sealing-wax. In the ordinary form glass is perhaps the most completely elastic body that we know, and may be bent till just ready to snap, and yet completely recovers its first form, and takes no set whatever; but when heated to such a degree as just to be visible in the dark, it loses its brittleness, and becomes so tough that it cannot be broken by any blow; but it is no longer elastic, it takes any set, and keeps it. When more heated, it becomes as plastic as clay; but in this state is remarkably distinguished from clay by a quality which we may call *viscidity*, which is something like elasticity, of which clay and other bodies purely plastic exhibit no appearance. This

What is meant by a set.

Ductility.

Viscidity.

Strength of Materials.

is the joint operation of strong adhesion and softness. When a rod of perfectly soft glass is suddenly stretched a little, it does not at once take the shape which it acquires after some little time. It is owing to this that, in taking the impression of a seal, if we take off the seal while the wax is yet very hot, the sharpness of the impression is immediately destroyed. Each part drawing its neighbour, and each part yielding, the prominent parts are pulled down and blunted, and the sharp hollows are pulled upwards and also blunted. The seal must be kept on till the wax has become not only stiff, but hard.

Observed in all homogeneous plastic bodies.

This viscidity is to be observed in all plastic bodies which are homogeneous. It is not observed in clay, because clay is not homogeneous, but consists of hard particles of argillaceous earth sticking together by their attraction for water. Something like it might be made of finely powdered glass and a clammy fluid such as turpentine. Viscidity has all degrees of softness, till it degenerates to ropy fluidity like that of olive oil. Perhaps something of it may be found even in the most perfect fluid with which we are acquainted, as we observed in the experiments for ascertaining specific gravity.

When ductility and elasticity are combined in different proportions, an immense variety of sensible modes of aggregation may be produced. Some degree of both are probably to be observed in all bodies of complex constitution; that is, which consist of particles made up of many different kinds of atoms. Such a constitution of a body must afford many situations permanent, but easily deranged.

Particles acted on by attractions and repulsions.

In all these changes of disposition which take place among the particles of a ductile body, the particles are at such distance that they still cohere. The body may be stretched a little; and on removing the extending force, the body shrinks into its first form. It also resists moderate compressions; and when the compressing force is removed, the body again swells out. Now the corpuscular *fact* here is, that the particles are acted on by attractions and repulsions, which balance each other when no external force is acting on the body, and which augment as the particles are made, by any external cause, to recede from this situation of mutual inactivity; for since force is requisite to produce either the dilatation or the compression, and to maintain it, we are obliged, by the constitution of our minds, to infer that it is opposed by a force accompanying or inherent in every particle of dilatable or compressible matter; and as this necessity of employing force to produce a change indicates the agency of these corpuscular forces, and marks their kind, according as the tendencies of the particles appear to be toward each other in dilatation, or from each other in compression; so it also measures the degrees of their intensity. Should it require three times the force to produce a double compression, we must reckon the mutual repulsions triple when the compression is doubled; and so in other instances. We see from all this that the phenomena of cohesion indicate some relation between the centres of the particles. To discover this relation is the great problem in corpuscular mechanism, as it was in the Newtonian investigation of the force of gravitation. Could we discover this law of action between the corpuscles with the same certainty and distinctness, we might with equal confidence say what will be the result of any position which we give to the particles of bodies; but this is beyond our hopes. The law of gravitation is so simple, that the discovery or detection of it amid the variety of celestial phenomena required but one step; and in its own nature its possible combinations still do not greatly exceed the powers of human research. One is almost disposed to say that the Supreme Being has exhibited it to our reasoning powers as sufficient to employ with success our utmost efforts, but not so abstruse as to discourage us from the noble attempt. It seems to be otherwise with respect to cohesion. Mathematics informs us, that if it deviates sensibly from the law of gravitation, the simplest combinations will make the joint action of several particles an almost impenetrable mystery. We must therefore content ourselves, for a long time to come, with a careful observation of the simplest cases that we can propose, and with the discovery of secondary laws of action, in which many particles combine their influence. In pursuance of this plan, we observe,

The great problem in corpuscular mechanism.

Particles kept in their places by a balance of forces.

3. That whatever is the situation of the particles of a body with respect to each other, when in a quiescent state, they are kept in these situations by the balance of opposite forces. This cannot be refused, nor can we form to ourselves any other notion of the state of the particles of a body. Whether we suppose the ultimate particles to be of certain magnitudes and shapes, touching each other in single points of cohesion; or whether, with Boscovich, we consider them as at a distance from each other, and acting on each other by attractions and repulsions, we must acknowledge, in the first place, that the centres of the particles (by whose mutual distances we must estimate the distance of the particles) may and do vary their distances from each other. What else can we say when we observe a body increase in length, in breadth, and thickness, by heating it, or when we see it diminish in all these dimensions by an external compression? A particle, therefore, situated in the midst of many others, and remaining in that situation, must be conceived as maintained in it by the mutual balancing of all the forces which connect it with its neighbours. It is like a ball kept in its place by the opposite action of two springs. This illustration merits a more particular application. Suppose a number of balls ranged on the table in the angles of equilateral triangles, and that each ball is connected with the six which lie around it by means of an elastic wire curled like a cork-screw; suppose such another stratum of balls above this, and parallel to it, and so placed that each ball of the upper stratum is perpendicularly over the centre of the equilateral triangle below, and let these be connected with the balls of the under stratum by similar spiral wires. Let there be a third and a fourth, and any number of such strata, all connected in the same manner. It is plain that this may extend to any size, and fill any space. Now let this assemblage of balls be firmly contemplated by the imagination, and be supposed to shrink continually in all its dimensions, till the balls, and their distances from each other, and the connecting wires, all vanish from the sight as discrete individual objects. All this is very conceivable. It will now appear like a solid body, having length, breadth, and thickness; it may be compressed, and will again resume its dimensions; it may be stretched, and will again shrink; it will move away when struck; in short, it will not differ in its sensible appearance from a solid elastic body. Now when this body is in a state of compression, for instance, it is evident that any one of the balls is at rest, in consequence of the mutual balancing of the actions of all the spiral wires which connect it with those around it. It will greatly conduce to the full understanding of all that follows to recur to this illustration. The analogy or resemblance between the effects of this constitution of things and the effects of the corpuscular forces is very great; and wherever it obtains, we may safely draw conclusions from what we know would be the condition of a body of common tangible matter. We shall just give one instructive example, and then have done with this hypothetical body. We can suppose it of a long shape, resting on one point; we can suppose two weights A, B, suspended at the extremities, and the whole in equilibrio. We commonly express this state of things by saying that A and B are in equilibrio. This is very inaccurate. A is in fact in equilibrio with the united action of all the springs which connect the ball to which it is applied with the adjoining balls. These springs are brought into action, and each is in equilibrio with the joint action of

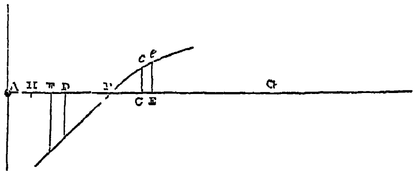
Illustration of this proposition.

By example.

all the rest. Thus through the whole extent of the hypothetical body the springs are brought into action in a way and in a degree which mathematics can easily investigate. We need not do this: it is enough for our purpose that our imagination readily discovers that some springs are stretched, others are compressed, and that a pressure is excited on the middle point of support, and the support exerts a reaction which precisely balances it; and the other weight is, in like manner, in immediate equilibrio with the equivalent of the actions of all the springs which connect the last ball with its neighbours. Now take the analogical or resembling case, an oblong piece of solid matter, resting on a fulcrum, and loaded with two weights in equilibrio; for the actions of the connecting springs substitute the corpuscular forces; and the result will resemble that of the hypothesis.

Now, as there is something that is at least analogous to a change of distance of the particles, and a concomitant change of the intensity of the connecting forces, we may express this in the same way that we are accustomed to do in similar cases. Let A and B (fig. 1) represent the centres of two particles of a coherent elastic body in their quiescent inactive state, and let us consider only the mechanical condition of B. The body may be

Fig. 1.



stretched. In this case the distance AB of the particles may become AC. In this state there is something which makes it necessary to employ a force to keep the particles at this distance. C has a tendency towards A, or we may say that A attracts C. We may represent the magnitude of this tendency of C *towards* A, or this attraction of A, by a line C*c* perpendicular to AC. Again, the body may be compressed, and the distance AB may become AD. Something obliges us to employ force to continue this compression, and D tends *from* A, or A appears to *repel* D. The intensity of this tendency or repulsion may be represented by another perpendicular D*d*; and, to represent the different directions of these tendencies, or the different nature of these actions, we may set D*d* on the opposite side of AB. It is in this manner that Boscovich has represented the actions of corpuscular forces in his celebrated Theory of Natural Philosophy. Newton had said, that as the great movements of the solar system were regulated by forces operating at a distance, and varying with the distance, so he strongly suspected (*valde suspicor*) that all the phenomena of cohesion, with all its modifications in the different sensible forms of aggregation, and in the phenomena of chemistry and physiology, resulted from the similar agency of forces varying with the distance of the particles. The learned Jesuit pursued this thought; and has shown, that if we suppose an ultimate atom of matter endowed with powers of attraction and repulsion, varying, both in kind and degree, with the distance, and if this force be the same in every atom, it may be regulated by such a relation to the distance from the neighbouring atom, that a collection of such may have all the sensible appearance of bodies in their different forms of solids, liquids, and vapours, elastic or unelastic, and endowed with all the properties which we perceive, by whose immediate operation the phenomena of motion by impulse, and all the phenomena of chemistry, and of animal and vegetable economy, may be produced. He shows, that notwithstanding a perfect sameness, and even a great simplicity, in this atomical constitution, there will result from this union all that unspeakable variety of form and property which diversifies and embellishes the face of

How Boscovich represents the action of corpuscular forces.

nature. We shall take another opportunity of giving such an account of this celebrated work as it deserves. We mention it only by the by, as far as a general notion of it will be of some service on the present occasion. For this purpose, we just observe that Boscovich conceives a particle of any individual species of matter to consist of an unknown number of particles of simpler constitution; each of which particles, in their turn, is compounded of particles still more simply constituted, and so on through an unknown number of orders, till we arrive at the simplest possible constitution of a particle of tangible matter, susceptible of length, breadth, and thickness, and necessarily consisting of four atoms of matter. And he shows that the more complex we suppose the constitution of a particle, the more must the sensible qualities of the aggregate resemble the observed qualities of tangible bodies. In particular, he shows how a particle may be so constituted, that although it act on one other particle of the same kind through a considerable interval, the interposition of a third particle of the same kind may render it totally, or almost totally, inactive; and therefore an assemblage of such particles would form such a fluid as air. All these curious inferences are made with uncontrovertible evidence; and the greatest encouragement is thus given to the mathematical philosopher to hope, that by cautious and patient proceeding in this way, we may gradually approach to a knowledge of the laws of cohesion, that will not shun a comparison even with the Principia of Newton. No step can be made in this investigation, but by observing with care, and generalizing with judgment, the phenomena, which are abundantly numerous, and much more at our command than those of the great and sensible motions of bodies. Following this plan, we observe,

Every body compressible and dilatable.

4. It is a matter of fact, that every body has some degree of compressibility and dilatability; and when the changes of dimension are so moderate that the body completely recovers its original dimensions on the cessation of the changing force, the extensions or compressions are sensibly proportional to the extending of compressing forces; and therefore *the connecting forces are proportional to the distances of the particles from their quiescent, neutral, or inactive positions.* This seems to have been first viewed as a law of nature by the penetrating eye of Dr Robert Hooke, one of the most eminent philosophers of the last century. He published a cipher, which he said contained the theory of springiness and of the motions of bodies by the action of springs. It was this, *c e i i i n o s s s t t u u*. When explained in his dissertation, published some years after, it was *ut tensio sic vis*. This is precisely the proposition now asserted as a general fact, a law of nature. This dissertation is full of curious observations of facts in support of his assertion. In his application to the motion of bodies, he gives his noble discovery of the balance-spring of a watch, which is founded on this law. The spring, as it is more and more coiled up, or unwound, by the motion of the balance, acts on it with a force proportional to the distance of the balance from its quiescent position. The balance, therefore, is acted on by an accelerating force, which varies in the same manner as the force of gravity acting on a pendulum swinging in a cycloid. Its vibrations therefore must be performed in equal time, whether they are wide or narrow. In the same dissertation Hooke mentions all the facts which John Bernoulli afterwards adduced in support of Leibnitz's whimsical doctrine of the force of bodies in motion, as the doctrine of the *vires vivæ;* a doctrine which Hooke might justly have claimed as his own, had he not seen its futility.

Law of nature discovered by Dr Hooke;

Experiments made since the time of Hooke show that this law is strictly true in the extent to which we have limited it, viz. in all the changes of form which will be completely undone by the elasticity of the body. It is nearly true to a much greater extent. James Bernoulli, in his dis-

and confirmed by the experiments of others.

sertation on the elastic curve, relates some experiments of his own, which seem to deviate considerably from it; but on close examination they do not. The finest experiments are those of Coulomb, published in some late volumes of the Memoirs of the Academy of Paris. He suspended balls by wires, and observed their motions of oscillation, which he found accurately corresponding with this law.

This we shall find to be a very important fact in the doctrine of the strength of bodies, and we desire the reader to make it familiar to his mind. If we apply to this our manner of expressing these forces by perpendicular ordinates C*c*, D*d* (fig. 1), we must take other situations E, F, of the particle B, and draw E*e*, F*f*; and we must have D*d* : F*f* = BD : BF, or C*c* : E*e* = BC : BE. In such a supposition F*d*B*ce* must be a straight line. But we shall have abundant evidence by and by that this cannot be strictly true, and that the line B*ce*, which limits the ordinates expressing the attractive forces, becomes concave towards the line ABE, and that the part B*df* is convex towards it. All that can be safely concluded from the experiments hitherto made is, that *to a certain extent* the forces, both attractive and repulsive, are *sensibly* proportional to the dilatations and compressions. For,

When a body is much dilated, a small addition of force will increase its dilatation.

5. It is universally observed, that when the dilatations have proceeded a certain length, a less addition of force is sufficient to increase the dilatation in the same degree. This is always observed when the body has been so far stretched that it takes a set, and does not completely recover its form. The like may be generally observed in compressions. Most persons will recollect, that in violently stretching an elastic cord, it becomes suddenly weaker, or more easily stretched. But these phenomena do not positively prove a diminution of the corpuscular force acting on one particle: it more probably arises from the disunion of some particles whose action contributed to the whole or sensible effect. And in compressions we may suppose something of the same kind; for when we compress a body in one direction, it commonly bulges out in another; and in cases of very violent action some particles may be disunited, whose transverse action had formerly balanced *part* of the compressing force. For the reader will see on reflection, that since the compression in one direction causes the body to bulge out in the transverse direction, and since this bulging out is in opposition to the transverse forces of attraction, it must employ some part of the compressing force. And the common appearances are in perfect uniformity with this conception of things. When we press a bit of dryish clay, it swells out and cracks transversely. When a pillar of wood is overloaded, it swells out, and small crevices appear in the direction of the fibres. After this it will not bear half of the load. This the carpenters call *crippling;* and a knowledge of the circumstances which modify it is of great importance, and enables us to understand some very paradoxical appearances, as will be shown by and by.

This partial disuniting of particles formerly cohering, is, we imagine, the chief reason why the totality of the forces which really oppose an external strain does not increase in the proportion of the extensions and compressions. But sufficient evidence will also be given that the forces which would connect one particle with one other particle do not augment in the accurate proportion of the change of distance; that in extensions they increase more slowly, and in compressions more rapidly.

Ductility another cause of deviation.

But there is another cause of this deviation perhaps equally effectual with the former. Most bodies manifest some degree of ductility. Now what is this? The fact is, that the parts have taken a new arrangement, in which they again cohere. Therefore, in the passage to this new arrangement, the sensible forces, which are the joint result of many corpuscular forces, begin to respect this new arrangement instead of the former. This must change the simple law of corpuscular force, characteristic of the particular species of matter under examination. It does not require much reflection to convince us that the possible arrangements which the particles of a body may acquire, without appearing to change their nature, must be more numerous according as the particles are of a more complex constitution; and it is reasonable to suppose that the constitution even of the most simple kind of matter that we are acquainted with is exceedingly complex. Our microscopes show us animals so minute, that a heap of them must appear to the naked eye an uniform mass with a grain finer than that of the finest marble or razor hone; and yet each of these has not only limbs, but bones, muscular fibres, blood-vessels, fibres, and a blood consisting in all probability of globules organized and complex like our own. The imagination is here lost in wonder; and nothing is left us but to adore inconceivable art and wisdom, and to exult in the thought that we are the only spectators of this beautiful scene who can derive pleasure from the view. But let us proceed to observe,

The forces which connect the particles of tangible bodies change by a change of distance.

6. That the forces which connect the particles of tangible bodies change by a change of distance, not only in degree, but also in kind. The particle B (fig. 1) is attracted by A when in the situation C or E. It is repelled by it when at D or F. It is not affected by it when in the situation B. The reader is requested carefully to remark, that this is not an inference founded on the authority of our mathematical figure. The figure is an expression (to assist the imagination) of facts in nature. It requires no force to keep the particles of a body in their quiescent situations: but if they be separated by stretching the body, they endeavour (pardon the figurative expression) to come together again. If they be brought nearer by compression, they endeavour to recede. This endeavour is manifested by the necessity of employing force to maintain the extension or condensation; and we represent this by the different position of our lines. But this is not all: the particle B, which is repelled by A when in the situation F or D, is neutral when at B, and is attracted when at C or E, may be placed at such a distance AG from A greater than AB that it shall be again repelled, or at such a distance AH that it shall be again attracted; and these alterations may be repeated again and again. This is curious and important, and requires something more than a bare assertion for its proof.

Light alternately attracted and repelled.

In the article OPTICS we mentioned the most curious and valuable observations of Sir Isaac Newton, by which it appears that light is thus alternately attracted and repelled by bodies. The rings of colour which appear between the object-glasses of long telescopes showed, that in the small interval of $\frac{1}{1000}$th of an inch, there are at least an hundred such changes observable, and that it is highly probable that these alternations extend to a much greater distance. At one of these distances the light actually converges towards the solid matter of the glass, which we express shortly by saying that it is attracted by it, and that at the next distance it declines from the glass, or is repelled by it. The same thing is more simply inferred from the phenomena of light passing by the edges of knives and other opaque bodies. We refer the reader to the experiments themselves, the detail being too long for this place; and we request him to consider them minutely and attentively, and to form distinct notions of the inferences drawn from them. And we desire it to be remarked, that although Newton, in his discussion, always considers light as a set of corpuscles moving in free space, and obeying the actions of external forces like any other matter, the particular conclusion in which we are just now interested does not at all depend on this notion of the nature of light. Should we, with Descartes or Huygens, suppose light to be the undulation of an elastic medium, the

Strength of Materials.

conclusion will be the same. The undulations at certain distances are disturbed by forces directed towards the body, and at a greater distance the disturbing forces tend *from* the body.

The same alternations of attraction and repulsion observable in the particles of other bodies, as glass.

But the same alternations of attraction and repulsion may be observed between the particles of common matter. If we take a piece of very flat and well-polished glass, such as is made for the horizon-glasses of a good Hadley's quadrant, and if we wrap round it a fibre of silk as it comes from the cocoon, taking care that the fibre shall nowhere cross another, and then press this pretty hard on such another piece of glass, it will lift it up and keep it suspended. The particles therefore of the one do most certainly attract those of the other, and this at a distance equal to the thickness of the silk fibre. This is nearly the limit; and it sometimes requires a considerable pressure to produce the effect. The pressure is effectual only by compressing the silk fibre, and thus diminishing the distance between the glass plates. This adhesion cannot be attributed to the pressure of the atmosphere, because there is nothing to hinder the air from insinuating itself between the plates, since they are separated by the silk. Besides, the experiment succeeds equally well under the receiver of an air-pump. This most valuable experiment was first made by Huygens, who reported it to the Royal Society. It is narrated in the Philosophical Transactions, No. 86.

Here, then, is an attraction acting, like gravity, at a distance. But take away the silk fibre, and try to make the glasses touch each other, and we shall find a very great force necessary. By Newton's experiments it appears, that unless the prismatic colours begin to appear between the glasses, they are at least $\frac{1}{890}$th of an inch asunder or more. Now we know that a very considerable force is necessary for producing these colours, and that the more we press the glasses together the more rings of colours appear. It also appears from Newton's measures, that the difference of distance between the glasses where each of these colours appears is about the 89,000th part of an inch. We know further, that when we have produced the last appearance of a greasy or pearly colour, and then augment the pressure, making it about 1000 pounds on the square inch, all colours vanish, and the two pieces of glass seem to make one transparent undistinguishable mass. They appear now to have no air between them, or to be in mathematical contact. But another fact shows this conclusion to be premature. The same circles of colours appear in the top of a soap-bubble; and as it grows thinner at top, there appears an unreflecting spot in the middle. We have the greatest probability therefore that the perfect transparency in the middle of the two glasses does not arise from their being in contact, but because the thickness of air between them is too small in that place for the reflection of light. Nay, Newton expressly found no reflection where the thickness was $\frac{3}{8}$ths or more of the $\frac{1}{89000}$th part of an inch.

All this while the glasses are strongly repelling each other, for great pressure is necessary for continuing the appearance of those colours, and they vanish in succession as the pressure is diminished. This vanishing of the colours is a proof that the glasses are moving off from each other, or repelling each other. But we can put an end to this repulsion by very strong pressure, and at the same time sliding the glasses on each other. We do not pretend to account for this effect of the sliding motion; but the fact is, that by so doing, the glasses will cohere with very great force, so that we shall break them by any attempt to pull them asunder. It commonly happens (at least it did so with us), that in this sliding compression of two smooth flat plates of glass, they scratch and mutually destroy each other's surface. It is also worth remarking, that different kinds of glass exhibit different properties in this respect. Flint glass will attract even though a silk fibre lies double between them, and they much more readily cohere by this sliding pressure.

Here, then, are two distances at which the plates of glass attract each other; namely, when the silk fibre is interposed, and when they are forced together with this sliding motion. And in any intermediate situation they repel each other. We see the same thing in other solid bodies.

Lead and iron.

Two pieces of lead, made perfectly clean, may be made to cohere by grinding them together in the same manner. It is in this way that pretty ornaments of silver are united to iron. The piece is scraped clean, and a small bit of silver like a fish scale is laid on. The die which is to strike it into a flower or other ornament is then set on it, and we give it a smart blow, which forces the metals into contact as firm as if they were soldered together. It sometimes happens that the die adheres to the coin so that they cannot be separated: and it is found that this frequently happens when the engraving is such that the raised figure is not completely surrounded with a smooth flat ground. The probable cause of this is curious. When the coin has a flat surface all around, this is produced by the most prominent part of the die. This applies to the metal, and completely confines the air which filled the hollow of the die.

Probable cause why the die adheres to the coin.

As the pressure goes on, the metal is squeezed up into the hollow of the die; but there is still air compressed between them, which cannot escape by any passage. It is therefore prodigiously condensed, and exerts an elasticity proportioned to the condensation. This serves to separate the die from the metal when the stroke is over. The hollow part of the die has not touched the metal all the while, and we may say that the impression was made by air. If this air escape by any engraving reaching through the border, they cohere inseparably.

We have admitted that the glass plates are in contact when they adhere thus firmly. But we are not certain of this: for if we take these cohering glasses, and touch them with water, it quickly insinuates itself between them. Yet they still cohere, but can now be pretty easily separated.

Repulsion the cause of somebodies swimming in a fluid specifically lighter than themselves.

It is owing to this repulsion, exerted through its proper sphere, that certain powders swim on the surface of water, and are wetted with great difficulty. Certain insects can run about on the surface of water. They have brushy feet, which occupy a considerable surface, and if their steps be viewed with a magnifying glass, the surface of the water is seen depressed all around, resembling the footsteps of a man walking on feather beds. This is owing to a repulsion between the brush and the water. A common fly cannot walk in this manner on water. Its feet are wetted, because they attract the water instead of repelling it. A steel needle, slightly greased, will lie on the surface of water, make an impression as a great bar would make on a feather bed; and its weight is less than that of the displaced water. A dew-drop lies on the leaves of plants without touching them mathematically, as is plain from the extreme brilliancy of the reflection at the posterior surface; nay, it may be sometimes observed that the drops of rain lie on the surface of water, and roll about on it like balls on a table. Yet all these substances can be wetted; that is, water can be applied to them at such distances that they attract it.

What we lately remarked of water insinuating itself between the glass plates without altogether destroying their cohesion, shows that this cohesion is not the same that obtains between the particles of one of the plates; that is, the two plates are not in the state of one continued mass. It is highly probable, therefore, that between these two states there is an intermediate state of repulsion, nay, perhaps, many such, alternated with attractive states.

A piece of ice is elastic, for it rebounds and rings. Its particles, therefore, when compressed, resile; and when

stretched, contract again. The particles are therefore in the state represented by B in figure 1, acted on by repulsive forces if brought nearer, and by attractive forces if drawn further asunder. Ice expands, like all other bodies, by heat. It absorbs a vast quantity of fire, which, by combining its attractions and repulsions with those of the particles of ice, changes completely the law of action, and the ice becomes water. In this new state the particles are again in limits between attractive and repulsive forces; for water has been shown, by the experiments of Canton and Zimmerman, to be elastic or compressible. It again expands by heat. It again absorbs a prodigious quantity of heat, and becomes elastic vapour; its particles repelling each other at all distances yet observed. The distance between the particles of one plate of glass and those of another which lies on it, and is carried by it, is a distance of repulsion; for the force which supports the upper piece is acting in opposition to its weight. This distance is less than that at which it would *suspend* it below it with a silk fibre interposed; for no prismatic colours appear between them when the silk fibre is interposed. But the distance at which glass attracts water is much less than this, for no colours appear when glass is wetted with water. This distance is less, and not greater, than the other; for when the glasses have water interposed between them instead of air, it is found, that when any particular colour appears, the thickness of the plate of water is to that of the plate of air which would produce the same colour, nearly as three to four. Now, if a piece of glass be wetted, and exhibit no colour, and another piece of glass be simply laid on it, no colour will appear; but if they are strongly pressed, the colours appear in the same manner as if the glasses had air between. Also, when glass is simply wetted, and the film of water is allowed to evaporate, when it is thus reduced to a proper thinness the colours show themselves in great beauty.

Particles of matter connected by forces acting at a distance.

These are a few of many thousand facts, by which it is unquestionably proved that the particles of tangible matter are connected by forces acting at a distance, varying with the distance, and alternately attractive and repulsive. If we represent these forces, as we have already done in fig. 1, by the ordinates C*c*, D*d*, E*e*, F*f*, &c. of a curve, it is evident that this curve must cross the axis at all those distances where the forces change from attractive to repulsive, and the curve must have branches alternately above and below the axis.

All these alternations of attraction and repulsion take place at small and insensible distances. At all sensible distances the particles are influenced by the attraction of gravitation; and therefore this part of the curve must be a hyperbola whose equation is $y=\frac{a^3}{x^2}$. What is the form of the curve corresponding to the smallest distance of the particles? that is, what is the mutual action between the particles just before their coming into absolute contact? Analogy should lead us to suppose it to be repulsion; for solidity is the last and simplest form of bodies with which we are acquainted. Fluids are more compounded, containing fire as an essential ingredient. We should conclude that this ultimate repulsion is insuperable, for the hardest bodies are the most elastic. We are fully entitled to say that this repelling force exceeds all that we have ever yet applied to overcome it; nay, there are good reasons for saying that this ultimate repulsion, by which the particles are kept from mathematical contact, is really insuperable in its own nature, and that it is impossible to produce mathematical contact.

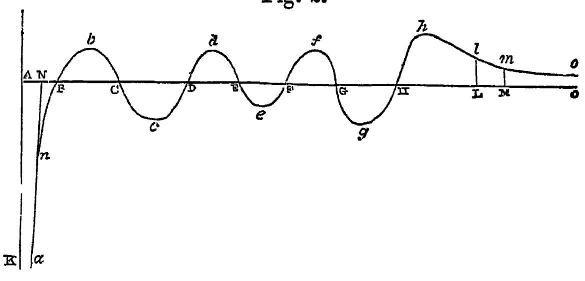
Mathematical contact impossible.

We shall just mention one of these, which we consider as unanswerable. Suppose two atoms, or ultimate particles of matter, A and B. Let A be at rest, and B move up to it with the velocity 2; and let us suppose that it comes into mathematical contact, and impels it (according to the common acceptation of the word). Both move with the velocity 1. This is granted by all to be the final result of the collision. Now the instant of time in which this communication happens is no part either of the duration of the solitary motion of A, nor of the joint motion of A and B: it is the separation or boundary between them. It is at once the end of the first and the beginning of the second, belonging equally to both. A was moving with the volocity 2. The distinguishing circumstance, therefore, of its mechanical state is, that it has a determination (however incomprehensible) by which it would move for ever with the velocity 2, if nothing changed it. This it has during the whole of its solitary motion, and therefore in the last instant of this motion. In like manner, during the whole of the joint motion, and therefore in the first instant of this motion, the atom A has a determination by which it would move for ever with the velocity 1. In one and the same instant, therefore, the atom A has two incompatible determinations. Whatever notion we can form of this state, which we call velocity, as a distinction of condition, the same impossibility of conception, or the same absurdity, occurs. Nor can it be avoided in any other way than by saying, that this change of A's motion is brought about by insensible gradations; that is, that A and B influence each other precisely as they would do if a slender spring were interposed. The reader is desired to look at what we have said in the article PHYSICS.

The two magnets there spoken of are good representatives of two atoms endowed with mutual powers of repulsion; and the communication of motion is accomplished in both cases in precisely the same manner.

If, therefore, we shall ever be so fortunate as to discover the law of variation of that force which connects one *atom* of matter with another atom, and which is therefore characteristic of matter, and the ultimate source of all its sensible qualities, the curve whose ordinates represent the kind and the intensity of this atomical force will be something like that sketched in fig. 2. The first branch *a n* B will have

Fig. 2.



AK (perpendicular to the axis AH) for its assymptote, and the last branch *lmo* will be to all sense a hyperbola, having AO for its assymptote; and the ordinates *l*L, *m*M, &c. will be proportional to $\frac{1}{AL^2}$, $\frac{1}{AM^2}$, &c. expressing the universal gravitation of matter. It will have many branches B*b*C, D*d*E, F*f*G, &c. expressing attractions, and alternate repulsive branches C*c*D, E*e*F, G*g*H, &c. All these will be contained within a distance AH, which does not exceed a very minute fraction of an inch.

The simplest extended particle consists of four atoms.

The simplest particle which can be a constituent of a body having length, breadth, and thickness, must consist of four such atoms, all of which combine their influence on each atom of another such particle. It is evident that the curve which expresses the force that connects two such particles must be totally different from this original curve, this hylarchic principle. Supposing the last known, our mathematical knowledge is quite able to discover the first; but when we proceed to compose a body of particles, each of

which consists of four such particles, we may venture to say that the compound force which connects them is almost beyond our search, and that the discovery of the primary force from an *accurate* knowledge of the corpuscular forces of *this* particular matter is absolutely out of our power.

All that we can learn is, the possibility, nay, the certainty, of an innumerable variety of external sensible forms and qualities, by which different kinds of matter will be distinguished, arising from the number, the order of composition, and the arrangement of the subordinate particles of which a particle of this or that kind of matter is composed. All these varieties will take place at those small and insensible distances which are between A and H, and may produce all that variety which we observe in the tangible or mechanical forms of bodies, such as elasticity, ductility, hardness, softness, fluidity, vapour, and all those unseen motions or actions which we observe in fusion and congelation, evaporation and condensation, solution and precipitation, crystallization, vegetable and animal assimilation and secretion, &c.; while all bodies must be, in a certain degree, elastic, all must gravitate, and all must be incompenetrable.

This general and satisfactory resemblance between the appearance of tangible matter and the legitimate consequence of this general hypothetical property of an atom of matter, affords a considerable probability that such is the origin of all the phenomena. We earnestly recommend to our readers a careful perusal of Boscovich's celebrated treatise. A careful perusal is necessary for seeing its value; and nothing will be got by a hasty inspection. The reader will be particularly pleased with the facility and evidence with which the ingenious author has deduced all the ordinary principles of mechanics, and with the explanation which he has given of fluidity, and his deduction from thence of the laws of hydrostatics. No part of the treatise is more valuable than the doctrine of the propagation of pressure through solid bodies. This, however, is but just touched on in the course of the investigation of the principles of mechanics. We shall borrow as much as will suffice for our present inquiry into the strength of materials; and we trust that our readers are not displeased with this general sketch of the doctrine (if it may be so called) of the cohesion of bodies. It is curious and important in itself, and is the foundation of all the knowledge which we can acquire of the present article. We are sorry to say that it is as yet a new subject of study; but it is a very promising one, and we by no means despair of seeing the whole of chemistry brought by its means within the pale of mechanical science. The great and distinguishing agent in chemistry is heat, or fire the cause of heat; and one of its most singular effects is the conversion of bodies into elastic vapour. We have the clearest evidence that this is brought about by mechanical forces; for it can be opposed or prevented by external pressure, a very familiar mechanical force. We may perhaps find another mechanical force which will prevent fusion.

The doctrine of cohesion yet a new subject.

Having now made our readers familiar with the mode of action in which cohesion operates in giving strength to solid bodies, we proceed to consider the strains to which this strength is opposed.

Strains to which strength is opposed.

A piece of solid matter is exposed to four kinds of strains, different in the manner of their operation.

1. It may be torn asunder, as in the case of ropes, stretchers, king-posts, tie-beams, &c.

2. It may be crushed, as in the case of pillars, posts, and truss-beams.

3. It may be broken across, as happens to a joist or lever of any kind.

4. It may be wrenched or twisted, as in the case of the axle of a wheel the nail of a press, &c.

1.—IT MAY BE PULLED ASUNDER.

Matter may be pulled asunder;

This is the simplest of all strains, and the others are indeed modifications of it. To this the force of cohesion is *directly* opposed, with very little modification of its action by any particular circumstances.

When a long cylindrical or prismatic body, such as a rod of wood or metal, or a rope, is drawn by one end, it must be resisted at the other, in order to bring its cohesion into action. When it is fastened at one end, we cannot conceive it any other way than as equally stretched in all its parts; for all our observations and experiments on natural bodies concur in showing us that the forces which connect their particles in any way whatever are equal and opposite. This is called the *third law of motion;* and we admit its universality, while we affirm that it is purely experimental. Yet we have met with dissertations by persons of eminent knowledge, where propositions are maintained inconsistent with this. During the dispute about the communication of motion, some of the ablest writers have said, that a spring compressed or stretched at the two ends was gradually less and less compressed or stretched from the extremities towards the middle: but the same writers acknowledged the universal equality of action and re-action, which is quite incompatible with this state of the spring. No such inequality of compression or dilatation has ever been observed; and a little reflection will show it to be impossible, in consistency with the equality of action and re-action.

Since all parts are thus equally stretched, it follows that the strain in any transverse section is the same, as also in every point of that section. If therefore the body be supposed of a homogeneous texture, the cohesion of the parts is equable; and since every part is equally stretched, the particles are drawn to equal distances from their quiescent positions, and the forces which are thus excited, and now exerted in opposition to the straining force, are equal. This external force may be increased by degrees, which will gradually separate the parts of the body more and more from each other, and the connecting forces increase with this increase of distance, till at last the cohesion of some particles is overcome. This must be immediately followed by a rupture, because the remaining forces are now weaker than before.

It is the united force of cohesion, immediately before the disunion of the first particles, that we call the *strength* of the section. It may also be properly called its *absolute strength*, being exerted in the simplest form, and not modified by any relation to other circumstances.

a circumstance to be attended to in every construction requiring strength.

If the external force have not produced any permanent change on the body, and it therefore recovers its former dimensions when the force is withdrawn, it is plain that this strain may be repeated as often as we please, and the body which withstands it once will always withstand it. It is evident that this should be attended to in all constructions, and that in all our investigations on this subject this should be kept strictly in view. When we treat a piece of soft clay in this manner, and with this precaution, the force employed must be very small. If we exceed this, we produce a permanent change. The rod of clay is not indeed torn asunder, but it has become somewhat more slender; the number of particles in a cross section is now smaller; and therefore, although it will again, in this new form, suffer or allow an endless repetition of a *certain* strain without any farther permanent change, this strain is smaller than the former.

Something of the same kind happens in all bodies which receive a *set* by the strain to which they are exposed. All ductile bodies are of this kind. But there are many bodies which are not ductile. Such bodies break completely whenever they are stretched beyond the limit of their perfect elasticity. Bodies of a fibrous structure exhibit very great

Great varieties in cohesion, but

varieties in their cohesion. In some the fibres have no lateral cohesion, as in the case of a rope. The only way in which all the fibres can be made to unite their strength, is to twist them together. This causes them to bind each other so fast, that any one of them will break before it can be drawn out of the bundle. In other fibrous bodies, such as timber, the fibres are held together by some cement or gluten. This is seldom as strong as the fibre. Accordingly timber is much easier pulled asunder in a direction transverse to the fibres. There is, however, every possible variety in this particular.

In stretching and breaking fibrous bodies, the visible extension is frequently very considerable. This is not solely the increasing of the distance of the particles of the cohering fibre; the greatest part chiefly arises from drawing the crooked fibre straight. In this, too, there is great diversity; and it is accompanied with important differences in their power of withstanding a strain. In some woods, such as fir, the fibres on which the strength most depends are very straight. Such woods are commonly very elastic, do not take a set, and break abruptly when overstrained: others, such as oak and birch, have their resisting fibres very undulating and crooked, and stretch very sensibly by a strain. They are very liable to take a set, and they do not break so suddenly, but give warning by *complaining*, as the carpenters call it; that is, by giving visible signs of a derangement of texture. Hard bodies of an uniform glassy structure, or granulated like stones, are elastic through the whole extent of their cohesion, and take no set, but break at once when overloaded.

Notwithstanding the immense variety which nature exhibits in the structure and cohesion of bodies, there are certain general facts of which we may now avail ourselves with advantage. In particular,

the absolute cohesion or strength proportional to the area of the section perpendicular to the extending force.

The absolute cohesion is proportional to the area of the section. This must be the case where the texture is perfectly uniform, as we have reason to think it is in glass and the ductile metals. The cohesion of each particle being alike, the whole cohesion must be proportional to their number, that is, to the area of the section. The same must be admitted with respect to bodies of a granulated texture, where the granulation is regular and uniform. The same must be admitted of fibrous bodies, if we suppose their fibres equally strong, equally dense, and similarly disposed through the whole section; and this we must either suppose, or must state the diversity, and measure the cohesion accordingly.

We may therefore assert, as a general proposition on this subject, that the absolute strength in any part of a body, by which it resists being pulled asunder, or the force which must be employed to tear it asunder *in that part*, is proportional to the area of the section perpendicular to the extending force.

Therefore all cylindrical or prismatical rods are equally strong in every part, and will break alike in any part; and bodies which have unequal sections will always break in the slenderest part. The length of the cylinder or prism has no effect on the strength. Also the absolute strengths of bodies which have similar sections are proportional to the squares of their diameters or homologous sides of the section.

The weight of the body itself may be employed to strain it and to break it. It is evident, that a rope may be so long as to break by its own weight. When the rope is hanging perpendicularly, although it is equally strong in every part, it will break towards the upper end, because the strain on

Relative strength.

any part is the weight of all that is below it. Its *relative strength* in any part, or power of withstanding the strain which is actually laid on it, is inversely as the quantity below that part.

When the rope is stretched horizontally, as in towing a ship, the strain arising from its weight often bears a very sensible proportion to its whole strength.

These are the chief general rules which can be safely deduced from our clearest notions of the cohesion of bodies. In order to make any practical use of them, it is proper to have some measures of the cohesion of such bodies as are commonly employed in our mechanics, and other structures where they are exposed to this kind of strain. These must be deduced solely from experiment; therefore they must be considered as no more than general values, or as the averages of many particular trials. The irregularities are very great, because none of the substances are constant in their texture and firmness. Metals differ by a thousand circumstances unknown to us, according to their purity, to the heat with which they were melted, to the moulds in which they were cast, and the treatment they have afterwards received, by forging, wire-drawing, tempering, &c.

The cohesion of metals depends on various circumstances.

It is a very curious and inexplicable fact, that by forging a metal, or by frequently drawing it through a smooth hole in a steel plate, its cohesion is greatly increased. This operation undoubtedly deranges the natural situation of the particles. They are squeezed closer together in one direction, but it is not in the direction in which they resist the fracture. In this direction they are rather separated to a greater distance. The general density, however, is augmented in all of them except lead, which grows rather rarer by wire-drawing; but its cohesion may be more than tripled by this operation. Gold, silver, and brass, have their cohesion nearly tripled; copper and iron have it more than doubled. In this operation they also grow much harder. It is proper to heat them to redness after drawing a little. This is called *nealing* or *annealing*. It softens the metal again, and renders it susceptible of another drawing without the risk of cracking in the operation.

We do not pretend to give any explanation of this remarkable and very important fact, which has something resembling it in woods and other fibrous bodies, as will be mentioned afterwards.

The varieties in the cohesion of stones and other minerals, and of vegetable and animal substances, are hardly susceptible of any description or classification.

Cohesion and strength of different metals.

We shall take for the measure of cohesion the number of pounds avoirdupois which are just sufficient to tear asunder a rod or bundle of one inch square. From this it will be easy to compute the strength corresponding to any other dimension.

1*st*, *Metals.*

		lbs.
Gold, cast		20,000 / 24,000
Silver, cast		40,000 / 43,000
Copper, cast,	Japan	19,000
	Barbary	22,000
	Hungary	31,000
	Anglesea	34,000
	Sweden	37,000
Iron, cast		42,000 / 59,000
Iron, bar	Ordinary	68,000
	Stirian	75,000
	Best Swedish and Russian	84,000
	Horse-nails	71,000[1]

[1] This was an experiment by Muschenbroeck, to examine the vulgar notion that iron forged from old horse-nails was stronger than all others, and shows its falsity.

Strength of Materials.

Steel, bar	Soft	120,000
	Razor temper	150,000
Tin, cast	Malacca	3,100
	Banca	3,600
	Block	3,800
	English block	5,200
	——— grain	6,500
Lead, cast		860
Regulus of antimony		1,000
Zinc		2,600
Bismuth		2,900

Tenacity of metals increased by mixtures.

It is very remarkable, that almost all the mixtures of metals are more tenacious than the metals themselves. The change of tenacity depends much on the proportion of the ingredients, and the proportion which produces the most tenacious mixture is different in the different metals. We have selected the following from the experiments of Muschenbroeck. The proportion of ingredients here selected is that which produces the greatest strength.

Two parts of gold with one of silver	28,000
Five parts of gold with one of copper	50,000
Five parts of silver with one of copper	48,500
Four parts of silver with one of tin	41,000
Six parts of copper with one of tin	41,000
Five parts of Japan copper with one of Banca tin	57,000
Six parts of Chili copper with one of Malacca tin	60,000
Six parts of Swedish copper with one of Malacca tin	64,000
Brass consists of copper and zinc in an unknown proportion; its strength is	51,000
Three parts of block-tin with one part of lead	10,200
Eight parts of block-tin with one part of zinc	10,000
Four parts of Malacca tin with one part of regulus of antimony	12,000
Eight parts of lead with one of zinc	4,500
Four parts of tin with one of lead and one of zinc	13,000

These numbers are of considerable use in the arts. The mixtures of copper and tin are particularly interesting in the fabric of great guns. We see that, by mixing copper, whose greatest strength does not exceed 37,000, with tin, which does not exceed 6000, we produce a metal whose tenacity is almost double, at the same time that it is harder and more easily wrought. It is, however, more fusible, which is a great inconvenience. We also see that a very small addition of zinc almost doubles the tenacity of tin, and increases the tenacity of lead five times; and a small addition of lead doubles the tenacity of tin. These are economical mixtures. This is very valuable information to the plumbers, for augmenting the strength of water-pipes.

By having recourse to these tables, the engineer can proportion the thickness of his pipes, of whatever metal, to the pressures to which they are exposed.

2d, *Woods.*

We may premise to this part of the table the following general observations.

Tenacity or strength of wood.

1. The wood immediately surrounding the pith or heart of the tree is the weakest, and its inferiority is so much more remarkable as the tree is older. In this assertion, however, we speak with some hesitation. Muschenbroeck's *detail* of experiments is decidedly in the affirmative. M. Buffon, on the other hand, says that his experience has taught him that the heart of a sound tree is the strongest; but he gives no instances. From many observations of our own on very *large* oaks and firs, we are certain that the heart is much weaker than the exterior parts.

2. The wood next the bark, commonly called the *white* or *blea*, is also weaker than the rest; and the wood gradually increases in strength as we recede from the centre to the blea.

3. The wood is stronger in the middle of the trunk than at the springing of the branches or at the root; and the wood of the branches is weaker than that of the trunk.

4. The wood of the north side of all trees which grow in our European climates is the weakest, and that of the south-east side is the strongest; and the difference is most remarkable in hedge-row trees, and such as grow singly. The heart of a tree is never in its centre, but always nearer to the north side, and the annual coats of wood are thinner on that side. In conformity with this, it is a general opinion of carpenters that timber is stronger whose annual plates are thicker. The trachea or air-vessels are weaker than the simple ligneous fibres. The air-vessels are the same in diameter and number of rows in trees of the same species, and they make the visible separation between the annual plates. Therefore, when these are thicker, they contain a greater proportion of the simple ligneous fibres.

5. All woods are more tenacious while green, and lose very considerably by drying after the trees are felled.

The only author who has put it in our power to judge of the propriety of his experiments is Muschenbroeck. He has described his method of trial minutely, and it seems unexceptionable. The woods were all formed into slips fit for his apparatus, and part of the slip was cut away to a parallelopiped of $\frac{1}{5}$th of an inch square, and therefore $\frac{1}{25}$th of a square inch in section. The absolute strengths of a square inch were as follow:

Absolute strength of different kinds of wood.

	lib.		lib.
Locust tree	20,100	Pomegranate	9750
Juleb	18,500	Lemon	9250
Beech, oak	17,300	Tamarind	8750
Orange	15,500	Fir	8330
Alder	13,900	Walnut	8130
Elm	13,200	Pitch-pine	7650
Mulberry	12,500	Quince	6750
Willow	12,500	Cypress	6000
Ash	12,000	Poplar	5500
Plum	11,800	Cedar	4880
Elder	10,000		

Muschenbroeck has given a very minute detail of the experiments on the ash and the walnut, stating the weights which were required to tear asunder slips taken from the four sides of the tree, and on each side, in a regular progression from the centre to the circumference. The number of this table corresponding to these two timbers may therefore be considered as the average of more than fifty trials made of each; and he says that all the others were made with the same care. We cannot therefore see any reason for not confiding in the results; yet they are considerably higher than those given by some other writers. Mr Pitot, on the authority of his own experiments, and of those of Mr Parent, avers that sixty pounds will just tear asunder a square line of sound oak, and that it will bear fifty with safety. This gives 8640 for the utmost strength of a square inch, which is much inferior to Muschenbroeck's valuation.

We may add to these,

and of other substances.

Ivory	16,270
Bone	5,250
Horn	8,750
Whalebone	7,500
Tooth of sea-calf	4,075

No substance to be strained in architecture above one half its strength.

The reader will surely observe, that these numbers express something more than the utmost cohesion; for the weights are such as will very quickly, that is, in a minute or two, tear the rods asunder. It may be said in general, that two thirds of these weights will sensibly impair the strength after a considerable while, and that one half is the utmost that can remain suspended at them without risk for ever; and it is upon this last allotment that the engineer should reckon in his constructions. There is, however, considerable difference in this respect. Woods of a very straight

fibre, such as fir, will be less impaired by any load which is not sufficient to break them immediately.

According to Mr Emerson, the load which may be safely suspended to an inch square is as follows:

Iron	76,400
Brass	35,600
Hempen rope	19,600
Ivory	15,700
Oak, box, yew, plum-tree	7,850
Elm, ash, beech,	6,070
Walnut, plum	5,360
Red fir, holly, elder, plane, crab	5,000
Cherry, hazel	4,760
Alder, asp, birch, willow	4,290
Lead	430
Freestone	914

He gives us a practical rule, that a cylinder whose diameter is 1 inch, loaded to one fourth of its absolute strength, will carry as follows:

Iron	135	cwt.
Good rope	22	cwt.
Oak	14	cwt.
Fir	9	cwt.

The rank which the different woods hold in this list of Mr Emerson's is very different from what we find in Muschenbroeck's. But precise measures must not be expected in this matter. It is wonderful, that in a matter of such unquestionable importance the public has not enabled some persons of judgment to make proper trials. They are beyond the abilities of private persons.

II.—BODIES MAY BE CRUSHED.

It is of importance to know what will crush bodies.

It is of equal, perhaps greater, importance to know the strain which may be laid on solid bodies without danger of crushing them. Pillars and posts of all kinds are exposed to this strain in its simplest form; and there are cases where the strain is enormous, viz. where it arises from the oblique position of the parts, as in the struts, braces, and trusses, which occur very frequently in our great works. It is therefore most desirable to have some general knowledge of the principle which determines the strength of bodies, in opposition to this kind of strain. But, unfortunately, we are much more at a loss in this than in the last case. The mechanism of nature is, in the present case, much more complicated. It must be in some circuitous way that compression can have any tendency to tear asunder the parts of a solid body, and it is very difficult to trace the steps.

If we suppose the particles insuperably hard and in contact, and disposed in lines which are in the direction of the external pressures, it does not appear how any pressure can disunite the particles; but this is a gratuitous supposition. There are infinite odds against this precise arrangement of the lines of particles; and the compressibility of all kinds of matter in some degree shows that the particles are in a situation equivalent to distance. This being the case, and the particles, with their intervals, or what is equivalent to intervals, being in situations that are oblique with respect to the pressures, it must follow, that by squeezing them together in one direction, they are made to bulge out or separate in other directions. This may proceed so far that some may be thus pushed laterally beyond their limits of cohesion. The moment that this happens the resistance to compression is diminished, and the body will now be crushed together. We may form some notion of this by supposing a number of spherules, like small shot, sticking together by means of a cement. Compressing this in some particular direction causes the spherules to act among each other like so many wedges, each tending to penetrate through between the three which lie below it: and this is the simplest, and perhaps the only distinct, notion we can have of the matter.

We have reason to think that the constitution of very homogeneous bodies, such as glass, is not very different from this.

Their strength or power of resistance to such a force,

If this be the constitution of bodies, it appears probable that the strength, or the resistance which they are capable of making to an attempt to crush them to pieces, is proportional to the area of the section whose plane is perpendicular to the external force; for each particle being similarly and equally acted on and resisted, the whole resistance must be as their number, that is, as the extent of the section.

Accordingly this principle is assumed by the few writers who have considered the subject; but we confess that it appears to us very doubtful. Suppose a number of brittle or friable balls lying on a table uniformly arranged, but not cohering nor in contact, and that a board is laid over them and loaded with a weight; we have no hesitation in saying that the weight necessary to crush the whole collection is proportional to their number or to the area of the section. But when they are in contact, and still more if they cohere, we imagine that the case is materially altered. Any individual ball is crushed only in consequence of its being bulged outwards in the direction perpendicular to the pressure employed. If this could be prevented by a hoop put round the ball like an equator, we cannot see how any force can crush it. Any thing therefore which makes this bulging outwards more difficult, makes a greater force necessary. Now this effect will be produced by the mere contact of the balls before the pressure is applied; for the central ball cannot swell outward laterally without pushing away the balls on all sides of it. This is prevented by the friction on the table and upper board, which is at least equal to one third of the pressure. Thus any interior ball becomes stronger by the mere vicinity of the others; and if we further suppose them to cohere laterally, we think that its strength will be still more increased.

The analogy between these balls and the cohering particles of a friable body is very perfect. We should therefore expect that the strength by which it resists being crushed will increase in a greater ratio than that of the section, or the square of the diameter of similar sections; and that a square inch of any matter will bear a greater weight in proportion as it makes a part of a greater section. Accordingly this appears in many experiments, as will afterwards be noticed. Muschenbroeck, Euler, and some others, have supposed the strength of columns to be as the biquadrates of their diameters. Euler deduced this from formulæ which occurred to him in the course of his algebraic analysis; and he boldly adopts it as a principle, without looking for its foundation in the physical assumptions which he had made in the beginning of his investigation. But some of his original assumptions were as paradoxical, or at least as gratuitous, as these results; and those, in particular, from which this proportion of the strength of columns was deduced, were almost foreign to the case; and therefore the inference was of no value. Yet it was received as a principle by Muschenbroeck and by the academicians of St Petersburg. We make these very few observations, because the subject is of great practical importance; and it is a great obstacle to improvements when deference to a great name, joined to incapacity or indolence, causes authors to adopt his careless reveries as principles from which they are afterwards to draw important consequences. It must be acknowledged that we have not as yet established, on solid mechanical principles, the relation between the dimensions and the strength of a pillar. Experience plainly contradicts the general opinion, that the strength is proportional to the area of the section; but it is still more inconsistent with the opinion, that it is in the quadruplicate ratio of the diameters of similar sections. It would seem that the ratio depends much on the internal structure of the body; and experiment seems the only method for ascertaining its general laws.

Strength of Materials.

to be ascertained only by experiment.

If we suppose the body to be of a fibrous texture, having the fibres situated in the direction of the pressure, and slightly adhering to each other by some kind of cement, such a body will fail only by the bending of the fibres, by which they will break the cement and be detached from each other. Something like this may be supposed in wooden pillars. In such cases, too, it would appear that the resistance must be as the number of equally resisting fibres, and as their mutual support, jointly; and, therefore, as some function of the area of the section. The same thing must happen if the fibres be naturally crooked or undulated, as is observed in many woods, provided we suppose some similarity in their form. Similarity of some kind must always be supposed, otherwise we need never aim at any general inferences.

In all cases therefore we can hardly refuse admitting that the strength in opposition to compression is proportional to a function of the area of the section.

As the whole length of a cylinder or prism is equally pressed, it does not appear that the strength of a pillar is at all affected by its length. If indeed it be supposed to bend under the pressure, the case is greatly changed, because it is then exposed to a transverse strain; and this increases with the length of the pillar. But this will be considered with due attention under the next class of strains.

Few experiments have been made on this species of strength and strain. Mr Pitot says that his experiments and those of Mr Parent show that the force necessary for crushing a body is nearly equal to that which will tear it asunder. He says that it requires something more than sixty pounds on every square line to crush a piece of sound oak. But the rule is by no means general: glass, for instance, will carry a hundred times as much as oak in this way, that is, resting on it; but will not *suspend* four or five times as much. Oak will suspend a great deal more than fir; but fir, as a pillar, will carry twice as much. Woods of a soft texture, although consisting of very tenacious fibres, are more easily crushed by their load. This softness of texture is chiefly owing to their fibres not being straight but undulated, and there being considerable vacuities between them, so that they are easily bent laterally and crushed. When a post is overstrained by its load, it is observed to swell sensibly in diameter. Increasing the load causes longitudinal cracks or shivers to appear, and it presently after gives way. This is called *crippling.*

In all cases where the fibres lie oblique to the strain, the strength is greatly diminished, because the parts can then be made to slide on each other when the cohesion of the cementing matter is overcome.

Muschenbroeck has given some experiments on this subject; but they are cases of long pillars, and therefore do not belong to this place. They will be considered afterwards.

The only experiments of which we have seen any detail (and it is useless to insert mere assertions) are those of Mr Gauthey, in the fourth volume of Rozier's *Journal de Physique.* This engineer exposed to great pressures small rectangular parallelopipeds, cut from a great variety of stones, and noted the weights which crushed them. The following table exhibits the medium results of many trials on two very uniform kinds of freestone, one of them among the hardest and the other among the softest used in building.

Column first expresses the length AB of the section, in French lines or 12ths of an inch; column second expresses the breadth BC; column third is the area of the section, in square lines; column fourth is the number of ounces required to crush the piece; column fifth is the weight which was then borne by each square line of the section; and column sixth is the round numbers to which Mr Gauthey imagines that those in column fifth approximate.

Experiments for this purpose made on freestone

	AB.	BC.	AB×BC.	Weight.	Force.	
			Hard Stone.			
1	8	8	64	736	11·5	12
2	8	12	96	2625	27·3	24
3	8	16	128	4496	35·1	36
			Soft Stone.			
4	9	16	144	560	3·9	4·
5	9	18	162	848	5·3	4·5
6	18	18	324	2928	9·	9·
7	18	24	432	5296	12·2	12·

Little can be deduced from these experiments: the first and third, compared with the fifth and sixth, should furnish similar results; for the first and fifth are respectively half of the third and sixth; but the third is three times stronger (that is, a line of the third) than the first, whereas the sixth is only twice as strong as the fifth.

It is evident, however, that the strength increases much faster than the area of the section, and that a square line can carry more and more weight, according as it makes a part of a larger and larger section. In this series of experiments on the soft stone, the individual strength of a square line seems to increase nearly in the proportion of the section of which it makes a part.

Mr Gauthey deduces, from the whole of his numerous experiments, that a pillar of hard stone of Givry, whose section is a square foot, will bear with perfect safety 664,000 pounds, and that its extreme strength is 871,000; and the smallest strength observed in any of his experiments was 460,000. The soft bed of Givry stone had for its smallest strength 187,000, for its greatest 311,000, and for its safe load 249,000. Good brick will carry with safety 320,000; chalk will carry only 9000. The boldest piece of architecture in this respect which he has seen is a pillar in the church of All-Saints at Angers. It is twenty-four feet long and eleven inches square, and is loaded with 60,000, which is not one seventh of what is necessary for crushing it.

We may observe here by the way, that Mr Gauthey's measure of the suspending strength of stone is vastly small in proportion to its power of supporting a load laid above it. He finds that a prism of the hard bed of Givry, of a foot section, is torn asunder by 4600 pounds; and if it be firmly fixed horizontally in a wall, it will be broken by a weight of 56,000 suspended a foot from the wall. If it rest on two props at a foot distance, it will be broken by 206,000 laid on its middle. These experiments agree so ill with each other, that little use can be made of them. The subject is of great importance, and well deserves the attention of the patriotic philosopher.

not satisfactory.

A set of good experiments would be very valuable, because it is against this kind of strain that we must guard by judicious construction in the most delicate and difficult problems which come through the hands of the civil and military engineer. The construction of stone arches, and the construction of great wooden bridges, and particularly the construction of the frames of carpentry called *centres* in the erection of stone bridges, are the most difficult jobs that occur. In the centres on which the arches of the bridge of Orleans were built, some of the pieces of oak were carrying upwards of two tons on every square inch of their scantling. All who saw it said that it was not able to carry the fourth part of the intended load. But the engineer understood the principles of his art, and ran the risk, and the result completely justified his confidence; for the centre did not complain in any part, only it was found too supple; so that it went out of shape while the haunches only of the arch were laid on it. The engineer corrected this by loading it at the crown, and thus kept it completely in shape during the progress of the work.

Good experiments much wanted.

In the Memoirs of the Academy of St Petersburg for

1778, there is a dissertation by Euler on this subject, but particularly limited to the strain on columns, in which the bending is taken into the account. Mr Fuss has treated the same subject with relation to carpentry in a subsequent volume. But there is little in these papers besides a dry mathematical disquisition, proceeding on assumptions which (to speak favourably) are extremely gratuitous. The most important consequence of the compression is wholly overlooked, as we shall presently see. Our knowledge of the mechanism of cohesion is as yet far too imperfect to entitle us to a confident application of mathematics. Experiments should be multiplied.

How they are to be made useful.

The only way in which we can hope to make these experiments useful, is to pay a careful attention to the *manner* in which the fracture is produced. By discovering the general resemblances in this particular, we advance a step in our power of introducing mathematical measurement. Thus, when a cubical piece of chalk is slowly crushed between the chaps of a vice, we see it uniformly split in a surface oblique to the pressure, and the two parts then slide along the surface of fracture. This should lead us to examine mathematically what relation there is between this surface of fracture and the necessary force; then we should endeavour to determine experimentally the position of this surface. Having discovered some general law or resemblance in this circumstance, we should try what mathematical hypothesis will agree with this. Having found one, we may then apply our simplest notions of cohesion, and compare the result of our computations with experiment.

III.—A BODY MAY BE BROKEN ACROSS.

It is of importance to know what strain will break a body transversely.

The most usual, and the greatest strain, to which materials are exposed, is that which tends to break them transversely. It is seldom, however, that this is done in a manner perfectly simple; for when a beam projects horizontally from a wall, and a weight is suspended from its extremity, the beam is commonly broken near the wall, and the intermediate part has performed the functions of a lever. It sometimes, though rarely, happens that the pin in the joint of a pair of pincers or scissors is cut through by the strain; and this is almost the only case of a simple transverse fracture. Being so rare, we may content ourselves with saying, that in this case the strength of the piece is proportional to the area of the section.

Experiments made to ascertain it.

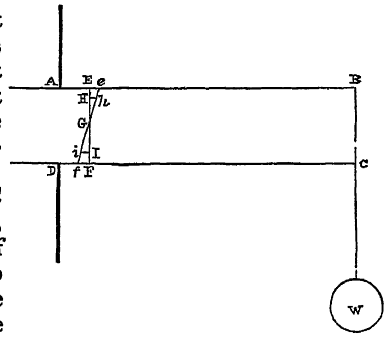
Experiments were made for discovering the resistances made by bodies to this kind of strain in the following manner. Two iron bars were disposed horizontally at an inch distance; a third hung perpendicularly between them, being supported by a pin made of the substance to be examined. This pin was made of a prismatic form, so as to fit exactly the holes in the three bars, which were made very exact, and of the same size and shape. A scale was suspended at the lower end of the perpendicular bar, and loaded till it tore out that part of the pin which filled the middle hole. This weight was evidently the measure of the lateral cohesion of two sections. The side-bars were made to grasp the middle bar pretty strongly between them, that there might be no distance interposed between the opposite pressures. This would have combined the energy of a lever with the purely transverse pressure. For the same reason it was necessary that the internal parts of the holes should be no smaller than the edges. Great irregularities occurred in our first experiments from this cause, because the pins were somewhat tighter within than at the edges; but when this was corrected they were extremely regular. We employed three sets of holes, viz. a circle, a square (which was occasionally made a rectangle whose length was twice its breadth), and an equilateral triangle. We found in all our experiments the strength exactly proportional to the area of the section, and quite independent of its figure or position, and we found it considerably above the direct cohesion; that is, it took considerably more than twice the force to tear out this middle piece that it did to tear the pin asunder by a direct pull. A piece of fine freestone required 205 pounds to pull it directly asunder, and 575 to break it in this way. The difference was very constant in any one substance, but varied from four thirds to six thirds in different kinds of matter, being smallest in bodies of a fibrous texture. But indeed we could not make the trial on any bodies of considerable cohesion, because they required such forces as our apparatus could not support. Chalk, clay baked in the sun, baked sugar, brick, and freestone, were the strongest that we could examine.

Their result.

But the more common case, where the energy of a lever intervenes, demands a minute examination.

Let ABCD (fig. 3) be the longitudinal section of a beam inserted into a wall at the end AD, and supporting a weight at the free end BC: it is required to find what tendency the weight will have to break the beam over at the section EF.

Fig. 3.



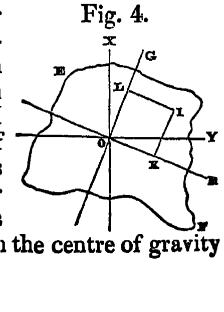
The weight at C will, in the first place, cause a tendency of the part EBCF to slide down on the surface EF, but the strength of the beam in resisting this kind of dislocation is much greater than its power of resisting common fracture: it is therefore unnecessary to examine this case.

The weight at C will cause the beam to bend; that is, it will distend the upper and compress the under part of the beam, and, acting at the extremity of the lever FC, its power of causing such compression and distention will be W × FC. Since the weight at C acts in a vertical direction, it cannot tend either to lengthen or to shorten the beam, and thus the repulsion of the compressed part must be exactly equal to the attraction of the distended parts.

Let G be the neutral point, and draw through it the line *f* G *e*, contiguous to FGE; draw also H*h* and I*i* parallel to CD. The lines I*i*, in the under side of the cross section, will represent the degrees of compression, and also (since within the limits of security the repulsion is proportional to the degree of compression) the force of repulsion, while the lines H*h* on the upper side will serve to represent the attractions. The sum of all the lines on the upper side, that is, the wedge EG*e*, will thus represent the entire amount of attraction, while the wedge FG*f* will represent the total amount of repulsion. These two wedges, then, must be equal to each other; and this equality determines the position of the axis of flexure represented by the point G. In the case of a rectangular beam, G must clearly be in the middle of the line EF; but when the cross section of the beam is irregular, the position of the axis of flexure is not quite so easily found.

Let EF be the cross section of an irregular beam, and OH the axis of flexure, or the place where the beam is neither compressed nor distended. Then the wedges generated by turning the section EF upon OH as an axis must be equal to each other. This is always the case when OH passes through the centre of gravity of the cross section, and thus it follows that those points which are neither compressed nor distended are always ranged in a straight line drawn through the centre of gravity of the cross section.

Fig. 4.



The position of the fulcrum of the lever being now known, we can proceed to ascertain the effects of the various forces.

Returning, for the sake of simplicity, to the rectangular beam; the sum of the repulsions iI will be represented by the triangle GfF: but the rectangle under GF and Ff would measure the entire strength of the under half of the beam, and therefore the force actually exerted when the beam is about to be broken across, is just half of the absolute strength of the beam; one quarter being exhibited as attraction, another quarter as repulsion. These forces act at different distances from the fulcrum G, and it is well known that the influence of a number of weights in turning a lever round is the same as if all these weights were to act at their common centre of gravity; so that to find the entire action in this case, we have to suppose one fourth of the whole strength of the beam to act at the distance $\frac{2}{3}$ of GF or $\frac{1}{3}$ of EF from the fulcrum G, and another quarter of the strength at $\frac{2}{3}$ of GE. Now, if s be the strength of one square inch of the beam, and if D, B, and L be its depth, breadth, and length, measured in inches, DBs will be the absolute strength of the whole beam; and therefore the tendencies of the above forces to straighten the beam will be

$$\tfrac{1}{4}\,DBs \times \tfrac{1}{3}\,D + \tfrac{1}{4}\,DBs \times \tfrac{1}{3}\,D;$$

that is, $\frac{1}{6}\,D^2 \cdot B \cdot s$. And again, the tendency of the weight W to bend the beam is WL; so that

$$\tfrac{1}{6}\,D^2 \cdot B \cdot s = WL,$$

$$\text{or } 6L : D :: DBs : W;$$

that is, *as six times the length of the beam is to its depth, so is the absolute strength of the beam to the weight which it can carry at the free end.*

Throughout this investigation we have supposed that the force needed to extend or compress a fibre is exactly proportional to the quantity of extension or compression. This hypothesis, though not perhaps strictly true, and though it certainly errs when we approach to dislocation or fracture, is yet confirmed by all experiments when the extensions have been kept within the limits of safety: the results of this hypothesis therefore are what must guide us in forming any structure.

It may now be interesting to inquire into the strength of a beam when bent in different directions.

EF being, as before, the cross section of an irregular beam, let that beam be bent in the direction OG, the axis of flexure being OH perpendicular to OG; and let us consider the action of a small portion ds of the surface situated at I. Having drawn the perpendiculars IK and IL, it is clear that the compression of the fibre I must be proportional to KI; and therefore the force exerted by it may be denoted by $C \cdot IK \cdot ds$, C being some constant depending on the nature of the material and the degree of flexure. This force, conceived to act at the extremity of the lever KI, will tend to bend the beam round the axis OH; but again acting at the end of the lever LI, it will tend to bend the beam on OG as an axis. Putting Σ to denote the integral for the entire surface, $C \cdot \Sigma \cdot IK^2 ds$ will be the entire tendency to rectify the form of the beam, and $C\Sigma IK \cdot IL \cdot ds$ will be the entire tendency to take a flexure in a plane at right angles to that which it actually has. A beam therefore will not bend in the direction in which the pressure is applied to it unless $\Sigma \cdot IK \cdot IL ds = 0$. This is a circumstance overlooked in all treatises on flexure; but it is one that must be carefully attended to in practice. It may easily be illustrated thus: Take a thin slip of wood, such perhaps as is used for Venetian blinds, and fix it in a vice so that while its length is horizontal its flat sides may be inclined at a considerable angle. Attach now a weight to the free end, and it will be found that that end does not descend vertically, but that it moves obliquely, the flexure not happening in that direction in which the force is applied. The force necessary to bend the beam in the plane of OG is not a force in that direction, but is the resultant of two forces, $\Sigma\, IK^2 \cdot ds$ in the direction OG, and $\Sigma \cdot IK \cdot IL \cdot ds$ in the direction OH. For the present we shall call $\Sigma IK^2 ds$ the *stiffness in the direction* OG, and $\Sigma \cdot IL^2 ds$ of course the stiffness in the direction OH. The sum of these two stiffnesses is manifestly $\Sigma \cdot OI^2 ds$, which is a constant quantity, depending not at all upon the directions of OG, OH, but only on the form of the cross section: hence follows the remarkable law, that the sum of the stiffnesses of a beam in two directions perpendicular to each other is constant; and that therefore, whatever may be the form of the beam, its directions of greatest and least stiffness are always perpendicular to each other.

For the purpose of discovering in what directions the greatest and least stiffness lie, let us refer all the points in the cross section to the axes OX and OY, putting the angle $XOG = \varphi$. We have then $IK = x \cos.\varphi + y \sin.\varphi$, $IL = -x \sin.\varphi + y \cos.\varphi$; and thus the tendency of the beam to redress itself in the direction GO is $\Sigma \cdot (x \cos.\varphi + y \sin.\varphi)^2\, ds$, while the deflecting tendency in the direction HO is $\Sigma \cdot (x \cos.\varphi + y \sin.\varphi)(-x \sin.\varphi + y \cos.\varphi)\, ds$. Regarding φ as the variable quantity, and differentiating the former for the purpose of discovering its maximum, we obtain $\Sigma \cdot (x \cos.\varphi + y \sin.\varphi)(-x \sin.\varphi + y \cos.\varphi)\, ds = 0$; now it will be observed that this expression is just that for the deflecting tendency, and hence this law,

That when a beam is bent in the direction of greatest or of least stiffness, the pressure to be applied is exactly in the direction of the bending.

The value of φ may easily be found from the above equation; the result is

$$\tan.\, 2\,\varphi = \frac{2\,\Sigma \cdot xy\, ds}{\Sigma x^2 ds - \Sigma y^2 ds}.$$

The lines OX and OY will coincide with the directions of greatest and least stiffness when $\varphi = 0$, or when $\tan.\, 2\,\varphi = 0$, that is, when $\Sigma \cdot xy\, ds = 0$.

If, then, the directions of greatest and least stiffness be taken for the axes of x and of y, we shall have $\Sigma \cdot xy\, ds = 0$, $\Sigma\, x^2 ds =$ greatest stiffness $= A$, $\Sigma\, y^2 ds =$ least stiffness $= B$. These being once known, the stiffness in any other direction, as well as the deflecting tendency, can readily be obtained. Putting P and Q respectively for these quantities, we have

$$P = A \cos.\varphi^2 + B \sin.\varphi^2,$$

$$Q = \tfrac{1}{2}\,(B - A) \sin.\, 2\,\varphi.$$

The deflecting tendency is thus greatest when $\varphi = 45°$, that is, when the actual direction of flexure is equally inclined to the directions of greatest and least stiffness. In this case

$$P^1 = \tfrac{1}{2}\,(A + B),\ Q = \tfrac{1}{2}\,(B - A).$$

Galileo, who was the first to investigate the law of transverse strain, conceived the lower edge of the beam to be the fulcrum, and each fibre to be exerting its whole strength; Professor Robison, in the former editions of this work, corrected the supposition in the case of rectangular beams: the above investigation extends it to beams of all forms.

We must now remark, that this correction of the Galilean hypothesis of equal forces was suggested by the bending which is observed in all bodies which are strained transversely. Because they are bent, the fibres on the convex side have been extended. We cannot say in what proportion this obtains in the different fibres. Our most distinct notions of the internal equilibrium between the particles render it highly probable that their extension is proportional to their distance from that fibre which retains its former dimensions. But by whatever law this is regulated, we see plainly that the actions of the stretched fibres must follow the proportions of some function of this distance, and that therefore the relative strength of a beam is in all cases susceptible of mathematical determination.

Bernoulli's problem of the elastic curve.

We also see an intimate connection between the strain and the curvature. This suggested to the celebrated James Bernoulli the problem of the *elastic curve, i. e.* the curve into which an extensible rigid body will be bent by a transverse strain. His solution in the *Acta Eruditorum* 1694 and 1695, is a very beautiful specimen of mathematical discussion, and we recommend it to the perusal of the curious reader. He will find it very perspicuously treated in the first volume of his works, published after his death, where the wide steps which he had taken in his investigation are explained so as to be easily comprehended. His nephew, Daniel Bernoulli, has given an elegant abridgement in the Petersburg Memoirs for 1729. The problem is too intricate to be fully discussed in a work like ours, but it is also too intimately connected with our present subject to be entirely omitted. We must content ourselves with showing the leading mechanical properties of this curve, from which the mathematician may deduce all its geometrical properties.

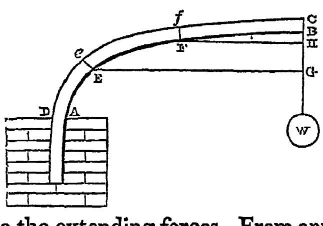
Its leading mechanical property described.

When a bar of uniform depth and breadth, and of a given length, is bent into an arch of a circle, the extension of the outer fibres is proportional to the curvature; for, because the curves formed by the inner and outer sides of the beam are similar, the circumferences are as the radii, and the radius of the inner circle is to the difference of the radii as the length of the inner circumference is to the difference of the circumferences. The difference of the radii is the depth of the beam, the difference of the circumferences is the extension of the outer fibres, and the inner circumference is supposed to be the primitive length of the beam. Now the second and third quantities of the above analogy, viz. the depth and length of the beam, are constant quantities, as is also their product. Therefore the product of the inner radius and the extension of the outer fibre is also a constant quantity, and the whole extension of the outer fibre is inversely as the radius of curvature, or is directly as the curvature of the beam.

The mathematical reader will readily see, that into whatever curve the elastic bar is bent, the whole extension of the outer fibre is equal to the length of a similar curve having the same proportion to the thickness of the beam that the length of the beam has to the radius of curvature.

Now let ADCB (fig. 5) be such a rod of uniform breadth and thickness, firmly fixed in a vertical position, and bent into a curve AEFB by a weight W suspended at B, and of such magnitude that the extremity B has its tangent perpendicular to the action of the weight, or parallel to the horizon. Suppose, too, that the extensions are proportional to the extending forces. From any two points E and F draw the horizontal ordinates EG, FH. It is evident that the exterior fibres of the sections E*e* and F*f* are stretched by forces which are in the proportion of EG to FH (these being the long arms of the levers, and the equal thicknesses E*e*, F*f* being the short arms). Therefore (by the hypothesis) their extensions are in the same proportion. But because the extensions are proportional to some similar functions of the distance from the axes of fracture E and F, the extension of any fibre in the section E*e* is to the contemporaneous extension of the similarly situated fibre in the section F*f*, as the extension of the exterior fibre in the section E*e* is to the extension of the exterior fibre in the section F*f*: therefore the whole extension of E*e* is to the whole extension of F*f* as EG to FH, and EG is to FH as the curvature in E to the curvature in F.

Fig. 5.



Here let it be remarked, that this proportionality of the curvature to the extension of the fibres is not limited to the hypothesis of the proportionality of the extensions to the extending forces: it follows from the extension in the different sections being as some similar function of the distance from the axis of fracture; an assumption which cannot be refused.

This, then, is the fundamental property of the elastic curve, from which its equation, or relation between the abscissa and ordinate, may be deduced in the usual forms, and all its other geometrical properties. These are foreign to our purpose; and we shall notice only such properties as have an immediate relation to the strain and strength of the different parts of a flexible body, and which in particular serve to explain some difficulties in the valuable experiments of Buffon on the Strength of Beams.

It is not a circle.

We observe, in the first place, that the elastic curve cannot be a circle, but is gradually more incurvated as it recedes from the point of application B of the straining forces. At B it has no curvature; and if the bar were extended beyond B there would be no curvature there. In like manner, when a beam is supported at the ends and loaded in the middle, the curvature is greatest in the middle; but at the props, or beyond them, if the beam extend farther, there is no curvature. Therefore, when a beam projecting twenty feet from a wall is bent to a certain curvature at the wall by a weight suspended at the end, and a beam of the same size projecting twenty feet is bent to the very same curvature at the wall by a greater weight at ten feet distance, the figure and the mechanical state of the beam in the vicinity of the wall is different in these two cases, though the curvature at the very wall is the same in both. In the first case every part of the beam is incurvated; in the second, all beyond the ten feet is without curvature. In the first experiment the curvature at the distance of five feet from the wall is three fourths of the curvature at the wall; in the second, the curvature at the same place is but one half of that at the wall. This must weaken the long beam in this whole interval of five feet, because the greater curvature is the result of a greater extension of the fibres.

Every beam has a certain determinate curvature.

In the next place we may remark, that there is a certain determinate curvature for every beam, which cannot be exceeded without breaking it; for there is a certain separation of two adjoining particles that puts an end to their cohesion. A fibre can therefore be extended only a certain proportion of its length. The ultimate extension of the outer fibres must bear a certain determinate proportion to its length, and this proportion is the same with that of the thickness (or what we have hitherto called the depth) to the radius of ultimate curvature, which is therefore determinate.

And when of uniform breadth and depth, is most incurvated where the strain is greatest.

A beam of uniform breadth and depth is therefore most incurvated where the strain is greatest, and will break in the most incurvated part. But by changing its form, so as to make the strength of its different sections in the ratio of the strain, it is evident that the curvature may be the same throughout, or may be made to vary according to any law. This is a remark worthy of the attention of the watchmaker. The most delicate problem in practical mechanics is so to taper the balance-spring of a watch that its wide and narrow vibrations may be isochronous. Hooke's principle *ut tensio sic vis* is not sufficient when we take the *inertia* and motion of the spring itself into the account. The figure into which it bends and unbends has also an influence. Our readers will take notice that the artist aims at an accuracy which will not admit an error of $\frac{1}{86400}$th, and that Harrison and Arnold have actually attained it in several instances. The taper of a spring is at present a nostrum in the hands of each artist, and he is careful not to impart its secret.

Again, since the depth of the beam is thus proportional to the radius of ultimate curvature, this ultimate or breaking curvature is inversely as the depth. It may be expressed by $\frac{1}{d}$.

To what the curvature is proportional.

When a weight is hung on the end of a prismatic beam, the curvature is nearly as the weight and the length directly, and as the breadth and the cube of the depth inversely; for the strength is $=f\frac{bd^2}{6l}$. Let us suppose that this produces the ultimate curvature $\frac{1}{d}$. Now let the beam be loaded with a smaller weight w, and let the curvature produced be C; we have this analogy, $f\frac{bd^2}{6l}:w=\frac{1}{d}:\mathrm{C}$, and $\mathrm{C}=\frac{6lw}{fbd^3}$. It is evident that this is also true of a beam supported at the ends and loaded between the props; and we see how to determine the curvature in its different parts, whether arising from the load, or from its own weight, or from both.

Deflection.

When a beam is thus loaded at the end or middle, the loaded point is pulled down, and the space through which it is drawn may be called the *deflection*. This may be considered as the subtense of the angle of contact, or as the versed sine of the arch into which the beam is bent, and is therefore as the curvature when the length of the arches is given (the flexure being moderate), and as the square of the length of the arch when the curvature is given. The deflection therefore is as the curvature and as the square of the length of the arch jointly; that is, as $\frac{6lw}{fbd^3}\times l^2$, or as $\frac{6l^3w}{fbd^3}$. The deflection from the primitive shape is therefore as the bending weight and the cube of the length directly, and as the breadth and cube of the depth inversely.

In beams just ready to break, the curvature is as the depth inversely, and the deflection is as the square of the length divided by the depth; for the ultimate curvature at the breaking part is the same whatever is the length; and in this case the deflection is as the square of the length.

The theorems resulting from this subject afford the finest methods of examining the laws of corpuscular action.

We have been the more particular in our consideration of this subject, because the resulting theorems afford us the finest methods of examining the laws of corpuscular action, that is, for discovering the variation of the force of cohesion by a change of distance. It is true it is not the atomical law, or *hylarchic principle* as it may justly be called, which is thus made accessible, but the specific law of the particles of the substance or kind of matter under examination. But even this is a very great point; and coincidences in this respect among the different kinds of matter are of great moment. We may thus learn the nature of the corpuscular action of different substances, and perhaps approach to a discovery of the *mechanism* of chemical affinities. For that chemical actions are insensible cases of local motion is undeniable, and local motion is the province of mechanical discussion; nay, we see that these hidden changes are produced by mechanical forces in many important cases, for we see them promoted or prevented by means purely mechanical. The conversion of bodies into elastic vapour by heat can at all times be prevented by a *sufficient* external pressure. A strong solution of Glauber's salts will congeal in an instant by agitation, giving out its latent heat; and it will remain fluid for ever, and retain its latent heat in a close vessel which it completely fills. Even water will by such treatment freeze in an instant by agitation, or remain fluid for ever by confinement. We know that heat is produced or extricated by friction, that certain compounds of gold or silver with saline matters explode with irresistible violence by the smallest pressure or agitation. Such facts should rouse the mathematical philosopher, and excite him to follow out the conjectures of the illustrious Newton, encouraged by the ingenious attempts of Boscovich; and the proper beginning of this study is to attend to the laws of attraction and repulsion exerted by the particles of cohering bodies, discoverable by experiments made on their actual extensions and compressions. The experiments of simple extensions and compressions are quite insufficient, because the total stretching of a wire is so small a quantity, that the mistake of the 1000th part of an inch occasions an irregularity which deranges any progression so as to make it useless. But by the bending of bodies a distention of $\frac{1}{100}$th of an inch may be easily magnified in the deflection of the spring ten thousand times. We know that the investigation is intricate and difficult, but not beyond the reach of our present mathematical attainments; and it will give very fine opportunities of employing all the address of analysis. In the 17th century and the beginning of the 18th this was a sufficient excitement to the first geniuses of Europe. The cycloid, the catenaria, the elastic curve, the velaria, the caustics, were reckoned an abundant recompense for much study; and James Bernoulli requested, as an honourable monument, that the logarithmic spiral might be inscribed on his tombstone. The reward for the study to which we now presume to incite the mathematicians is the almost unlimited extension of natural science, important in every particular branch. To go no further than our present subject, a great deal of important practical knowledge respecting the strength of bodies is derived from the single observation, that in the moderate extensions which happen before the parts are overstrained, the forces are nearly in the proportion of the extensions or separations of the particles. To return to our subject.

Bernoulli calls in question this law,

James Bernoulli, in his second dissertation on the elastic curve, calls in question this law, and accommodates his investigation to any hypothesis concerning the relation of the forces and extensions. He relates some experiments of lutestrings where the relation was considerably different. Strings of three feet long,

stretched by	2,	4,	6,	8,	10 pounds,
were lengthened	9,	17,	23,	27,	30 lines.

But this is a most exceptionable form of the experiment. The strings were twisted, and the mechanism of the extensions is here exceedingly complicated, combined with compressions and with transverse twists, &c. We made experiments on fine slips of the gum caoutchouc, and on the juice of the berries of the white bryony, of which a single grain will draw to a thread of two feet long, and again return into a perfectly round sphere. We measured the diameter of the thread by a microscope with a micrometer, and thus could tell in every state of extension the proportional number of particles in the sections. We found, that through the whole range in which the distance of the particles was changed in the proportion of thirteen to one, the extensions did not *sensibly* deviate from the proportion of the forces. The same thing was observed in the caoutchouc as long as it perfectly recovered its first dimensions. And it is on the authority of these experiments that we presume to announce this as a law of nature.

which was first assumed by Dr Hooke.

Dr Robert Hooke was undoubtedly the first who attended to this subject, and assumed this as a law of nature. Mariotte indeed was the first who expressly used it for determining the strength of beams: this he did about the year 1679, correcting the simple theory of Galileo. Leibnitz, indeed, in his dissertation in the *Acta Eruditorum* 1684, *De Resistentia Solidorum*, introduces this consideration, and wishes to be considered as the discoverer; and he is always acknowledged as such by the Bernoullis, and others who adhered to his peculiar doctrines. But Mariotte had published the doctrine in the most express terms long before; and Bulfinger, in the *Comment. Petropol.* 1729, completely vindicates his claim. But Hooke was unquestionably the discoverer of this law. It made the foundation of his theory of springs, announced to the Royal Society about the year 1661, and read in 1666. On this occasion he mentions

many things on the strength of bodies as quite familiar to his thoughts, which are immediate deductions from this principle; and among these *all* the facts which John Bernoulli so vauntingly adduces in support of Leibnitz's finical dogmas about the force of bodies in motion; a doctrine which Hooke might have claimed as his own, had he not perceived its frivolous inanity.

Though corrected by Mariotte, it does not properly explain the mechanism of transverse strain.

But even with this first correction of Mariotte, the mechanism of transverse strain is not fully nor justly explained. The force acting in the direction BW (fig 3), and bending the body ABCD, not only stretches the fibres on the side opposite to the axis of fracture, but compresses the side CD, which becomes concave by the strain. Indeed it cannot do the one without doing the other; for, in order to stretch the fibres at D, there must be some fulcrum, some support, on which the virtual lever BAD may press, that it may tear asunder the stretched fibres. This fulcrum must sustain both the pressure arising from the cohesion of the distended fibres, and also the action of the external force, which immediately tends to cause the prominent part of the beam to slide along the section EF.

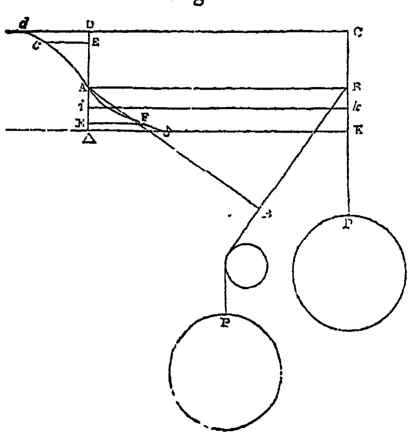
as is fully verified by experiment.

This is fully verified by experiment. If we attempt to break a long slip of cork, or any such very compressible body, we always observe it to bulge out on the concave side before it cracks on the other side. If it is a body of fibrous or foliated texture, it seldom fails splintering off on the concave side; and in many cases this splintering is very deep, even reaching half way through the piece. In hard and granulated bodies, such as a piece of freestone, chalk, dry clay, sugar, and the like, we generally see a considerable splinter or shiver fly off from the hollow side. If the fracture be slowly made by a force at B gradually augmented, the formation of the splinter is very distinctly seen. It forms a triangular piece, which generally breaks in the middle.

Consequences resulting from the state of the case.

Let us see what consequences result from this state of the case respecting the strength of bodies. Let DΔKC (fig. 6) represent a vertical section of a prism of compres-

Fig. 6.



sible materials, such as a piece of timber. Suppose it loaded with a weight P hung at its extremity. Suppose it of such a constitution that all the fibres in AD are in a state of dilatation, while those in AΔ are in a state of compression. In the instant of fracture the particles at D and E are withheld by forces Dd, Ee, and the particles at Δ and F repel, resist, or support, with forces Δδ, Fε.

Some line, such as deA$\varepsilon\delta$, will limit all these ordinates, which represent the forces actually exerted in the instant of fracture. If the forces be as the extensions and compressions, as we have great reason to believe, deA and A$\varepsilon\delta$ will be two straight lines. They will form *one* straight line dAδ, if the forces which resist a certain dilatation are equal to the forces which resist an equal compression. But this is quite accidental, and is not strictly true in any body. In most bodies which have any considerable firmness, the compressions made by any external force are not so great as the dilatations which the same force would produce; that is, the repulsions which are excited by any supposed degree of compression are greater than the attractions excited by the same degree of dilatation. Hence it will generally follow, that the angle dAD is less than the angle δAΔ, and the ordinates Dd, Ee, &c. are less than the corresponding ordinates Δδ, Eε, &c.

An important consequence of the compressibility of body fully proved.

But whatever be the nature of the line dAδ, we are certain of this, that the whole area ADd is equal to the whole area AΔδ; for as the force at B is gradually increased, and the parts between A and D are more extended, and greater cohesive forces are excited, there is always such a degree of repulsive forces excited in the particles between A and Δ that the one set precisely balances the other. The force at B, acting perpendicularly to AB, has no tendency to push the whole piece closer on the part next the wall, or to pull it away. The sum of the attractive and repulsive forces actually excited must therefore be equal. These sums are represented by the two triangular areas, which are therefore equal.

The greater we suppose the repulsive forces corresponding to any degree of compression, in comparison with the attractive forces corresponding to the same degree of extension, the smaller will AΔ be in comparison of AD. In a piece of cork or sponge, AΔ may chance to be equal to AD, or even to exceed it; but in a piece of marble, AΔ will perhaps be very small in comparison of AD.

Now it is evident that the repulsive forces excited between A and Δ have no share in preventing the fracture. They rather contribute to it, by furnishing a fulcrum to the lever by whose energy the cohesion of the particles in AD is overcome. Hence we see an important consequence of the compressibility of the body. Its power of resisting this transverse strain is diminished by it, and so much the more diminished as the stuff is more compressible.

This is fully verified by some very curious experiments made by Duhamel. He took sixteen bars of willow two feet long and half an inch square, and supporting them by props under the ends, he broke them by weights hung on the middle. He broke four of them by weights of 40, 41, 47, and 52 pounds: the mean is 45. He then cut four of them one third through on the upper side, and filled up the cut with a thin piece of harder wood stuck in pretty tight. These were broken by 48, 54, 50, and 52 pounds; the mean of which is 51. He cut other four half through, and they were broken by 47, 49, 50, 46; the mean of which is 48. The remaining four were cut two thirds, and their mean strength was 42.

Another set of his experiments is still more remarkable.

Six battens of willow thirty-six inches long and one and a half square were broken by 525 pounds at a medium.

Six bars were cut one third through, and the cut filled with a wedge of hard wood stuck in with a little force: these broke with 551.

Six bars were cut half through, and the cut was filled in the same manner: they broke with 542.

Six bars were cut three fourths through: these broke with 530.

A batten cut three fourths through, and loaded till nearly broken, was unloaded, and the wedge taken out of the cut. A thicker wedge was put in tight, so as to make the batten straight again by filling up the space left by the compression of the wood: this batten broke with 577 pounds.

From this it is plain that more than two thirds of the thickness (perhaps nearly three fourths) contributed nothing to the strength.

The point A is the centre of fracture in this case; and in order to estimate the strength of the piece, we may sup-

pose that the crooked lever virtually concerned in the strain is DAB. We must find the point I, which is the centre of effort of all the attractive forces, or that point where the full cohesion of AD must be applied, so as to have a momentum equal to the accumulated momenta of all the variable forces. We must in like manner find the centre of effort i of the repulsive or supporting forces exerted by the fibres lying between A and Δ.

It is plain, and the remark is important, that this last centre of effort is the real fulcrum of the lever, although A is the point where there is neither extension nor contraction; for the lever is supported in the same manner as if the repulsions of the whole line AΔ were exerted at that point. Therefore let S represent the surface of fracture from A to D, and f represent the absolute cohesion of a fibre at D in the instant of fracture. We shall have $f\mathrm{S} \times \overline{\mathrm{I}+i} = pl$, or $l : \mathrm{I}+i = f\mathrm{S} : p$; that is, the length AB is to the distance between the two centres of effort I and i, as the absolute cohesion of the section between A and D is to the relative strength of the section.

It would be perhaps more accurate to make AI and Ai equal to the distances of A from the horizontal lines passing through the centres of gravity of the triangles of dAD and δAΔ. It is only in this construction that the points I and i are the centres of real effort of the accumulated attractions and repulsions. But I and i, determined as we have done, are the points where the full equal actions may be all applied, so as to produce the same momenta. The final results are the same in both cases. The attentive and duly informed reader will see that Mr Bulfinger, in a very elaborate dissertation on the strength of beams, in the *Comment. Petropolitan.* 1729, has committed several mistakes in his estimation of the actions of the fibres. We mention this because his reasonings are quoted and appealed to as authorities by Muschenbroeck and other authors of note. The subject has been considered by many authors on the continent. We recommend to the reader's perusal the very minute discussions in the Memoirs of the Academy of Paris for 1702 by Varignon, the Memoirs for 1708 by Parent, and particularly that of Coulomb in the *Mém. par les Sçavans Etrangers*, tom. vii.

It is evident from what has been said above, that if S and s represent the surfaces of the sections above and below A, and if G and g are the distances of their centres of gravity from A, and O and o the distances of their centres of oscillation, and D and d their whole depths, the momentum of cohesion will be $\frac{f\mathrm{S}\cdot\mathrm{G}\cdot\mathrm{O}}{\mathrm{D}} = \frac{fs\cdot g\cdot o}{d} = pl$.

If, as is most likely, the forces are proportional to the extensions and compressions, the distances AI and Ai, which are respectively $= \frac{\mathrm{G}\cdot\mathrm{O}}{\mathrm{D}}$ and $\frac{g\cdot o}{d}$, are respectively $= \frac{1}{3}$DA and $\frac{1}{3}\,\Delta$A, and when taken together are $= \frac{1}{3}$DΔ. If, moreover, the extensions are equal to the compressions in the instant of fracture, and the body is a rectangular prism like a common joist or beam, then DA and ΔA are also equal; and therefore the momentum of cohesion is $fb \times \frac{1}{2}d \times \frac{1}{3}d = \frac{fbd^2}{6} = fb\,d \times \frac{1}{6}d = pl$. Hence we obtain this analogy: "six times the length is to the depth as the absolute cohesion of the section is to its relative strength."

This consequence farther explained. Thus we see that the compressibility of bodies has a very great influence on their power of withstanding a transverse strain. We see that in this most favourable supposition of equal dilatations and compressions, the strength is reduced to one half of the value of what it would have been had the body been incompressible. This is by no means obvious; for it does not readily appear how compressibility, which does not diminish the cohesion of a single fibre, should impair the strength of the whole. The reason, however, is sufficiently convincing when pointed out. In the instant of fracture, a smaller portion of the section is actually exerting cohesive forces, while a part of it is only serving as a fulcrum to the lever by whose means the strain on the section is produced. We see, too, that this diminution of strength does not so much depend on the sensible compressibility, as on its proportion to the dilatability by equal forces. When this proportion is small, AΔ is small in comparison of AD, and a greater portion of the whole fibre is exerting attractive forces. The experiments already mentioned, of Duhamel de Monceau, on battens of willow, show that its compressibility is nearly equal to its dilatability. But the case is not very different in tempered steel. The famous Harrison, in the delicate experiments which he made while occupied in making his longitude watch, discovered that a rod of tempered steel was nearly as much diminished in its length as it was augmented by the same external force. But it is not by any means certain that this is the proportion of dilatation and compression which obtains in the very instant of fracture. We rather imagine that it is not. The forces are nearly as the dilatations till very near breaking; but we think that they diminish when the body is just going to break. But it seems certain that the forces which resist compression increase faster than the compressions, even before fracture. We know incontestably that the ultimate resistances to compression are insuperable by any force which we can employ. The repulsive forces, therefore, in their whole extent, increase faster than the compressions, and are expressed by an assymptotic branch of the Boscovician curve formerly explained. It is therefore probable, especially in the more simple substances, that they increase faster, even in such compressions as frequently obtain in the breaking of hard bodies. We are disposed to think that this is always the case in such bodies as do not fly off in splinters on the concave side; but this must be understood with the exception of the permanent changes which may be made by compression when the bodies are crippled by it. This always increases the compression itself, and causes the neutral point to shift still more towards D. The effect of this is sometimes very great and fatal.

Experiment alone can help us to discover the proportion between the dilatability and compressibility of bodies. The strain now under consideration seems the best calculated for this research. Thus if we find that a piece of wood an inch square requires 12,000 pounds to tear it asunder by a direct pull, and that 200 pounds will break it transversely by acting 10 inches from the section of fracture, we must conclude that the neutral point A is in the middle of the depth, and that the attractive and repulsive forces are equal. Any notions that we can form of the constitution of such fibrous bodies as timber, make us imagine that the *sensible* compressions, including what arises from the bending up of the compressed fibres, is much greater than the real corpuscular extensions. One may get a general conviction of this unexpected proposition by reflecting on what must happen during the fracture. An undulated fibre can only be drawn straight, and then the corpuscular extension begins; but it may be bent up by compression to any degree, the corpuscular compression being little affected all the while. This observation is very important; and though the forces of corpuscular repulsion may be almost insuperable by any compression that we can employ, a *sensible* compression may be produced by forces not enormous, sufficient to cripple the beam. Of this we shall see very important instances afterwards.

It deserves to be noticed, that although the relative strength of a prismatic solid is extremely different in the three hypotheses now considered, yet the proportional

The proportional strengths of different pieces follow the same ratio.

strengths of different pieces follow the same ratio, namely, the direct ratio of the breadth, the direct ratio of the square of the depth, and the inverse ratio of the length. In the first hypothesis (of equal forces) the strength of a rectangular beam was $\frac{fbd^2}{2l}$; in the second (of attractive forces proportioned to the extensions) it was $\frac{fbd^2}{3l}$; and in the third (equal attractions and repulsions proportional to the extensions and compressions) it was $\frac{fbd^2}{6l}$, or more generally $\frac{fbd^2}{ml}$, where m expresses the unknown proportion between the attractions and repulsions corresponding to an equal extension and compression.

The strength of a piece depends chiefly on its depth;

Hence we derive a piece of useful information, which is confirmed by unexceptionable experience, that the strength of a piece depends chiefly on its depth, that is, on that dimension which is in the direction of the strain. A bar of timber of one inch in breadth and two inches in depth is four times as strong as a bar only one inch deep, and it is twice as strong as a bar two inches broad and one deep; that is, a joist or lever is always strongest when laid on its edge.

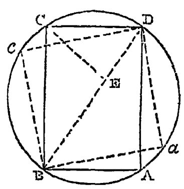
and therefore a choice in the manner in which the cohesion is opposed to the strain.

There is therefore a choice in the manner in which the cohesion is opposed to the strain. The general aim must be to put the centre of effort I as far from the fulcrum or the neutral point A as possible, so as to give the greatest energy or momentum to the cohesion. Thus if a triangular bar projecting from a wall is loaded with a weight at its extremity, it will bear thrice as much when one of the sides is uppermost as when it is undermost.

The strongest joist has not the greatest quantity of timber.

Hence it follows that the strongest joist that can be cut out of a round tree is not the one which has the greatest quantity of timber in it, but such that the product of its breadth by the square of its depth shall be the greatest possible. Let ABCD (fig. 7) be the section of this joist inscribed in the circle, AB being the breadth and AD the depth. Since it is a rectangular section, the diagonal BD is a diameter of the circle, and BAD is a right-angled triangle. Let BD be called a, and BA be called x; then $AD = \sqrt{a^2 - x^2}$. Now we must have $AB \cdot AD^2$, or $x\,(a^2 - x^2)$, or $a^2 x - x^3$, a minimum; its differential $(a^2 - 3x^2)\,dx$ must be 0, or $a^2 = 3x^2$, or $x^2 = \frac{a^2}{3}$. If therefore we make $DE = \frac{1}{3}$ DB, and draw EC perpendicular to BD, it will cut the circumference in the point C, which determines the depth BC and the breadth CD.

Fig. 7.



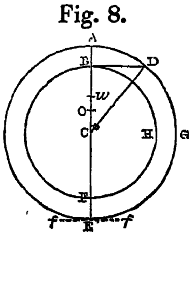
Because $BD : BC = CD : CE$, we have the area of the section $BC \cdot CD = BD \cdot CE$. Therefore the different sections having the same diagonal BD, are proportional to their heights CE. Therefore the section BCDA is less than the section B*c* D*a*, whose four sides are equal. The joist so shaped, therefore, is stronger, lighter, and cheaper.

A hollow tube stronger than a solid rod containing the same quantity of matter,

The strength of ABCD is to that of *a* B *c* D as 10,000 to 9186, and the weight and expense as 10,000 to 10,607; so that ABCD is preferable to *a* B *c* D, in the proportion of 10,607 to 9186, or nearly 115 to 100.

From the same principles it follows that a hollow tube is stronger than a solid rod containing the same quantity of matter. Let fig. 8 represent the section of a cylindric tube, of which AF and BE are the exterior and interior diameters, and C the centre. Draw BD perpendicular to BC, and join DC. Then, because $BD^2 = CD^2 - CB^2$, BD is the radius of a circle containing the same quantity of matter with the ring. If we estimate the strength by the first hypothesis, it is evident that the strength of the tube will be to that of the solid cylinder, whose radius is BD, as $BD^2 \times AC$ to $BD^2 \times BD$; that is, as AC to BD; for BD^2 expresses the cohesion of the ring of the circle, and AC and BD are equal to distances of the centres of effort (the same with the centres of gravity) of the ring and circle from the axis of the fracture.

Fig. 8.



The proportion of these strengths will be different in the other hypothesis, and is not easily expressed by a general formula; but in both it is still more in favour of the ring or hollow tube.

The following very simple solution will be readily understood by the intelligent reader. Let O be the centre of oscillation of the exterior circle, *o* the centre of oscillation of the inner circle, and *w* the centre of oscillation of the ring included between them. Let M be the quantity of surface of the exterior circle, *m* that of the inner circle, and μ that of the ring.

We have $Fw = \frac{M \cdot FO - m \cdot Fo}{\mu} = \frac{5}{4}\,\frac{FC^2 + EC^2}{FC}$, and the strength of the ring $= \frac{f\mu \times Fw}{2}$, and the strength of the same quantity of matter in the form of a solid cylinder is $f\mu \times \frac{5}{8}$ BD; so that the strength of the ring is to that of the solid rod of equal weight as F w to $\frac{5}{4}$ BD, or nearly as FC to BD. This will easily appear by recollecting that FO is $= \frac{\text{sum of } p \cdot r^2}{m \cdot FC}$ (see ROTATION), and that the momentum of cohesion is $\frac{fm \cdot FC \cdot Ca}{2\,FC} = \frac{fm \cdot Fo}{2}$ for the inner circle, &c.

Emerson has given a very inaccurate approximation to this value in his Mechanics, 4to.

and more stiff.

This property of hollow tubes is accompanied also with greater stiffness; and the superiority in strength and stiffness is so much the greater as the surrounding shell is thinner in proportion to its diameter.

Hence the wisdom of God in forming the bones, &c. hollow.

Here we see the admirable wisdom of the Author of nature in forming the bones of animal limbs hollow. The bones of the arms and legs have to perform the office of levers, and are thus opposed to very great transverse strains. By this form they become incomparably stronger and stiffer, and give more room for the insertion of muscles, while they are lighter and therefore more agile; and the same wisdom has made use of this hollow for other valuable purposes of the animal economy. In like manner the quills in the wings of birds acquire by their thinness the very great strength which is necessary, while they are so light as to give sufficient buoyancy to the animal in the rare medium in which it must live and fly about. The stalks of many plants, such as all the grasses, and many reeds, are in like manner hollow, and thus possess an extraordinary strength. Our best engineers now begin to imitate nature by making many parts of their machines hollow, such as their axles of cast iron, &c.; and the ingenious Mr Ramsden made the axes and framings of his great astronomical instruments in the same manner.

In the supposition of homogeneous texture, it is plain that the fracture happens as soon as the particles at D are separated beyond their utmost limit of cohesion. This is a determined quantity, and the piece bends till this degree of extension is produced in the uttermost fibre. It follows, that the smaller we suppose the distance between A and D, the greater will be the curvature which the beam will acquire before it breaks. Greater depth therefore makes a beam not only stronger, but also stiffer. But if the parallel fibres can slide on each other, both the strength and the stiffness will be diminished. Therefore, if, instead of one beam DAKC (fig. 6), we suppose two, DABC and

AΔKB, not cohering, each of them will bend, and the extension of the fibres AB of the under beam will not hinder the compression of the adjoining fibres AB of the upper beam. The two together therefore will not be more than twice as strong as one of them (supposing DA = AΔ), instead of being four times as strong; and they will bend as much as either of them alone would bend by half the load. This may be prevented, if it were possible to unite the two beams all along the seam AB, so that the one shall not slide on the other. This may be done in small works by gluing them together with a cement as strong as the natural lateral cohesion of the fibres. If this cannot be done (as it cannot in large works), the sliding is prevented by *joggling* the beams together, that is, by cutting down several rectangular notches in the upper side of the lower beam, and making similar notches in the under side of the upper beam, and filling up the square spaces with pieces of very hard wood firmly driven in, as represented in fig. 9. Some employ iron bolts by way of joggles. But when the joggle is much harder than the wood into which it is driven, it is very apt to work loose, by widening the hole into which it is lodged. The same thing is sometimes done by scarphing the one upon the other, as represented in fig. 10; but this wastes more timber, and is not so strong, because the mutual hooks which this method form on each beam are very apt to tear each other up. By one or other of these methods, or something similar, may a compound beam be formed, of any depth, which will be almost as stiff and strong as an entire piece.

How a strong compound beam may be formed.

Fig. 9.

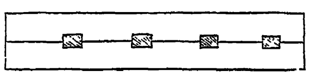


Fig. 10.

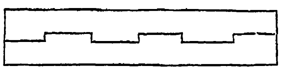
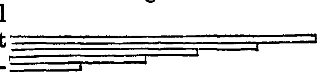


How strength may be combined with pliableness.

On the other hand, we may combine strength with pliableness, by composing our beam of several thin planks laid on each other, till they make a proper depth, and leaving them at full liberty to slide on each other. It is in this manner that coach-springs are formed, as is represented in fig. 11. In this assemblage there must be no joggles nor bolts of any kind put through the planks or plates, for this would hinder their mutual sliding. They must be kept together by straps which surround them, or by something equivalent.

Fig. 11.



Maxims of construction.

The preceding observations show the propriety of some maxims of construction, which the artists have derived from long experience.

Thus, if a mortise is to be cut out of a piece which is exposed to a cross strain, it should be cut out from that side which becomes concave by the strain.

If a piece is to be strengthened by the addition of another, the added piece must be joined to the side which grows convex by the strain.

Before we proceed any farther, it will be convenient to recall the reader's attention to the analogy between the strain on a beam projecting from a wall and loaded at the extremity, and a beam supported at both ends and loaded in some intermediate point. It is sufficient on this occasion to read attentively what is delivered in the article ROOF. We learn there that the strain on the middle point C (fig. 16 of the present article) of a rectangular beam AB, supported on props at A and B, is the same as if the part CA projected from a wall, and were loaded with the half of the weight W suspended at A. The momentum of the strain is therefore $\frac{1}{2}W \times \frac{1}{2}AB = W \times \frac{1}{4}AB = p\frac{1}{4}l$, or $\frac{pl}{4}$. The momentum of cohesion must be equal to this in every hypothesis.

Having now considered in sufficient detail the circumstances which affect the strength of any section of a solid body that is strained transversely, it is necessary to take notice of some of the chief modifications of the strain itself. We shall consider only those that occur most frequently in our constructions.

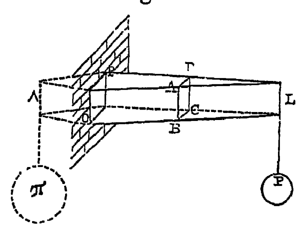
The strain depends on the external force, and also on the lever by which it acts.

The strain depends on the external force,

It is evidently of importance, that since the strain is exerted in any section by means of the cohesion of the parts intervening between the section under consideration and the point of application of the external force, the body must be able in all these intervening parts to propagate or excite the strain in the remote section. In every part it must be able to resist the strain excited in that part. It should therefore be equally strong; and it is useless to have any part stronger, because the piece will nevertheless break where it is not stronger throughout; and it is useless to make it stronger (relatively to its strain) in any part, for it will nevertheless equally fail in the part that is too weak.

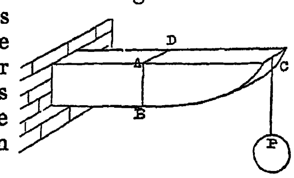
Suppose, then, in the first place, that the strain arises from a weight suspended at one extremity, while the other end is firmly fixed in a wall. Supposing also the cross sections to be all rectangular, there are several ways of shaping the beam so that it shall be equally strong throughout. Thus it may be equally deep in every part, the upper and under surfaces being horizontal planes. The condition will be fulfilled by making all the horizontal sections triangles, as in fig. 12. The two sides are vertical planes, meeting in an edge at the extremity L. For the equation expressing the balance of strain and strength is $pl = fbd^2$. Therefore, since d^2 is the same throughout, and also p, we must have $fb = l$, and b (the breadth AD of any section ABCD) must be proportional to l (or AL), which it evidently is.

Fig. 12.



Or, if the beam be of uniform breadth, we must have d^2 everywhere proportional to l. This will be obtained by making the depths the ordinates of a common parabola, of which L is the vertex and the length is the axis. The upper or under side may be a straight line, as in fig. 13, or the middle line may be straight, and then both upper and under surfaces will be curved. It is almost indifferent what is the shape of the upper and under surfaces, provided the distances between them in every part be at the ordinates of a common parabola.

Fig. 13.



Or, if the sections are all similar, such as circles, squares, or any other similar polygons, we must have d^3 or b^3 proportional to l, and the depths or breadths must be as the ordinates of a cubical parabola.

and on the form of the levers by which it acts.

It is evident that these are also the proper forms for a lever moveable round a fulcrum, and acted on by a force at the extremity. The force comes in the place of the weight suspended in the cases already considered; and as such levers always are connected with another arm, we readily see that both arms should be fashioned in the same manner. Thus in fig. 12 the piece of timber may be supposed a kind of steelyard, moveable round a horizontal axis in the front of the wall, and having the two weights P and ϖ in equilibrio. The strain occasioned by each at the section in which the axis OP is placed must be the same, and each

arm OL and Oλ must be equally strong in all its parts. The longitudinal sections of each arm must be a triangle, a common parabola, or a cubic parabola, according to the conditions previously given.

And, moreover, all these forms are equally strong; for any one of them is equally strong in all its parts, and they are all supposed to have the same section at the front of the wall or at the fulcrum. They are not, however, equally stiff. The first, represented in fig. 12, will bend least upon the whole, and the one formed by the cubic parabola will bend most. But their curvature at the very fulcrum will be the same in all.

It is also plain, that if the lever is of the second or third kind, that is, having the fulcrum at one extremity, it must still be of the same shape; for in abstract mechanics it is indifferent which of the three points is considered as the axis of motion. In every lever the two forces at the extremities act in one direction, and the force in the middle acts in the opposite direction, and the great strain is always at that point. Therefore a lever such as fig. 12, moveable round an axis passing horizontally through λ, and acting against an obstacle at OP, is equally able in all its parts to resist the strains excited in those parts.

The same principles and the same construction will apply to beams, such as joists, supported at the ends L and λ (fig. 12), and loaded at some intermediate part OP. This will appear evident by merely inverting the directions of the forces at these three points, or by recurring to the article ROOF, p. 444.

The external straining force may be distributed over the beam.

Hitherto we have supposed the external straining force as acting only in one point of the beam. But it may be uniformly distributed all over the beam. To make a beam in such circumstances equally strong in all its parts, the shape must be considerably different from the former.

To make a beam strong which projects from a wall.

Thus suppose the beam to project from a wall. If it be of equal breadth throughout, its sides being vertical planes parallel to each other and to the length, the vertical section in the direction of its length must be a triangle instead of a common parabola; for the weight uniformly distributed over the part lying beyond any section, is as the length beyond that section: and since it may all be conceived as collected at its centre of gravity, which is the middle of that length, the lever by which this load acts or strains the section is also proportioned to the same length. The strain on the section (or momentum of the load) is as the square of that length. The section must have strength in the same proportion. Its strength being as the breadth and the square of the depth, and the breadth being constant, the square of the depth of any section must be as the square of its distance from the end, and the depth must be as that distance; and therefore the longitudinal vertical section must be a triangle.

But if all the transverse sections are circles, squares, or any other similar figures, the strength of every section, or the cube of the diameter, must be as the square of the lengths beyond that section, or the square of its distance from the end; and the sides of the beam must be a semicubical parabola.

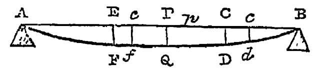
If the upper and under surfaces are horizontal planes, it is evident that the breadth must be as the square of the distance from the end, and the horizontal sections may be formed by arches of the common parabola, having the length for their tangent at the vertex.

By recurring to the analogy so often quoted between a projecting beam and a joist, we may determine the proper form of joists which are uniformly loaded through their whole length.

The strain upon a beam supported at both ends.

This is a frequent and important case, being the office of joists, rafters, &c.; and there are some circumstances which must be particularly noticed, because they are not so obvious, and have been misunderstood. When a beam AB (fig. 14) is supported at the ends, and a weight is laid on any point P, a strain is excited in every part of the beam. The load on P causes the beam to press on A and B, and the props re-act with forces equal and opposite to these pressures. The load at P is to the pressures at A and B as AB to PB and PA, and the pressure at A is to that at B as BP to PA; the beam therefore is in the same state, with respect to strain in every part of it, as if it were resting on a prop at P, and were loaded at the ends with weights equal to the two pressures on the props: and observe, these pressures are such as will balance each other, being inversely as their distances from P. Let P represent the weight or load at P. The pressure on the prop P must be $P \times \frac{PA}{AB}$. This is therefore the re-action of the prop B, and is the weight which we may suppose suspended at B, when we conceive the beam resting on a prop at P, and carrying the balancing weights at A and B.

Fig. 14.



The strain occasioned at any other point C, by the load P at P, is the same with the strain at C, by the weight $P \times \frac{PA}{AB}$ hanging at B, when the beam rests on P, in the manner now supposed; and it is the same if the beam, instead of being balanced on a prop at P, had its part AP fixed in a wall. This is evident. Now we have shown at length that the strain at C, by the weight $P \times \frac{PA}{AB}$ hanging at B, is $P \times \frac{PA}{AB} \times BC$. We desire it to be particularly remarked, that the pressure at A has no influence on the strain at C, arising from the action of any load between A and C; for it is indifferent how the part AP of the projecting beam PB is supported. The weight at A just performs the same office with the wall in which we suppose the beam to be fixed. We are thus particular, because we have seen even persons not unaccustomed to discussions of this kind puzzled in their conceptions of this strain.

Now let the load P be laid on some point p between C and B. The same reasoning shows us that the point is, with respect to strain, in the same state as if the beam were fixed in a wall, embracing the part pB, and a weight $= P \times \frac{pB}{AB}$ were hung on at A, and the strain at C is $P \times \frac{pB}{AB} \times AC$.

A general proposition.

In general, therefore, the strain on any point C, arising from a load P laid on another point P, is proportional to the rectangle of the distances of P and C from the ends nearest to each. It is $P \times \frac{PA \times CB}{AB}$, or $P \times \frac{pB \times CA}{AB}$, according as the load lies between C and A or between C and B.

Cor. 1. The strains which a load on any point P occasions on the points C, c, lying on the same side of P, are as the distances of these points from the end B. In like manner the strains on E and e are as EA and eA.

Cor. 2. The strain which a load occasions in the part on which it rests is as the rectangle of the parts on each side. Thus the strain occasioned at C by a load is to that at D by the same load as AC × CB to AD × DB. It is therefore greatest in the middle.

The strain arising from a load distributed along the beam.

Let us now consider the strain on any point C arising from a load uniformly distributed along the beam. Let AP be represented by x, and Pp by dx, and the whole weight on the beam by a. Then

Strength of Materials.

The weight on Pp is.....................$= a\dfrac{dx}{AB}$.

Pressure on B by the weight on $Pp = a\dfrac{dx}{AB} \times \dfrac{AP}{AB}$,

Or..$= a\dfrac{xdx}{AB^2}$.

Pressure on B by whole wt. on $AC = a\dfrac{\frac{1}{2}AC^2}{AB^2} = a\dfrac{AC^2}{2AB^2}$.

Strain at C by the weight on $AC = a\dfrac{AC^2 \times BC}{2AB^2}$.

Strain at C by the weight on $BC = a\dfrac{BC^2 \times AC}{2AB^2}$.

Do. by whole weight on $AB = a\dfrac{AC^2 \times BC + BC^2 \times AC}{2AB^2}$

$$= a\frac{AC \times BC \times \overline{AC + CB}}{2AB^2} = a\frac{AC \times BC}{2AB}.$$

Thus we see that the strain is proportional to the rectangle of the parts, in the same manner as if the load a had been laid directly on the point C, and is indeed equal to one half of the strain which would be produced at C by the load a laid on there.

Mistakes on this subject committed by authors of reputation.

It was necessary to be thus particular, because we see in some elementary treatises on mechanics, published by authors of reputation, mistakes which are very plausible, and mislead the learner. It is there said that the pressure at B from a weight uniformly diffused along AB, is the same as if it were collected at its centre of gravity, which would be the middle of AB; and then the strain at C is said to be this pressure at B multiplied by BC. But surely it is not difficult to see the difference of these strains. It is plain that the pressure of gravity downwards on any point between the end A and the point C has no tendency to diminish the strain at C, arising from the upward re-action of the prop B; whereas the pressure of gravity between C and B is almost in direct opposition to it, and must diminish it. We may however avoid the fluxionary calculus with safety by the consideration of the centre of gravity, by supposing the weights of AC and BC to be collected at their respective centres of gravity; and the result of this computation will be the same as above: and we may use either method, although the weight be not uniformly distributed, provided only that we know in what manner it is distributed.

This investigation is evidently of importance in the practice of the engineer and architect, informing them what support is necessary in the different parts of their constructions. We considered some cases of this kind in the article Roof.

To form a joist which may have the same relative strength in all its parts.

It is now easy to form a joist so that it shall have the same relative strength in all its parts.

I. To make it equally able in all its parts to carry a given weight laid on any point C taken at random, or uniformly diffused over the whole length, the strength of the section at the point C must be as $AC \times CB$. Therefore,

1. If the sides be parallel vertical planes, the square of the depth (which is the only variable dimension), or CD^2, must be as $AC \times CB$, and the depths must be ordinates of an ellipse.

2. If the transverse sections be similar, we must make CD^3 as $AC \times CB$.

3. If the upper and under surfaces be parallel, the breadth must be as $AC \times CB$.

II. If the beam be necessarily loaded at some given point C, and we would have the beam equally able in all its parts to resist the strain arising from the weight at C, we must make the strength of every transverse section between C and either end as its distance from that end. Therefore,

1. If the sides be parallel vertical planes, we must make $CD^2 : EF^2 = AC : AE$.

2. If the sections be similar, then $CD^3 : EF^3 = AC : AE$.

3. If the upper and under surfaces be parallel, then breadth at C : breadth at E $= AC : AE$.

The strain and strength of square or circular plates of different extent but of equal thickness may be determined from the same principles.

The same principles enable us to determine the strain and strength of square or circular plates of different extent but equal thickness. This may be comprehended in this general proposition.

Similar plates of equal thickness supported all round will carry the same absolute weight, uniformly distributed, or resting on similar points, whatever be their extent.

Suppose two similar oblong plates of equal thickness, and let their lengths and breadths be L, l, and B, b. Let their strength or momentum of cohesion be C, c, and the strains from the weights W, w, be S, s.

Suppose the plates supported at the ends only, and resisting fracture transversely. The strains, being as the weights and lengths, are as WL and wl, but their cohesions are as the breadths; and since they are of equal relative strength, we have $WL : wl = B : b$, and $WLb = wlB$, and $L : l = wB : Wb$; but since they are of similar shapes, $L : l = B : b$, and therefore $w = W$.

The same reasoning holds again when they are also supported along the sides, and therefore holds when they are supported all round (in which case the strength is doubled).

And if the plates be of any other figure, such as circles or ellipses, we need only conceive similar rectangles inscribed in them. These are supported all around by the continuity of the plates, and therefore will sustain equal weights; and the same may be said of the segments which lie without them, because the strengths of any similar segments are equal, their lengths being as their breadths.

Therefore the thickness of the bottoms of vessels holding heavy liquors or grains should be as their diameters and as the square root of their depths jointly.

Also the weight which a square plate will bear is to that which a bar of the same matter and thickness will bear as twice the length of the bar to its breadth.

The strain of a beam arising from its own weight.

There is yet another modification of the strain which tends to break a body transversely, which is of very frequent occurrence, and in some cases must be very carefully attended to, viz. the strain arising from its own weight.

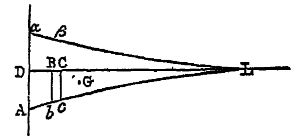
When a beam projects from a wall, every section is strained by the weight of all that projects beyond it. This may be considered as all collected at its centre of gravity. Therefore the strain on any section is in the joint ratio of the weight of what projects beyond it, and the distance of its centre of gravity from the section.

General principle respecting it.

The determination of this strain, and of the strength necessary for withstanding it, must be more complicated than the former, because the form of the piece which results from this adjustment of strain and strength influences the strain. The general principle must evidently be, that the strength or momentum of cohesion of every section must be as the product of the weight beyond it, multiplied by the distance of its centre of gravity. For example:

Suppose the beam DLA (fig. 15) to project from the wall, and that its sides are parallel vertical planes, so that the depth is the only variable dimension. Let $LB = x$ and $Bb = y$. The element $BbcC$ is $= ydx$. Let G be the centre of gravity of the part lying without Bb, and g be its distance from the extremity L. Then $x - g$ is the arm of the lever by which the strain is excited in the section Bb.

Fig. 15.



Let Bb or y be as some power m of LB; that is, let $y=x^m$. Then the contents of LBb is $\frac{x^{m+1}}{m+1}$. The momentum of gravity round a horizontal axis at L is $yxdx=x^{m+1}dx$, and the whole momentum round the axis is $\frac{x^{m+2}}{m+2}$. The distance of the centre of gravity from L is had by dividing this momentum by the whole weight, which is $\frac{x^{m+1}}{m+1}$. The quotient or g is $\frac{x\times\overline{m+1}}{m+2}$, and the distance of the centre of gravity from the section Bb is $x-\frac{x\times m+1}{m+2}=\frac{x\times\overline{m+2}-x\times\overline{m+1}}{m+2}=\frac{x}{m+2}$. Therefore the strain on the section Bb is had by multiplying $\frac{x^{m+1}}{m+1}$ by $\frac{x}{m+2}$. The product is $\frac{x^{m+2}}{\overline{m+2}\times\overline{m+1}}$. This must be as the square of the depth, or as y^2. But y is as x^m, and y^2 as x^{2m}. Therefore we have $m+2=2m$, and $m=2$; that is, the depth must be as the square of the distance from the extremity, and the curve LbA is a parabola touching the horizontal line in L.

A conoid equally able in every section to bear its own weight.

It is easy to see that a conoid formed by the rotation of this figure round DL will also be equally able in every section to bear its own weight.

We need not prosecute this farther. When the figure of the piece is given, there is no difficulty in finding the strain; and the circumstance of equal strength to resist this strain is chiefly a matter of curiosity.

The more a beam projects, the less able it is to bear its own weight.

It is evident, from what has been already said, that a projecting beam becomes less able to bear its own weight as it projects farther. Whatever may be the strength of the section DA, the length may be such that it will break by its own weight. If we suppose two beams A and B of the same substance and similar shapes, that is, having their lengths and diameters in the same proportion; and further suppose that the shorter can just bear its own weight; then the longer beam will not be able to do the same; for the strengths of the sections are as the cubes of the diameters, while the strains are as the biquadrates of the diameters; because the weights are as the cubes, and the levers by which these weights act in producing the strain are as the lengths or as the diameters.

Small bodies more able to withstand the strain produced by the weight of the machine than great bodies.

These considerations show us, that in all cases where strain is affected by the weight of the parts of the machine or structure of any kind, the smaller bodies are more able to withstand it than the greater; and there seem to be bounds set by nature to the size of machines constructed of any given materials. Even when the weight of the parts of the machine is not taken into the account, we cannot enlarge them in the same proportion in all their parts. Thus a steam-engine cannot be doubled in all its parts, so as to be still efficient. The pressure on the piston is quadrupled. If the lift of the pump be also doubled in height while it is doubled in diameter, the load will be increased eight times, and will therefore exceed the power. The depth of lift, therefore, must remain unchanged; and in this case the machine will be of the same relative strength as before, independent of its own weight. For the beam being doubled in all its dimensions, its momentum of cohesion is eight times greater, which is again a balance for a quadruple load acting by a double lever. But if we now consider the increase of the weight of the machine itself, which must be supported, and which must be put in motion by the intervention of its cohesion, we see that the large machine is weaker and less efficient than the small one.

There is a similar limit set by nature to the size of plants and animals formed of the same matter. The cohesion of an herb could not support it if it were increased to the size of a tree, nor could an oak support itself if forty or fifty times bigger; nor could an animal of the make of a long-legged spider be increased to the size of a man; the articulations of its legs could not support it.

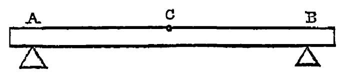
Even small animals are remarkable for strength and agility.

Hence may be understood the prodigious superiority of the small animals both in strength and agility. A man by falling twice his own height may break his firmest bones. A mouse may fall twenty times its height without risk; and even the tender mite or wood-louse may fall unhurt from the top of a steeple. But their greatest superiority is in respect of nimbleness and agility. A flea can leap above 500 times its own length, while the strength of the human muscles could not raise the trunk from the ground on limbs of the same construction.

The angular motions of small animals (in which consists their nimbleness or agility) must be greater than those of large animals, supposing the force of the muscular fibre to be the same in both. For supposing them similar, the number of equal fibres will be as the square of their linear dimensions; and the levers by which they act are as their linear dimensions. The energy therefore of the moving force is as the cube of these dimensions. But the momentum of inertia, or $\int p\cdot r^2$, is as the fourth power; therefore the angular velocity of the greater animals is smaller. The number of strokes which a fly makes with its wings in a second is astonishingly great; yet, being voluntary, they are the effects of its agility.

We have hitherto confined our attention to the simplest form in which this transverse strain can be produced. This was quite sufficient for showing us the mechanism of nature by which the strain is resisted; and a very slight attention is sufficient for enabling us to reduce to this every other way in which the strain can be produced. We shall not take up the reader's time with the application of the same principles to other cases of this strain, but refer him to what has been said in the article Roof. In that article we have shown the analogy between the strain on the section of a beam projecting from a wall and loaded at the extremity, and the strain on the same section of a beam simply resting on supports at the ends, and loaded at some intermediate point or points. The strain on the middle C of a beam AB (fig. 16) so supported, arising from a weight laid on there, is the same with the strain which half that weight hanging at B would produce on the same section C, if the other end of the beam were fixed in a wall.

Fig. 16.



If therefore 1000 pounds hung on the end of a beam projecting ten feet from a wall will just break it at the wall, it will require 4000 pounds on its middle to break the same beam resting on two props ten feet asunder. We have also shown in that article the additional strength which will be given to this beam by extending both ends beyond the props, and there framing it firmly into other pillars or supports.

Effects of obliquity of the external force.

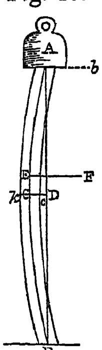
We can hardly add any thing to what has been said in that article, except a few observations on the effects of the obliquity of the external force. We have hitherto supposed it to act in the direction BP (fig. 6) perpendicular to the length of the beam. Suppose it to act in the direction BP′, oblique to BA. In the article Roof we supposed the strain to be the same as if the force p acted at the distance AB′, but still perpendicular to AB: so it is. But the strength of the section AΔ is not the same in both cases; for by the obliquity of the action the piece DCKΔ is pressed to the other. We are not sufficiently acquainted with the corpuscular forces to say precisely what will be the effect of the pressure arising from this obliquity; but we can clearly see in general, that the point A, which in the instant of fracture

is neither stretched nor compressed, must now be farther up, or nearer to D; and therefore the number of particles which are exerting cohesive forces is smaller, and therefore the strength is diminished. Therefore, when we endeavour to proportion the strength of a beam to the strain arising from an external force acting obliquely, we make too liberal allowance by increasing this external force in the ratio of AB to AB′. We acknowledge our inability to assign the proper correction. But this circumstance is of very great influence. In many machines, and many framings of carpentry, this oblique action of the straining force is unavoidable; and the most enormous strains to which materials are exposed are generally of this kind. In the frames set up for carrying the ringstones of arches, it is hardly possible to avoid them; for although the judicious engineer dispose his beams so as to sustain only pressures in the direction of their lengths, tending either to crush them or to tear them asunder, it frequently happens that, by the settling of the work, the pieces come to check and bear on each other transversely, tending to break each other across. This we have remarked upon in the article Roof, with respect to a truss by Mr Price (see Roof, p. 452–54). Now when a cross strain is thus combined with an enormous pressure in the direction of the length of the beam, it is in the utmost danger of snapping suddenly across. This is one great cause of the carrying away of masts. They are compressed in the direction of their length by the united force of the shrouds, and in this state the transverse action of the wind soon completes the fracture.

The strain on columns.

When considering the compressing strains to which materials are exposed, we deferred the discussion of the strain on columns, observing that it was not, in the cases which usually occur, a simple compression, but was combined with a transverse strain, arising from the bending of the column. When the column ACB (fig. 17), resting on the ground at B, and loaded at top with a weight A, acting in the vertical direction AB, is bent into a curve ACB, so that the tangent at C is perpendicular to the horizon, its condition somewhat resembles that of a beam firmly fixed between B and C, and strongly pulled by the end A, so as to bend it between C and A. Although we cannot conceive how a force acting on a straight column AB in the direction AB can bend it, we may suppose that the force acted first in the horizontal direction Ab till it was bent to this degree, and that the rope was then gradually removed from the direction Ab to the direction AB, increasing the force as much as is necessary for preserving the same quantity of flexure.

Fig. 17.



Observations on Euler's theory of the strength of columns.

The first author, we believe, who considered this important subject with scrupulous attention was the celebrated Euler, who published in the Berlin Memoirs for 1757 his Theory of the Strength of Columns. The general proposition established by this theory is, that the strength of prismatical columns is in the direct quadruplicate ratio of their diameters, and the inverse duplicate ratio of their lengths. He prosecuted this subject in the Petersburg Commentaries for 1778, confirming his former theory. We do not find that any other author has bestowed much attention on it, all seeming to acquiesce in the determinations of Euler, and to consider the subject as of very great difficulty, requiring the application of the most refined mathematics. Muschenbroeck has compared the theory with experiment; but the comparison has been very unsatisfactory, the difference from the theory being so enormous as to afford no argument for its justness. But the experiments do not contradict it, for they are so anomalous as to afford no conclusion or general rule whatever.

To say the truth, the theory can be considered in no other light than as a specimen of ingenious and very artful algebraic analysis. Euler was unquestionably the first analyst in Europe for resource and address. He knew this, and enjoyed his superiority, and without scruple admitted any physical assumptions which gave him an opportunity of displaying his skill. The inconsistency of his assumptions with the known laws of mechanism gave him no concern; and when his algebraic processes led him to any conclusion which would make his readers stare, being contrary to all our usual notions, he frankly owned the paradox, but went on in his analysis, saying, *Sed analysi magis fidendum*. Mr Robins has given some very risible instances of this confidence in his analysis, or rather of his confidence in the indolent submission of his readers. Nay, so fond was he of this kind of amusement, that after having published an untenable Theory of Light and Colours, he published several Memoirs, explaining the aberration of the heavenly bodies, deducing some very wonderful consequences, fully confirmed by experience, from the Newtonian principles, which were opposite and totally inconsistent with his own theory, merely because the Newtonian theory gave him *occasionem analyseos promovendæ*. We are thus severe in our observations, because his Theory of the Strength of Columns is one of the strongest instances of this wanton kind of proceeding, and because his followers in the Academy of St Petersburg, such as Fuss, Lexill, and others, adopt his conclusions, and merely echo his words. Since the death of Daniel Bernoulli, no member of that academy has controverted any thing advanced by their *Professor sublimis Geometriæ*, to whom they had been indebted for their places and for all their knowledge, having been (most of them) his amanuenses, employed by this wonderful man during his blindness, to make his computations and carry on his algebraic investigations. We are not a little surprised to see Mr Emerson, a considerable mathematician, and a man of very independent spirit, hastily adopting the same theory, of which we doubt not but our readers will easily see the falsity.

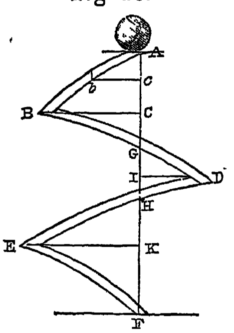
Euler considers the column ACB as in a condition precisely similar to that of an elastic rod bent into the curve by a cord AB connecting its extremities. In this he is not mistaken. But he then draws CD perpendicular to AB, and considers the strain on the section C as equal to the momentum or mechanical energy of the weight A, acting in the direction DE, upon the lever $k$$c$D, moveable round the fulcrum c, and tending to tear asunder the particles which cohere along the section cCk. This is the same principle (as Euler admits) employed by James Bernoulli in his investigation of the elastic curve ACB. Euler considers the strain on the section ck as the same with what it would sustain if the same power acted in the horizontal direction EF on a point E, as far removed from C as the point D is. We reasoned in the same manner (as has been observed) in the article Roof, where the obliquity of action was inconsiderable. But in the present case this substitution leads to the greatest mistakes, and has rendered the whole of this theory false and useless. It would be just if the column were of materials which are incompressible. But it is evident, by what has been said above, that by the compression of the parts the real fulcrum of the lever shifts away from the point c, so much the more as the compression is greater. In the great compressions of loaded columns, and the almost unmeasurable compressions of the truss-beams in the centres of bridges, and other cases of chief importance, the fulcrum is shifted far over towards k, so that very few fibres resist the fracture by their cohesion, and these few have a very feeble energy or momentum, on account of the short arm of the lever by which they act. This is a most important consideration in carpentry, yet makes no element of Euler's theory. The consequence of this is, that a very small degree of curvature is sufficient

to cause the column or strut to snap in an instant, as is well known to every experienced carpenter. The experiment by Muschenbroeck, which Euler makes use of in order to obtain a measure of strength in a particular instance, from which he might deduce all others by his theorem, is an incontestable proof of this. The force which broke the column is not the twentieth part of what is necessary for breaking it by acting at E in the direction EF. Euler takes no notice of this immense discrepancy, because it must have caused him to abandon the speculation with which he was then amusing himself.

This theory false and useless.

The limits of this work do not afford room to enter minutely upon the refutation of this theory; but we can easily show its uselessness, by its total inconsistency with common observation. It results legitimately from this theory, that if CD have no magnitude, the weight A can have no momentum, and the column cannot be broken. True, it cannot be broken in this way, snapped by a transverse fracture, if it do not bend; but we know very well that it can be crushed or crippled, and we see this frequently happen. This circumstance or event does not enter into Euler's investigation, and therefore the theory is at least imperfect and useless. Had this crippling been introduced in the form of a physical assumption, every topic of reasoning employed in the process must have been laid aside, as the intelligent reader will easily see. But the theory is not only imperfect, but false. The ordinary reader will be convinced of this by another legitimate consequence of it. Fig. 18 is the same with fig. 106 of Emerson's Mechanics, where this subject is treated on Euler's principles, and represents a crooked piece of matter resting on the ground at F, and loaded at A with a weight acting in the vertical direction AF. It results from Euler's theory that the strains at *b*, B, D, E, &c. are as *bc*, BC, DI, EK, &c. Therefore the strains at G and H are nothing; and this is asserted by Emerson and Euler as a serious truth; and the piece may be thinned *ad infinitum* in these two places, or even cut through, without any diminution of its strength. The absurdity of this assertion strikes at first hearing. Euler asserts the same thing with respect to a point of contrary flexure. Farther discussion is, we apprehend, needless.

Fig. 18.



Yet Euler's dissertations deserve a perusal.

This theory must therefore be given up. Yet these dissertations of Euler in the Petersburg Commentaries deserve a perusal, both as very ingenious specimens of analysis, and because they contain maxims of practice which are important. Although they give an erroneous measure of the comparative strength of columns, they show the immense importance of preventing all bendings, and point out with accuracy where the tendencies to bend are greatest, and how this may be prevented by very small forces, and what a prodigious accession of force this gives the column. There is a valuable paper in the same volume by Fuss on the Strains on framed Carpentry, which may also be read with advantage.

A new theory cannot be substituted in place of Euler's till many experiments be made.

It will now be asked, what shall be substituted in place of this erroneous theory? what is the true proportion of the strength of columns? We acknowledge our inability to give a satisfactory answer. This can only be obtained by a previous knowledge of the proportion between the extensions and compressions produced by equal forces, by the knowledge of the absolute compressions producible by a given force; and by a knowledge of the degree of that derangement of parts which is termed crippling. These circumstances are but imperfectly known to us, and there lies before us a wide field of experimental inquiry. Fortunately the force requisite for crippling a beam is prodigious, and a very small lateral support is sufficient to prevent that bending which puts the beam in imminent danger. A judicious engineer will always employ transverse bridles, as they are called, to stay the middle of long beams which are employed as pillars, struts, or truss-beams, and are exposed, by their position, to enormous pressures in the direction of their lengths. Such stays may be observed, disposed with great judgment and economy, in the centres employed by Mr Perronet in the erection of his great stone arches. He was obliged to correct this omission made by his ingenious predecessor in the beautiful centres of the bridge of Orleans, which we have no hesitation in affirming to be the finest piece of carpentry in the world.

It only remains on this head to compare these theoretical deductions with experiment.

Experiments on the transverse strength of bodies are easily made, and accordingly are very numerous, especially those made on timber, which is the case most common and most interesting. But in this great number of experiments there are very few from which we can draw much practical information. The experiments have in general been made on such small scantlings, that the unavoidable natural inequalities bear too great a proportion to the strength of the whole piece. Accordingly, when we compare the experiments of different authors, we find them differ enormously, and even the experiments by the same author are very anomalous. The completest series that we have yet seen is that detailed by Belidor in his *Science des Ingenieurs.* They are contained in the following table. The pieces were sound, even-grained oak. The column *b* contains the breadths of the pieces in inches; the column *d* contains their depths; the column *l* contains their lengths; column *p* contains the weights (in pounds) which broke them when hung on their middles; and *m* is the column of averages or mediums.

Table of experiments made by Belidor.

No.	*b*	*d*	*l*	*p*	*m*	
1	1	1	18	400 415 405	406	The ends lying loose.
2	1	1	18	600 600 624	608	The ends firmly fixed.
3	2	1	18	810 795 812	805	Loose.
4	1	2	18	1570 1580 1590	1580	Loose.
5	1	1	36	185 195 180	187	Loose.
6	1	1	36	285 280 285	283	Fixed.
7	2	2	36	1550 1620 1585	1585	Loose.
8	$2\frac{1}{3}$	$2\frac{1}{3}$	36	1665 1675 1640	1660	Loose.

Corollaries derived from them.

By comparing Experiments 1st and 3d, the strength appears proportional to the breadth.

Experiments 3d and 4th show the strength proportional to the square of the depth.

Experiments 1st and 5th show the strength nearly in the inverse proportion of the lengths, but with a sensible deficiency in the longer pieces.

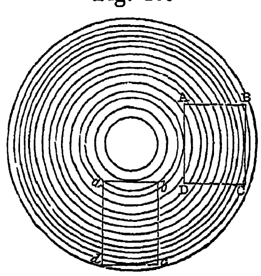
Experiments 5th and 7th show the strengths proportional to the breadths and the square of the depth.

Experiments 1st and 7th show the same thing, compounded with the inverse proportion of the length: here the deficiency relative to the length is not so remarkable.

Experiments 1st and 2d, and experiments 5th and 6th, show the increase of strength, by fastening the ends, to be in the proportion of two to three. The theory gives the proportion of two to four. But a difference in the manner of fixing may produce this deviation from the theory, which only supposed them to be held down at places beyond the props, as when a joist is held in the walls, and also rests on two pillars between the walls.

The chief source of irregularity in such experiments is the fibrous, or rather plated texture of timber. It consists of annual additions, whose cohesion with each other is vastly weaker than that of their own fibres. Let fig. 19 represent the section of a tree, and ABCD, *abcd* the section of two battens that are to be cut out of it for experiment, and let AD and *ad* be the depths, and DC, *dc* the breadths. The batten ABCD will be the stronger, for the same reason that an assemblage of planks set edgewise will form a stronger joist than planks laid above each other like the plates of a coach-spring. M. Buffon found by many trials that the strength of ABCD was to that of *abcd* (in oak) nearly as eight to seven. The authors of the different experiments were not careful that their battens had their plates all disposed similarly with respect to the strain. But even with this precaution they would not have afforded sure grounds of computation for large works; for great beams occupy much, if not the whole, of the section of the tree; and from this it has happened that their strength is less than in proportion to that of a small lath or batten. In short, we can trust no experiments but such as have been made on large beams. These must be very rare, for they are most expensive and laborious, and exceed the abilities of most of those who are disposed to study this subject.

Fig. 19.



But we are not wholly without such authority. M. Buffon and M. Duhamel, two of the first philosophers and mechanicians of the age, were directed by government to make experiments on this subject, and were supplied with ample funds and apparatus. The relation of their experiments is to be found in the Memoirs of the French Academy for 1740, 1741, 1742, 1768; as also in Duhamel's valuable performances *Sur l'Exploitation des Arbres, et sur la Conservation et le Transport de Bois.* We earnestly recommend these dissertations to the perusal of our readers, as containing much useful information relative to the strength of timber, and the best methods of employing it. We shall here give an abstract of M. Buffon's experiments.

M. Buffon's experiments on bars of sound oak.

He relates a great number which, during two years, he had prosecuted on small battens. He found that the odds of a single layer, or part of a layer, more or less, or even a different disposition of them, had such influence that he was obliged to abandon this method, and to have recourse to the largest beams that he was able to break. The following table exhibits one series of experiments on bars of sound oak, clear of knots, and four inches square. This is a specimen of all the rest.

Column 1st is the length of the bar in clear feet between the supports.

Column 2d is the weight of the bar (the second day after it was felled) in pounds. Two bars were tried of each length. Each of the first three pairs consisted of two cuts of the same tree. The one next the root was always found the heaviest, stiffest, and strongest. Indeed M. Buffon says that this was invariably true, that the heaviest was always the strongest; and he recommends it as a certain (or sure) rule for the choice of timber. He finds that this is always the case when the timber has grown vigorously, forming very thick annual layers. But he also observes that this is only during the advances of the tree to maturity; for the strength of the different circles approaches gradually to equality during the tree's healthy growth, and then it decays in these parts in a contrary order. Our tool-makers assert the same thing with respect to beech: yet a contrary opinion is very prevalent; and wood with a fine, that is, a small grain, is frequently preferred. Perhaps no person has ever made the trial with such minuteness as M. Buffon, and we think that much deference is due to his opinion.

Column 3d is the number of pounds necessary for breaking the tree in the course of a few minutes.

Column 4th is the number of inches which it bent down before breaking.

Column 5th is the time at which it broke.

1	2	3	4	5
7	60 56	5350 5275	3·5 4·5	29 22
8	68 63	4600 4500	3·75 4·7	15 13
9	77 71	4100 3950	4·85 5·5	14 12

12	100 98	3050 2925	7· 8·	... ...

The experiments on other sizes were made in the same way. A pair at least of each length and size was taken. The mean results are contained in the following table. The beams were all square, and their sizes in inches are placed at the head of the columns, and their lengths in feet are in the first column.

	4	5	6	7	8	A
7	5312	11525	18950	32200	47649	11525
8	4550	9787	15525	26050	39750	10085

24	...	2162	...	...	...	3362
28	...	1775	...	...	...	2881

M. Buffon had found, by numerous trials, that oak-timber lost much of its strength in the course of drying or season-

Strength of Materials.

ing; and therefore, in order to secure uniformity, his trees were all felled in the same season of the year, were squared the day after, and tried the third day. Trying them in this green state gave him an opportunity of observing a very curious and unaccountable phenomenon. When the weights were laid briskly on, nearly sufficient to break the log, a very sensible smoke was observed to issue from the two ends with a sharp hissing noise. This continued all the while the tree was bending and cracking. This shows that the log is affected or strained through its whole length. Indeed this must be inferred from its bending through its whole length. It also shows us the great effects of the compression. It is a pity M. Buffon did not take notice whether this smoke issued from the upper or compressed half of the section only, or whether it came from the whole.

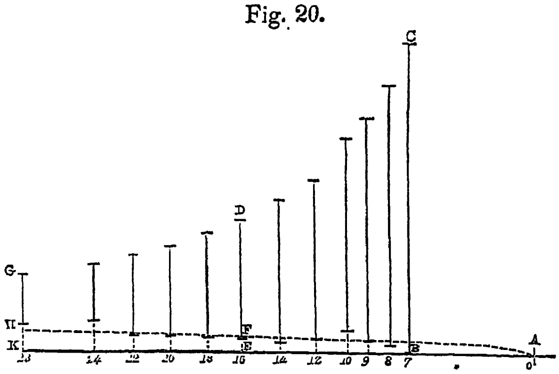
Observations on M. Buffon's experiments.

We must now make some observations on these experiments, in order to compare them with the theory which we have endeavoured to establish.

M. Buffon considers the experiments with the five-inch bars as the standard of comparison, having both extended these to greater lengths, and having tried more pieces of each length.

Our theory determines the relative strength of bars of the same section to be inversely as their lengths. But, if we except the five experiments in the first column, we find a very great deviation from this rule. Thus the five-inch bar of twenty-eight feet long should have half the strength of that of fourteen feet, or 2650; whereas it is but 1775. The bar of fourteen feet should have half the strength of that of seven feet, or 5762; whereas it is but 5300. In like manner, the fourth of 11,525 is 2881; but the real strength of the twenty-eight feet bar is 1775. We have added a column A, which exhibits the strength which each of the five-inch bars ought to have by the theory. This deviation is most distinctly seen in fig. 20, where BK is the scale

Fig. 20.



of lengths, B being at the point seven of the scale, and K at twenty-eight. The ordinate CB is $= 11,525$, and the other ordinates DE, GK, &c. are respectively $= \frac{7CB}{\text{length}}$. The lines DF, GH, &c. are made $= 4350$, 1775, &c., expressing the strengths given by experiment. The ten-feet bar and the twenty-four feet bar are remarkably anomalous. But all are deficient, and the defect has an evident progression from the first to the last. The same thing may be shown of the other columns, and even of the first, though it is very small in that column. It may also be observed in the experiments of Belidor, and in all that we have seen. We cannot doubt therefore of its being a law of nature, depending on the true principles of cohesion and the laws of mechanics.

But it is very puzzling, and we cannot pretend to give a satisfactory explanation of the difficulty. The only effect which we can conceive the length of a beam to have, is to increase the strain at the section of fracture, by employing the intervening beam as a lever. But we do not distinctly see what change this can produce in the mode of action of the fibres in this section, so as either to change their cohesion or the place of its centre of effort: yet something of this kind must happen.

We see indeed some circumstances which must contribute to make a smaller weight sufficient, in M. Buffon's experiments, to break a long beam, than in the exact inverse proportion of its length.

In the first place, the weight of the beam itself augments the strain as much as if half of it were added in the form of a weight. M. Buffon has given the weights of every beam on which he made experiments, which is very nearly seventy-four pounds per cubic foot. But they are much too small to account for the deviation from the theory. The half weights of the five-inch beams of seven, fourteen, and twenty-eight feet length, are only forty-five, ninety-two, and 182 pounds; which makes the real strains in the experiments 11,560, 5390, and 1956; which are far from having the proportions of four, two, and one.

Buffon says that healthy trees are universally strongest at the root end; therefore, when we use a longer beam, its middle point, where it is broken in the experiment, is in a weaker part of the tree. But the trials of the four-inch beams show that the difference from this cause is almost insensible.

The length must have some mechanical influence which the theory we have adopted has not yet explained. It may not however be inadequate to the task. The very ingenious investigation of the elastic curve by James Bernoulli and other celebrated mathematicians is perhaps as refined an application of mathematical analysis as we know. Yet in this investigation it was necessary, in order to avoid almost insuperable difficulties, to take the simplest possible case, viz. where the thickness is exceedingly small in comparison with the length. If the thickness be considerable, the quantities neglected in the calculus are too great to permit the conclusion to be accurate, or very nearly so. Without being able to define the form into which an elastic body of considerable thickness will be bent, we can say with confidence, that in an extreme case, where the compression in the concave side is very great, the curvature differs considerably from the Bernoullian curve. But as our investigation is incomplete and very long, we do not offer it to the reader. The following more familiar considerations will, we apprehend, render it highly probable that the relative strength of beams decreases faster than in the inverse ratio of their length. The curious observation by M. Buffon, of the vapour which issued with the hissing noise from the ends of a beam of green oak, while it was breaking by the load on its middle, shows that the whole length of the piece was affected: indeed it must be, since it is bent throughout. We have shown above, that a certain definite curvature of a beam of a given form is always accompanied by rupture. Now suppose the beam A of ten feet long, and the beam B of twenty feet long, bent to the same degree, at the place of their fixture in the wall; the weight which hangs on A is nearly double of that which must hang on B. The form of any portion, suppose five feet, of these two beams, immediately adjoining to the wall, is considerably different. At the distance of five feet the curvature of A is half of its curvature at the wall. The curvature of B in the corresponding point is three fourths of the same curvature at the wall. Through the whole of the intermediate five feet, therefore, the curvature of B is greater than that of A. This must make it weaker throughout. It must occasion the fibres to slide more on each other (that it may acquire *this* greater curvature), and thus affect their lateral union; and therefore those which are stronger will not assist their weaker neighbours. To this we must add, that in the shorter beams the force with which the fibres are pressed laterally on each other is double. This must impede the

Probable that the relative strength of beams decreases faster than in the inverse ratio of their length.

mutual sliding of the fibres which we mentioned a little ago; nay, this lateral compression may change the law of longitudinal cohesion (as will readily appear to the reader who is acquainted with Boscovich's doctrines), and increase the strength of the very surface of fracture, in the same way (however inexplicable) as it does in metals when they are hammered or drawn into wire.

The reader must judge how far these remarks are worthy of his attention. The engineer will carefully keep in mind the important fact, that a beam of quadruple length, instead of having one fourth of the strength, has only about one sixth; and the philosopher should endeavour to discover the cause of this diminution, that he may give the artist a more accurate rule of computation.

We cannot discover the precise relation between the curvature and the momentum of cohesion.

Our ignorance of the law by which the cohesion of the particles changes by a change of distance, hinders us from discovering the precise relation between the curvature and the momentum of cohesion; and all we can do is to multiply experiments, upon which we may establish some *empirical* rules for calculating the strength of solids. Those from which we must reason at present are too few and too anomalous to be the foundation of such an empirical formula. We may however observe, that M. Buffon's experiments gave us considerable assistance in this particular; for if to each of the numbers of the column for the five-inch beams, corrected by adding half the weight of the beam, we add the constant number 1245, we shall have a set of numbers which are very nearly reciprocals of the lengths. Let 1245 be called c, and let the weight which is known by experiment to be necessary for breaking the five-inch beam of the length a be called P. We shall have $\frac{\overline{P+c}\times a}{l}-c=p$.

Thus the weight necessary for breaking the seven-feet bar is 11,560. This added to 1245, and the sum multiplied by 7, gives $\overline{P+c}\times a=89{,}635$. Let l be 18; then $\frac{89{,}635}{18}-1245$ $=3725=p$, which differs not more than $\frac{1}{40}$th from what experiment gives us. This rule holds equally well in all the other lengths except the 10 and 24 feet beams, which are very anomalous. Such a formula is abundantly exact for practice, and will answer through a much greater variety of length, though it cannot be admitted as a true one; because, in a certain very great length, the strength will be nothing. For other sizes the constant number must change in the proportion of d^3, or perhaps of p.

Relation between the strength and the square of the depth of the section.

The next comparison which we have to make with the theory is the relation between the strength and the square of the depth of the section. This is made by comparing with each other the numbers in any horizontal line of the table. In making this comparison we find the numbers of the five-inch bars uniformly greater than the rest. We imagine that there is something peculiar to these bars; they are in general heavier than in the proportion of their section, but not so much so as to account for all their superiority. We imagine that this set of experiments, intended as a standard for the rest, has been made at one time, and that the season has had a considerable influence. The fact however is, that if this column be kept out, or uniformly diminished about one sixteenth in their strength, the different sizes will deviate very little from the ratio of the square of the depth, as determined by theory. There is however a small deficiency in the bigger beams.

We have been thus anxious in the examination of these experiments, because they are the only ones which have been related in sufficient detail, and made on a proper scale for giving us data from which we can deduce confidential maxims for practice. They are so troublesome and expensive that we have little hopes of seeing their number greatly increased; yet surely our navy board would do an unspeakable service to the public by appropriating a fund for such experiments under the management of some man of science.

Proportion between the absolute cohesion and the relative strength.

There remains another comparison which is of chief importance, namely, the proportion between the *absolute cohesion* and the *relative strength*. It may be guessed, from the very nature of the thing, that this must be very uncertain. Experiments on the absolute strength must be confined to very small pieces, by reason of the very great forces which are required for tearing them asunder. The values therefore deduced from them must be subject to great inequalities. Unfortunately we possess no detail of any experiments; all that we have to depend on are two passages of Muschenbroeck's *Essais de Physique;* in one of which he says, that a piece of sound oak $\frac{27}{100}$ths of an inch square is torn asunder by 1150 pounds; and in the other, that an oak plank twelve inches broad and one thick will just suspend 189,163 pounds. These give for the cohesion of an inch square 15,755 and 15,763 pounds. Bouguer, in his *Traité du Navire*, says that it is very well known that a rod of sound oak one fourth of an inch square will be torn asunder by 1000 pounds. This gives 16,000 for the cohesion of a square inch. We shall take this as a round number, easily used in our computations. Let us compare this with M. Buffon's trials of beams four inches square.

The absolute cohesion of this section is $16{,}000\times16=256{,}000$. Did every fibre exert its whole force in the instant of fracture, the momentum of cohesion would be the same as if it had all acted at the centre of gravity of the section at two inches from the axis of fracture, and is therefore 512,000. The four-inch beam, seven feet long, was broken by 5312 pounds hung on its middle. The half of this, or 2656 pounds, would have broken it, if suspended at its extremity, projecting $3\frac{1}{2}$ feet, or 42 inches, from a wall. The momentum of this strain is therefore $2656\times42=111{,}552$. Now this is in equilibrio with the actual momentum of cohesion, which is therefore 111,552 instead of 512,000. The strength is therefore diminished in the proportion of 512,000 to 111,552, or very nearly of 4·59 to 1.

As we are quite uncertain as to the place of the centre of effort, it is needless to consider the full cohesion as acting at the centre of gravity, and producing the momentum 512,000; and we may convert the whole into a simple multiplier m of the length, and say, *as* m *times the length is to the depth, so is the absolute cohesion of the section to the relative strength.* Therefore let the absolute cohesion of a square inch be called f, the breadth b, the depth d, and the length l (all in inches), the relative strength, or the external force, p, which balances it, is $\frac{fbd^2}{9\cdot18l}$, or, in round numbers, $\frac{fbd^2}{9l}$; for $m=2\times4\cdot59$.

This great diminution of strength cannot be wholly accounted for by the inequality of the cohesive forces exerted in the instant of fracture; for in this case we know that the centre of effort is at one third of the height in a rectangular section (because the forces really exerted are as the extensions of the fibres). The relative strength would be $\frac{fbd^2}{3l}$, and p would have been 8127 instead of 2656.

We must ascribe this diminution (which is three times greater than that produced by the inequality of the cohesive forces) to the compression of the under part of the beam; and we must endeavour to explain in what manner this compression produces an effect which seems so little explicable by such means.

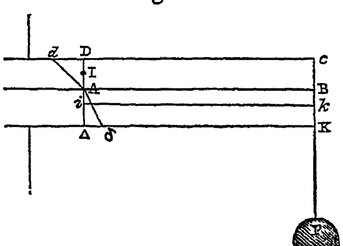
As we have repeatedly observed, it is a matter of nearly universal experience that the forces *actually* exerted by the

particles of bodies, when stretched or compressed, are very nearly in the proportion of the distances to which the particles are drawn from their natural positions. Now, although we are certain that, in enormous compressions, the forces increase faster than in this proportion, this makes no sensible change in the present question, because the body is broken before the compressions have gone so far; nay, we imagine that the compressed parts are crippled in most cases even before the extended parts are torn asunder Muschenbroeck asserts this with great confidence with respect to oak, on the authority of his own experiments. He says, that although oak will suspend half as much again as fir, it will not support, as a pillar, two thirds of the load which fir will support in that form.

We imagine therefore that the mechanism in the *present* case is nearly as follows:

Let the beam DCKΔ (fig. 21) be loaded at its extremity with the weight P, acting in the direction KP perpendicular to DC. Let DΔ be the section of fracture. Let DA be about one third of DΔ. A will be the particle or fibre which is neither extended nor compressed. Make $\Delta\delta : Dd = DA : A\Delta$. The triangles DAd, $\Delta A\delta$, will represent the accumulated attracting and repelling forces. Make AI and $Ai = \frac{1}{3}$ DA and $\frac{1}{3}$ ΔA. The point I will be that to which the full cohesion Dd or f of the particles in AD must be applied, so as to produce the same momentum which the variable forces at I, D, &c. really produce at their several points of application. In like manner, i is the circle of similar effort of the repulsive forces excited by the compression between A and Δ, and it is the real fulcrum of a bended lever IiK, by which the whole effect is produced. The effect is the same as if the full cohesion of the stretched fibres in AD were accumulated in I, and the full repulsion of all the compressed fibres in AΔ were accumulated in i. The forces which are balanced in the operation are the weight P, acting by the arm ki, and the full cohesion of AD acting by the arm Ii. The forces exerted by the compressed fibres between A and Δ only serve to give support to the lever, that it may exert its strain.

Fig. 21.



We imagine that this does not differ much from the real procedure of nature. The position of the point A may be different from what we have deduced from Buffon's experiments, compared with Muschenbroeck's value of the absolute cohesion of a square inch. If this last should be only 12,000, DA must be greater than we have here made it, in the proportion of 12,000 to 16,000. For Ii must still be made $= \frac{1}{3}$ AΔ, supposing the forces to be proportional to the extensions and compressions. There can be no doubt that a part only of the cohesion of DΔ operates in resisting the fracture in all substances which have any compressibility; and it is confirmed by the experiments of M. Duhamel on willow, and the inferences are by no means confined to that species of timber. We say, therefore, that when the beam is broken, the cohesion of AD alone is exerted, and that each fibre exerts a force proportional to its extension; and the accumulated momentum is the same as if the full cohesion of AD were acting by the lever Ii = $\frac{1}{3}$d of DΔ.

It may be said, that if only one third of the cohesion of oak be exerted, it may be cut two thirds through without weakening it. But this cannot be, because the cohesion of the whole is employed in preventing the lateral slide so often mentioned. We have no experiments to determine that it *may not* be cut through one third without loss of its strength.

This must not be considered as a subject of mere speculative curiosity. It is intimately connected with all the practical uses which we can make of this knowledge; for it is almost the only way that we can learn the compressibility of timber. Experiments on the direct cohesion are indeed difficult, and exceedingly expensive if we attempt them in large pieces. But experiments on compression are almost impracticable. The most instructive experiments would be, first to establish, by a great number of trials, the transverse force of a moderate batten; and then to make a great number of trials of the diminution of its strength, by cutting it through on the concave side. This would very nearly give us the proportion of the cohesion which really operates in resisting fractures. Thus if it be found that one half of the beam may be cut on the under side without diminution of its strength (taking care to drive in a slice of harder wood), we may conclude that the point A is at the middle, or somewhat above it.

Much lies before the curious mechanician, and we are as yet very far from a scientific knowledge of the strength of timber.

A useful practical rule may be deduced from M. Buffon's experiments.

In the mean time, we may derive from these experiments of Buffon a very useful practical rule, without relying on any value of the absolute cohesion of oak. We see that the strength is nearly as the breadth, as the square of the depth, and as the inverse of the length. It is most convenient to measure the breadth and depth of the beam in inches, and its length in feet. Since, then, a beam four inches square and seven feet between the supports is broken by 5312 pounds, we must conclude that a batten one inch square and one foot between the supports will be broken by 581 pounds. Then the strength of any other beam of oak, or the weight which will just break it when hung on its middle, is $581 \frac{bd^2}{l}$.

But we have seen that there is a very considerable deviation from the inverse proportion of the lengths, and we must endeavour to accommodate our rule to this deviation. We found, that by adding 1245 to each of the ordinates or numbers in the column of the five-inch bars, we had a set of numbers very nearly reciprocal of the lengths; and if we make a similar addition to the other columns in the proportion of the cubes of the sixes, we have nearly the same result. The greatest error (except in the case of experiments which are very irregular) does not exceed $\frac{1}{15}$th of the whole. Therefore, for a radical number, add to the 5312 the number 640, which is to 1245 very nearly as 4^3 to 5^3. This gives 5952. The 64th of this is 93, which corresponds to a bar of one inch square and seven feet long. Therefore 93×7 will be the reciprocal corresponding to a bar of one foot. This is 651. Take from this the present empirical correction, which is $\frac{b\,40}{b\,4}$, or 10, and there remains 641 for the strength of the bar. This gives us for a general rule $p = 651 \frac{bd^2}{l} - 10\,bd^2$.

Example. Required the weight necessary to break an oak beam eight inches square and twenty feet between the props, $p = 651 \times \frac{8 \times 8^2}{20}\ 10 \times 8 \times 8^2$. This is 11,545, whereas the experiment gives 11,487. The error is very small indeed. The rule is most deficient in comparison with the five-inch bars, which, we have already said, appear stronger than the rest.

The following process is easily remembered by such as are not algebraists.

Multiply the breadth in inches twice by the depth, and

call this product f. Multiply f by 651, and divide by the length in feet. From the quotient take 10 times f. The remainder is the number of pounds which will break the beam.

We are not sufficiently sensible of our principles to be confident that the correction $10f$ should be in the proportion of the section, although we think it most probable. It is quite empirical, founded on Buffon's experiments. Therefore the safe way of using this rule is to suppose the beam square, by increasing or diminishing its breadth till equal to the depth. Then find the strength by this rule, and diminish or increase it for the change which has been made in its breadth. Thus, there can be no doubt that the strength of the beam given as an example is double of that of a beam of the same depth and half the breadth.

The reader cannot but observe that all this calculation relates to the very greatest weight which a beam will bear for a very few minutes. M. Buffon uniformly found that two thirds of this weight sensibly impaired its strength, and frequently broke at the end of two or three months. One half of this weight brought the beam to a certain bend, which did not increase after the first minute or two, and may be borne by the beam for any length of time. But the beam contracted a bend, of which it did not recover any considerable portion. One third seemed to have no permanent effect on the beam; but it recovered its rectilineal shape completely, even after having been loaded several months, provided that the timber was seasoned when first loaded; that is to say, one third of the weight which would quickly break a seasoned beam, or one fourth of what would break one just felled, may lie on it for ever without giving the beam a set.

We have no detail of experiments on the strength of other kinds of timber: only M. Buffon says, that fir has about $\frac{6}{10}$ths of the strength of oak; Mr Parent makes it $\frac{10}{12}$ths; Emerson, $\frac{2}{3}$ds, &c.

We have been thus minute in our examination of the mechanism of this transverse strain, because it is the greatest to which the parts of our machines are exposed. We wish to impress on the minds of artists the necessity of avoiding this as much as possible. They are improving in this respect, as may be seen by comparing the centres on which stone arches of great span are now turned with those of former times. They were formerly a load of mere joists resting on a multitude of posts, which obstructed the navigation, and were frequently losing their shape by some of the posts sinking into the ground. Now they are more generally trusses, where the beams abut on each other, and are relieved from transverse strains. But many performances of eminent artists are still very injudiciously exposed to cross strains. We may instance one which is considered as a fine work, viz. the bridge at Walton on Thames. Here every beam of the great arch is a joist, and it hangs together by framing. The finest piece of carpentry that we have seen is the centre employed in turning the arches of the bridge at Orleans, described by Perronet. In the whole there is not one cross strain. The beam, too, of Hornblower's steam-engine is very scientifically constructed.

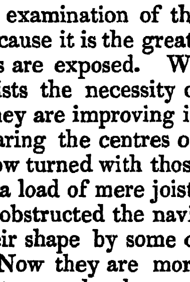
Strain produced by twisting.

IV. The last species of strain which we are to examine is that produced by twisting. This takes place in all axles which connect the working parts of machines.

The resistance must be proportional to the number of particles.

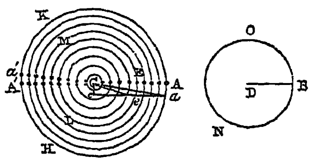
Although we cannot pretend to have a very distinct conception of that modification of the cohesion of a body by which it resists this kind of strain, we can have no doubt that, when all the particles act alike, the resistance must be proportional to the number. Therefore if we suppose the two parts ABCD, ABFE (fig. 22), of the body EFCD to be of insuperable strength, but cohering more weakly in the common surface AB, and that one part ABCD is pushed laterally in the direction AB, there can be no doubt that it will yield only there, and that the resistance will be proportional to the surface.

Fig. 22.



In like manner, we can conceive a thin cylindrical tube, of which KAH (fig. 23) is the section, as cohering more weakly in that section than anywhere else. Suppose it to be grasped in both hands, and the two parts twisted round the axis in opposite directions, as we would twist the joints of a flute; it is plain that it will first fail in this section, which is the circumference of a circle, and the particles of the two parts which are contiguous to this circumference will be drawn from each other laterally. The total resistance will be as the number of equally resisting particles, that is, as the circumference (for the tube being supposed very thin, there can be no sensible difference between the dilatation of the external and internal particles). We can now suppose another tube within this, and a third within the second, and so on till we reach the centre. If the particles of each ring exerted the same force (by suffering the same dilatation in the direction of the circumference), the resistance of each ring of the section would be as its circumference and its breadth (supposed indefinitely small), and the whole resistance would be as the surface; and this would represent the resistance of a solid cylinder. But when a cylinder is twisted in this manner by an external force applied to its circumference, the external parts will suffer a greater circular extension than the internal; and it appears that this extension (like the extension of a beam strained transversely) will be proportional to the distance of the particles from the axis. We cannot say that this is demonstrable, but we can assign no proportion that is more probable. This being the case, the forces simultaneously exerted by each particle will be as its distance from the axis. Therefore the whole force exerted by each ring will be as the square of its radius, and the accumulated force actually exerted will be as the cube of the radius; that is, the accumulated force exerted by the whole cylinder, whose radius is CA, is to the accumulated force exerted *at the same time* by the part whose radius is CE, as CA^3 to CE^3.

Fig. 23.



The whole cohesion now exerted is just two thirds of what it would be if all the particles were exerting the same attractive forces which are just now exerted by the particles in the external circumference. This is plain to any person in the least familiar with the fluxionary calculus. But such as are not may easily see it in this way.

Let the rectangle AC*ca* be set upright on the surface of the circle along the line CA, and revolve round the axis C*c*. It will generate a cylinder whose height is C*c* or A*a*, and having the circle KAH for its base. If the diagonal C*a* be supposed also to revolve, it is plain that the triangle *c*C*a* will generate a cone of the same height, and having for its base the circle described by the revolution of *ca*, and the point C for its apex. The cylindrical surface generated by A*a* will express the whole cohesion exerted by the circumference AHK, and the cylindrical surface generated by E*e* will represent the cohesion exerted by the circumference ELM, and the solid generated by the triangle CA*a* will represent the cohesion exerted by the whole circle AHK, and the cylinder generated by the rectangle AC*ca* will represent the cohesion exerted by the same surface if each particle had suffered the extension A*a*.

Now it is plain, in the first place, that the solid generated by the triangle *e*EC is to that generated by *a*AC as EC^3 to

Strength of Materials.

AC^3. In the next place, the solid generated by aAC is two thirds of the cylinder, because the cone generated by cCa is one third of it.

We may now suppose the cylinder twisted till the particles in the external circumference lose their cohesion. There can be no doubt that it will now be wrenched asunder, all the inner circles yielding in succession. Thus we obtain one useful information, viz. that a body of homogeneous texture resists a *simple twist* with two thirds of the force with which it resists an attempt to force one part laterally from the other, or with one-third part of the force which will cut it asunder by a square-edged tool; for to drive a square-edged tool through a piece of lead, for instance, is the same as forcing a piece of the lead as thick as the tool laterally away from the two pieces on each side of the tool. Experiments of this kind do not seem difficult, and they would give us very useful information.

With what force a body of a homogeneous texture resists a simple twist.

When two cylinders AHK and BNO are wrenched asunder, we must conclude that the external particles of each are just put beyond their limits of cohesion, are equally extended, and are exerting equal forces. Hence it follows, that in the instant of fracture the sum-total of the forces actually exerted are as the squares of the diameters.

The forces exerted in breaking two cylinders are as the squares of the diameters.

For drawing the diagonal Ce, it is plain that $Ee = Aa$ expresses the distension of the circumference ELM, and that the solid generated by the triangle CEe expresses the cohesion exerted by the surface of the circle ELM, when the particles in the circumference suffer the extension Ee equal to Aa. Now the solids generated by CAa and CEe being respectively two thirds of the corresponding cylinders, are as the squares of the diameters.

Relative strength of the section to the external force employed to break it.

Having thus ascertained the real strength of the section, and its relation to its absolute lateral strength, let us examine its strength relative to the external force employed to break it. This examination is very simple in the case under consideration. The straining force must act by some lever, and the cohesion must oppose it by acting on some other lever. The centre of the section may be the neutral point, whose position is not disturbed.

Let F be the force exerted laterally by an exterior particle. Let a be the radius of the cylinder, and x the indeterminate distance of any circumference, and dx the indefinitely small interval between the concentric arches; that is, let dx be the breadth of a ring and x its radius. The forces being as the extensions, and the extensions as the distances from the axis, the cohesion actually exerted at any part of any ring will be $f\frac{xdx}{a}$. The force exerted by the whole ring (being as the circumference or as the radius) will be $f\frac{x^2dx}{a}$. The momentum of cohesion of a ring, being as the force multiplied by its lever, will be $f\frac{x^3dx}{a}$. The accumulated momentum will be the sum or fluent of $f\frac{x^3dx}{a}$; that is, when $x = a$, it will be $\frac{1}{4}f\frac{a^4}{a} = \frac{1}{4}fa^3$.

The resistance of the axle is as the cube of its diameter.

Hence we learn that the strength of an axle, by which it resists being wrenched asunder by a force acting at a given distance from the axis, is as the cube of its diameter.

But, further, $\frac{1}{4}fa^3$ is $= fa^2 \times \frac{1}{4}a$. Now fa^2 represents the full lateral cohesion of the section. The momentum therefore is the same as if the full lateral cohesion were accumulated at a point distant from the axis by one fourth of the radius, or one eighth of the diameter of the cylinder.

Therefore let F be the number of pounds which measure the lateral cohesion of a circular inch, d the diameter of the cylinder in inches, and l the length of the lever by which the straining force p is supposed to act; we shall have $F \times \frac{1}{8}d^3 = pl$, and $F\frac{d^3}{8l} = p$.

We see in general that the strength of an axle, by which it resists being wrenched asunder by twisting, is as the cube of its diameter.

We see also that the internal parts are not acting so powerfully as the external. If a hole be bored out of the axle of half its diameter, the strength is diminished only one eighth, while the quantity of matter is diminished one fourth. Therefore hollow axles are stronger than solid ones containing the same quantity of matter. Thus let the diameter be 5, and that of the hollow 4; then the diameter of another solid cylinder having the same quantity of matter with the tube is 3. The strength of the solid cylinder of the diameter 5 may be expressed by 5^3, or 125. Of this the internal part (of the diameter 4) exerts 64; therefore the strength of the tube is $125 - 64 = 61$. But the strength of the solid axle of the same quantity of matter and diameter 3 is 3^3, or 27, which is not half of that of the tube.

Hollow axles more proper than solid ones.

Engineers, therefore, have of late introduced this improvement in their machines, and the axles of cast iron are all made hollow when their size will admit of it. They have the additional advantage of being much stiffer, and of affording much better fixture for the flanches which are used for connecting them with the wheels or levers by which they are turned and strained. The superiority of strength of hollow tubes over solid cylinders is much greater in this kind of strain than in the former or transverse. In this last case the strength of this tube would be to that of the solid cylinder of equal weight as 61 to 32 and a half nearly.

and now generally used.

The apparatus which we mentioned on a former occasion for trying the lateral strength of a square inch of solid matter, enabled us to try this theory of twist with all desirable accuracy. The bar which hung down from the pin in the former trials was now placed in a horizontal position, and loaded with a weight at the extremity. Thus it acted as a powerful lever, and enabled us to wrench asunder specimens of the strongest materials. We found the results perfectly conformable to the theory, in as far as it determined the proportional strength of different sizes and forms; but we found the ratio of the resistance to twisting to the simple lateral resistance considerably different, and it was some time before we discovered the cause.

The ratio of resistance to twisting to the simple lateral resistence appears different.

We had here taken the simplest view that is possible of the action of cohesion in resisting a twist. It is frequently exerted in a very different way. When, for instance, an iron axle is joined to a wooden one by being driven into one end of it, the extensions of the different circles of particles are in a very different proportion. A little consideration will show that the particles in immediate contact with the iron axle are in a state of violent extension; so are the particles of the exterior surface of the wooden part, and the intermediate parts are less strained. It is almost impossible to assign the exact proportion of the cohesive forces exerted in the different parts. Numberless cases can be pointed out where parts of the axle are in a state of compression, and where it is still more difficult to determine the state of the other particles. We must content ourselves with the deductions made from this simple case, which is fortunately the most common. In the experiments just now mentioned, the centre of the circle is by no means the neutral point, and it is very difficult to ascertain its place; but when this consideration occurred to us, we easily freed the experiments from this uncertainty, by extending the lever to both sides, and by means of a pulley applied equal force to each arm, acting in opposite directions. Thus the centre became the neutral point, and the resistance to twist was found to be two thirds of the simple lateral strength.

But when the experiment was altered, it was exactly the same.

We beg leave to mention here, that our success in these

Experiments on chalk, clay, and wax, satisfactory; but those on timber irregular.

experiments encouraged us to extend them much farther. We hoped by these means to discover the absolute cohesion of many substances, which would have required an enormous apparatus and a most unmanageable force to tear them asunder directly. But we could reason with confidence from the resistance to twist (which we could easily measure), provided that we could ascertain the proportion of the direct and the lateral strengths. Our experiments on chalk, finely prepared clay, and white bee's wax (of one melting and one temperature), were very consistent and satisfactory. But we have hitherto found great irregularities in this proportion in bodies of a fibrous texture like timber. These are the most important cases, and we still hope to be able to accomplish our project, and to give the public some valuable information. This being our sole object, it was our duty to mention the method which promises success, and thus excite others to the task; and it will be no mortification to us to be deprived of the honour of being the first who thus adds to the stock of experimental knowledge.

When the matter of the axle is of the most simple texture, such as that of metals, we do not conceive that the length of the axle has any influence on the fracture. It is otherwise if it be of a fibrous texture like timber; the fibres are bent before breaking, being twisted into spirals like a corkscrew. The length of the axle has somewhat of the influence of a lever in this case, and it is more easily wrenched asunder if long. Accordingly we have found it so; but we have not been able to reduce this influence to calculation.

Many useful deductions might be made from these premises respecting the manner of disposing and combining the strength of materials in our structures. The best form of joints, mortises, tenons, scarphs, the rules for joggling, tabling, faying, fishing, &c., practised in the delicate art of mast-making, are all founded on this doctrine; but the discussion of these would be equivalent to writing a complete treatise of carpentry.

The most recent experiments on the strength and elasticity of material give the results entered in the following tables:—

I.—*Distensions of Rods for a Strain of one Pound per Square Inch, computed from the results given in Tredgold, edition of* 1840, *as deduced from observations on transverse strain.*

British timber	Oak	$\frac{1}{92000}$
	Larch	$\frac{1}{36000}$
	Scotch fir	$\frac{1}{80000}$
	Ash	$\frac{1}{120000}$

(J. R.)

Practical Remarks.

We now give a few remarks on the foregoing subjects, which may be of use to practical men who may not be acquainted with the higher branches of mathematics. It has been seen that the foregoing treatise has explained the limit of the strength of materials, and that they fail in three ways:—1st, By tension, or being pulled asunder; 2d, By compression, or being crushed; 3d, By transverse strain, or being broken across, either by heavy weights or other similar causes.

Failure of material.

Tension.

With the first cause, the practical constructor has but little to do beyond consulting Mr Emerson's tables. They will afford a near approximation (quality being taken into the account) for weights to be suspended by iron-rods and other materials; but, since his time, iron-chains have been brought into much greater use, and iron wire-rope invented. It is impossible, in our space, to give anything like the information that has been published on this subject; our readers, however, will find full tables of the breaking weight, from 1 to 54 tons; the size in inches; the weight; and relative cost per fathom of wire-rope, hempen-rope, and chain, in Weale's *Engineers' Pocket-Book.*

For the tensile strength of iron and steel, we must refer to a very valuable paper in the *Transactions of the Institution of Engineers in Scotland,* by Mr Robert Napier, from experiments conducted by Mr David Kirkaldy, and the valuable tables subjoined thereto, just published. It would be impossible to give them in our limited space, as they extend over many columns of closely printed matter. It appears, however, that the breaking weight of bar-steel, per square inch of its original area, varied from 132,000 lb. to 62,000 lb., while that of iron has varied from 96,000 lb. to 44,000 lb. The like breaking weight of steel-plate varied from 96,000 lb. to 72,000 lb.; and that of iron from 56,000 lb. to 41,000 lb., and this is less than is generally given to iron; but it establishes the fact, that when used as bar and plate iron, for rough reckoning may be considered to have only about two-thirds the strength of steel.

Compression.

Practically it is seldom necessary to consider the weight any bodies would bear without crushing, except the wooden story posts, or iron columns that support the fronts of our houses, or the floors of our warehouses. The power of brick or stone to resist crushing being generally so very much more than those materials can have to carry, it does not come into the consideration of the builder, or engineer, except for very large works, where high professional assistance ought always to be sought. It will be seen, by an inspection of fig. 17, that posts generally fail first by crippling or buckling; and it is easy to perceive how any horizontal strut placed opposite to F, to prevent the timber bending in that direction, must add important strength to the post AB; and though it has been shown that Euler and his followers have pushed deductions drawn from such theories to the verge of absurdity, still, to the practical man, this is matter of grave consideration. If in a shop-front, for instance, we can get a strong transom between the story posts 3 feet from the pavement, those posts are much stronger than if they rose from floor to bressummer without any cross strut, or stay. Formulæ have been given again and again on the subject; but as they necessitate involution and evolution to cubic, and sometimes biquadratic, powers, they should not be used except by skilled mathematicians. There are, however, some very valuable tables given in Barlow's *Tredgold,* Nos. 16, 17, 18, and 19, for the scantlings of story posts to carry the fronts of ordinary houses, from two to five stories high, placed at various distances, from 4 to 8 feet apart, ranging from 8 to 16 feet in height; and some excellent information in Nicholson's *Carpentry,* chap. ii., 212, &c., on story posts generally.

Story posts.

Iron columns.

Their superiority, in many points of view, has led to the extensive use of iron columns. The best engineers, for some years, have been occupied in making series of experiments on their bearing and breaking weights; but none on so large a scale as those of Mr Eaton Hodgkinson. The

Mr Hodgkinson's experiments.

results of which were communicated to the Royal Society first in 1840, and again in 1857; and which, by the kindness of the author, are now before us; with an Appendix up to the present time. We regret we have not space for his valuable tables. The results, however, may be stated that he found that, in cylindrical pillars of cast-iron, the top and bottom of which were turned perfectly true and flat, the breaking weight varied as the 3·55th power of the diameter, and inversely as the 1·7th power of the length, so that, instead of the theory of Euler (commented on before in page 760), which comes out $\frac{d^4}{l^2}$, it was found to be $\frac{d^{3\cdot 55}}{l^{1\cdot 7}}$, d being the diameter, and l the length. In hollow pillars, as $\frac{d^{3\cdot 55} - d_1^{3\cdot 55}}{l^{1\cdot 7}}$, d and d_1 representing the outer and inner diameters, and this for cases where the lengths varied from 30 times the dimensions of the diameters to 120 times. But as it continually happens that practical men wish to employ cast-iron columns, we must refer them to a series of eleven tables, given in Weale's *Engineers' Pocket-Book;* and subsequently in his *Contractors' Price-Book*, which give the lengths in feet, the load in hundredweights, and the extent of floor solid cast-iron columns will support from 2 inches to 8 inches in diameter, and hollow columns from 3 inches to 18 inches of various thicknesses of metal.

Cross strains.

In the third branch of our subject, transverse strains, we have first to regard those of beams of wood, and it has been shown that in breaking a beam of wood by any weight pulling downwards in the centre, that the upper half of the beam is in a state of compression, and the lower in a state of tension. The practical man will understand this better if he will take a small lead tube, or a piece of a boy's rattan cane, and bend it downwards in the middle. He will find the top of the cane or tube will pucker up, the particles being crushed together, while the lower half will be torn asunder. In fact, we push together the fibres of the upper half and draw apart those of the lower half. From this simple fact all theories as to girders, whether of wood, or of cast or wrought iron are based. Several things must be borne in mind before we proceed; first, that a beam will bear twice the weight equally distributed over its surface than if collected in the middle; that a beam of double width will only carry a double load, but a beam of double depth will carry four times the load of a single beam. This may be understood by an inspection of fig. 3. If another beam of the same size were placed alongside of it, the two beams would do double the work of one; but if the beam ABCD were of double depth, the two triangles EG*e*, FG*f* would also be of double depth, and the power of the leverage of *each* would be doubled.

Tension and compression.

Distributed weight.

Proportion of depth to width.

If supported on both ends.

At one end.

If ends secured.

If a beam of any given length and width be fixed in a wall at one end only, it will break with half the weight a beam of half the length would bear, fixed at one end only. In other words, a fourth of its strength is taken away by removing the support from one end. If the ends are well wedged into a wall, instead of lying loose on the supports, the strength is much increased, as the ends which lie on a wall must "cock up;" if the middle bends down while they are loose, but should they be kept down tight by the superincumbent weight of the wall, they will counteract to a great degree the tendency to bending, and of course breaking. The securing the ends of beams into walls is said to increase their power to resist breaking weight from $\frac{1}{4}$ to $\frac{1}{3}$.

To calculate the strength of a beam.

The formulæ given by Tredgold are too abstruse for general purposes. There is, however, one given by Nicholson which is simple, and not far from the truth. A number of experiments were made on pieces of various woods, each one inch square and a foot long, and the weights which broke them recorded. Then as this weight c : is to the length of any given beam in feet l : : so is the weight the beam will have to bear (in pounds) W : to the breadth b multiplied into the square of the depth d of the intended beam; or as $c : l :: W : b \times d^2$. Any of these three being given, the fourth is easily found. The breaking weight of Memel fir he gives as 330, that of oak he gives as 810, but this last seems too much. Suppose there is a warehouse 16 feet wide, the girders of which are 10 feet apart, and each superficial foot is to carry 3 cwt. or 336 lb. Then as each girder supports $16 \times 10 = 160$ feet superficial, and as each foot is to carry 336 lb., the total weight to be carried is 53,760 lb. distributed over the whole, or half this 26,880 lb. in the centre. Then as 330 : 16 : : 26,880 : 1303, or the breadth multiplied into the square of the depth. But this is breaking weight, and no timber ought to be used of less strength than four times this. Then $1303 \times 4 = 5212$, the least amount we ought to reckon upon. Now we have our choice either to assume a breadth or a depth. Suppose we are confined to 17 inches for the latter. Then $\frac{5212}{17 \times 17} = 18$ inches very nearly. If we assume 15 inches as our breadth, then $\frac{5212}{15} = 347$, the square root of which is nearly 19 inches; so that we may have a girder 18 inches wide and 17 inches deep, or one 15 inches wide and 19 inches deep, as we please.

Scantlings of timber.

As has been said before, formulæ for calculating these have been given, but too abstruse for general practice. Valuable tables, however, will be found both in *Gwilt, Encyclopædia of Architecture*, in *Tredgold*, and several other books, both for floors and roofs. For floors, in *Gwilt*, Art. 2015 to 2022; in *Tredgold*, Tables Nos. 1 to 4: for roofs, in *Gwilt*, Art. 2036 to 2040; in *Tredgold*, Tables Nos. 5 to 15. The former author seems to give stronger scantlings in proportion than the second, but of course considerable discretion must be used, as we must take into account the weight of the covering and flatness of pitch. It must be remembered, also, that common joists are much strengthened by cross strutting, and all girders above 25 feet in length should be trussed. (See BUILDING, pp. 748-749.)

Inclined beams.

The strength of an inclined beam as a rafter has been shown to be as the cosine of the angle it forms with the horizon. Therefore the strength of the rafter AB, Art. ROOF, fig. 3, is the same as that of a beam of similar scantling in a horizontal position of the length between the perpendiculars of its two ends, as AF.

Advantages and disadvantages of timber beams.

The advantages of timber beams are, they do not shrink in length, and they show signs of fracture before there is danger, and yield gradually if overloaded. The disadvantages—they shrink a great deal in thickness, occupy much space, become rotten by time or damp, and, worst of all, are combustible.

Iron beams.

These circumstances have led to the use of cast-iron as horizontal supports. The history of its introduction and use have been given in our foregoing articles, and at greater length in Mr Fairbairn's book, *The Application of Cast and Wrought Iron to Building*, just published. It will be therefore useless to enumerate the various stages of the invention. Suffice it to say, that from a simple flat plate of iron, which was the original form, and which in fact was a simple imitation of a beam of wood, a top and bottom flanch have by degrees been added, which have proved a great addition of strength, as well as a saving of metal. We have before explained in this page that the upper part of a beam, when it is intended to be bent, is in a state of compression, and the lower half in a state of tension. We must now add, that between these there is a point affected by neither of these forces, and which is called the neutral axis. If a parallel beam of the thickness of EG be widened as at AB, the power to resist compression becomes greater, and the same thing happens with regard to tension if

Use of flanges.

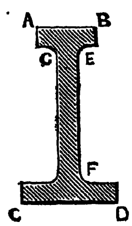

Fig. 24.

the thickness of the flitch EG be increased, as at CD. What is called the "web" EF is principally of use to keep the flanches apart, and increase the resistance by increased leverage.

The web. The works of Messrs Hodgkinson and Fairbairn amply show examples of all these, which we should gladly give *in extenso* did our space permit; and though these are valuable for reference in special cases, the practical constructor needs some tolerably simple rule to give him an idea what size an iron girder ought to be to support a given weight.

Rules to calculate. A number of formulæ have been published, the most elaborate, and perhaps the nearest the truth, is that of Mr H. Grissell, the eminent founder, in his evidence before the House of Lords, in which he takes into consideration the dimension of the top flange as well as that of the bottom. But by far the simplest is that of Mr Hodgkinson, adopted by Mr Fairbairn, viz.:—

$$W=\frac{cad}{l}$$

where W = breaking weight in the middle in tons.
a = the section of the bottom rib or flange.
d = the depth of the beam.
l = the length or distance between the supports (all these in inches).
c = a constant quantity derived from the result of various experiments, which varies according to the quality of iron, and other causes, from 25 to 27·5, and is generally taken at 26. An example is given of a bridge girder at Manchester 26 feet or 312 inches in the clear of the supports. The bottom flange CD is 16 inches wide and 3 inches deep. The whole depth A to C $27\frac{1}{2}$ inches. Then $l=312$ $a=48$ $d=27·5$ and $c=26$, as above.

Then $\frac{26\times 48\times 27·5}{312}=110$ tons, which is the breaking weight in the *middle* of the beam. No notice is here taken of the upper flange, but the omission is justified by the fact that the constant c has been taken from frequent experiments on girders having top and bottom flanges of proper proportions, and that therefore it comes into the account one way if not in another. In very particular instances, however, we think it ought to be calculated, as, it is said, cast-iron has eight times greater power to resist compression than tension.

Safe load. Much difference exists among engineers as to the proportion the permanent safe-load has to breaking weight; some saying it should be three times as much, others six, and some, where there is great momentum or impact, ten times as much. It was confessed, however, in the former cases the formulæ were fuller than ordinary. It is more common lately to take six times the load as the size on which to reckon.

Proof. But as there are so many hidden defects in cast-iron, and when a failure takes place, as it gives no warning, but all goes to ruin at once, and as there have been such fearful accidents with this material, every girder should be proved by placing actual weights on them.

Over-proof. But this precaution may be carried to excess, for instances have been known where a sound girder has been strained in the proof, and has afterwards broken with a very small weight. A good authority has laid it down as a rule, that a girder should be designed to carry six times the load it is intended at any time to bear, and should be proved to three times. By this rule the girder just described should be proved in the middle to 55 tons, and never have more than $18\frac{1}{3}$ tons in the centre, or 37 tons if the weight be equally distributed. It is well also to sound the girder throughout with a hammer, as they do railway axles.

Compound girders. These are partly of cast trussed with wrought-iron, but are seldom used except in very large structures. We fear, after all that has been said in their favour, that, as temperature changes, the particles of the two materials are often in a different state of tension, and therefore they are very unsafe. We have, however, no space here to enter into the argument.

Wrought-iron girders. The sudden accidents arising from the failure of cast-iron, and their fearful results, have suggested the use of wrought-iron; and as its manufacture is now so much cheaper from the great improvements in rolling T and L iron, and in punching and riveting machines, the wrought-iron girder is now a very important consideration to the designer of a building. We shall endeavour to give some short formulæ to guide the practical man, though, as has been said before, in all important works reference should be had to the higher branches of science.

Wrought girder. There are two sorts of wrought-iron beams now employed, generally called either plate-girders or box-girders. Fig. 25 shows the former, and fig. 26 the latter. Neither have been in use long enough, nor have there been such a multiplicity of experiments on them, to afford such certain formulæ as have been published for cast-iron beams. But we give what we gather to be a near approximation of the theories

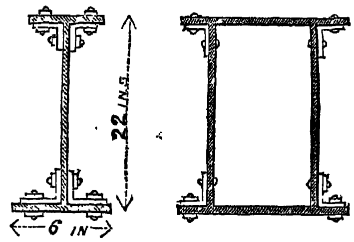

Fig. 25. Fig. 26.

just published as far as they go, and venture, under correction of such authorities, to suggest they are incomplete as regards the upper flange, just as in the former theories. Nay, more so, inasmuch as the upper flange requires to be the *strongest* in wrought-iron, that material being more easily compressed than rent by tension (which is just the contrary with cast-iron, where we have shown the lower flange ought to be of largest area). The constant c is given as 75. Taking the former formula, $W=\frac{cad}{l}$ in a case where the length between the supports is 30 feet (or 360 inches), the depth 22 inches of $\frac{5}{16}$ metal, and the bottom flanges 3×3 each, of $1\frac{1}{2}$ inch metal (see fig. 25), we have $\frac{75\times 6\times 22}{360}=27\frac{1}{2}$ tons as breaking weight. From Mr Fairbairn's careful experiments, however, we should gather that 75 is a fair constant where the top flange has double the strength of the lower flange.

Box girders. The formulæ collected for these is quite on another principle from those of the plate-girder. Instead of regarding the bottom flange alone, writers base their theories in the sectional area of the metal of top, bottom, and sides, and given as a formula $W=\frac{Ad\,C.}{l}$ Here A is the area of the entire cross-section (fig. 26). Now, as the girders vary very much in form, some being square in section, some flat, and some oblong, it follows that the constant C must vary according to each section; and not only so, but with the relative strength of the top and bottom flanges. Experiments have shown where the top has been only half the strength of the bottom flange, the constant was as low as under 10, but turning the very same girder bottom upwards, so that the top flange was then double the strength of the lower, a constant of nearly 18, or nearly double, was got out of the same section. Mr Fairbairn thinks that 21·5 is a fair constant to be reckoned for rectangular tubes, when the upper flange is double the strength of that below. Of course, these girders, like all others, ought to be proved; but, as has been before explained, there is always a greater security about them than those of cast-iron.

Trellis girders. The formulæ for these are the same as for plate-girders, but the constants vary enormously. Experiments show a

difference from 44 to 17. It seems, however, to be the opinion of many, that a well constructed trellis girder may be calculated to bear about half what a close plate-girder of the same dimension would carry; but as these are little used in building, we shall not go further into the investigation.

There are also many excellent articles interspersed in the *Transactions* of the Institution of Civil Engineers; Royal Institute of British Architects; the various French *Annales*; the Franklin Institute of America, &c.; and in the Architect and Civil Engineers' *Pocket-book*, the *Office-Book*, and various works of this description. (A. A.)

STRICKLAND, Hugh Edwin, the grandson of Sir George Strickland, and of the eminent Dr Edmund Cartwright, was born at Righton in the East Riding of Yorkshire, on the 2d of March 1811. He studied under Dr Arnold at Laleham, and subsequently at Oriel College, Oxford. While at Oxford his taste was directed by the teaching of Dr Buckland to the study of geology; and on his retirement to Tewkesbury he studied with great diligence and success the geology and natural history of the Cotswold Hills and of the great valley of the Severn. From numerous papers which appeared from Strickland's pen in the *Transactions of the Geological Society*, it appeared that he was a very industrious inquirer, an accurate observer, and a just reasoner on the geological phenomena which came under his observation. In 1835, he made a geological tour to Asia Minor, and published papers on the various topics which drew his attention during his travels. He succeeded Dr Buckland as reader in geology to the University of Oxford on the failure of that gentleman's health. In zoology he was distinguished as an ornithologist, and various contributions from Strickland appeared in the *Proceedings of the Zoological Society*. He likewise wrote a book on *The Dodo and its Kindred* in 1848, in which he concluded that this extinct bird belonged to the family of Columbidæ. He was one of the original founders of the Ray Society, and he had just edited the third volume of Agassiz's *Bibliographia Zoologiæ et Geologiæ*, when he was killed by a passenger-train on the Gainsborough and Retford Railway, a portion of the cuttings of which he was too diligently examining, on the 14th September 1853.

STRIEGAU, a town of the Prussian monarchy, Silesia, in the government and 27 miles W.S.W of Breslau. It has a court-house, Protestant and Roman Catholic churches, an ancient Carmelite convent, a Benedictine nunnery, hospital, and poor-house. Linen and woollen cloth are woven here, and some trade is carried on. Pop. 5884.

STROMBOLI (anc. *Strongyle*), one of the Lipari Islands, 35 miles off the north coast of Sicily. It is about 9 miles in circuit, and entirely volcanic in its formation, rising to the height of 2500 feet near the N.W. extremity. There is a crater 170 yards across, which is continually sending out smoke and flame, with loud explosions, but no proper eruption has taken place for a very long time. Wheat, barley, cotton, wine, raisins, and figs are raised on the island. There are a small town and a battery on the east side, and some ancient remains throughout the island. Pop. 1200.

STROMNESS, a seaport and burgh of barony of Scotland, on the island of Mainland, Orkney, 12 miles W.S.W. of Kirkwall. It is irregularly built, consisting of one main street extending along the shore, and lined with substantial stone houses. There are a parish church, Free church, and United Presbyterian church; several schools, a public library, and a museum. Boat and ship-building is carried on, and there is a small rope-work. The harbour is good, admitting vessels of all sizes. The trade of the place is considerable. Pop. 2055.

STROPHE (στρέφω, *I turn*), in Greek poetry, the first division of a choral ode, of which the other parts were the antistrophe and the epode.

STROUD, or Stroudwater, a market-town and parliamentary borough of England, Gloucestershire, in a beautiful valley, at the union of two streams which form the Stroud Water, 9 miles S. by E. from Gloucester, and 101 W. by N. of London. It is the centre of the woollen manufacture in the county, and has many dye-houses, woollen and fulling mills, which stand in deep ravines on the side of the valley, near streams which flow into the main river. The houses are irregularly scattered on the hill-sides; and the valley is also densely filled with them. The town was formerly very ill built, but has been much improved of late. The principal buildings are the large parish church, with nave, chancel, aisles, and spire; Trinity Church; and Baptist, Independent, and Methodist chapels. There are also National, British, and other schools; a dispensary, and an hospital. The Stroud water is believed to be peculiarly adapted for use in the process of dying scarlet. A considerable trade is carried on, for which the Great Western Railway and the Thames and Severn Canal afford important facilities. Weekly markets and two annual fairs are held. The borough of Stroud, which includes a large and important manufacturing district, is represented in parliament by two members. Pop. of the parl. borough, 36,535; of the parish, 8798.

STRUENSEE and BRANDT. See Denmark.

STRUTT, Joseph, an artist and antiquary of considerable merit, was born at Springfield in Essex, October 27, 1742. After spending sometime with Wynne Ryland, he afterwards became a student in the Royal Academy, and in 1771, while engaged in the reading-room of the British Museum, he obtained the embellishments for many of the subsequent works which were then simmering in his brain. In 1773 appeared his *Regal and Ecclesiastical Antiquities of England, containing the representations of the English Monarchs from Edward the Confessor to Henry VIII.*; in 1774 his *Horda-Angel-Cynnan*, a work which he completed in 3 volumes in 1776. His *Chronicle of England*, 2 volumes, appeared in 1777 and 1778. His next work was *A Biographical Dictionary of Engravers* in 2 vols., 1785 and 1786. His *Complete View of the Dress and Habits of the People of England* was published in 2 vols. 1796–99; and his work on *The Sports and Pastimes of the People of England* originally appeared in 1811. Strutt, after all his diligence and plodding industry, died in narrow circumstances in London, October 16th 1802. His manuscripts, which contained dramas, dramatic tales, &c., were published by his son after his death. His *Queen Hoo Hall*, a romance illustrative of ancient manners, was completed by Sir Walter Scott in 1808.

STRYPE, John, a meritorious labourer in ecclesiastical and literary history, was born at Stepney on the 1st of November 1643. His father, John van Stryp, was a native of Brabant, and sought refuge in England on account of his religion. He was a merchant and silk-thrower. The son received his early education at St Paul's school, where

he remained for six years. In 1662 he proceeded to Jesus College, Cambridge, from which he was transferred to Catherine Hall. In 1665, he there took the degree of A.B., and that of A.M. four years afterwards. He was appointed to the perpetual curacy of Theydon-Boys, in the county of Essex, in 1669; but he only retained it for a few months, having been appointed minister of Low Leyton, in the same county. When far advanced in life, Strype was presented by Archbishop Tenison to the sinecure of Tarring in Sussex. He was also appointed to the lectureship of Hackney, which he resigned in 1724. At Hackney he resided, in his old age, under the roof of one Harris, an apothecary, who was married to his grand-daughter. In this house he died on the 11th of December 1737, at the patriarchal age of ninety-four.

Strype's principal works are—*The Life of Archbishop Cranmer*, 1694, fol.; *The Life of Sir Thomas Smith*, 1698, 8vo; *The Life of Dr John Aylmer, Bishop of London*, 1701, 8vo; *The Life of Sir John Cheke*, 1705, 8vo; *Annals of the Reformation*, 4 vols.: vol. i. 1709, reprinted 1725; vol. ii., 1725; vol. iii., 1728; vol. iv., 1731; *The Life of Archbishop Grindal*, 1710, fol.; *The Life and Letters of Archbishop Parker*, 1711, fol.; *The Life of Archbishop Whitgift*, 1718, fol.; *Ecclesiastical Memorials*, 1721, 3 vols. fol.

The writings of Strype were for many years neglected, but they are now held in deserved estimation; and they have all been reprinted at the Clarendon press. He is not remarkable for the methodical arrangement of his materials, nor did he ever attain to much proficiency in the art of composition; but no one ever denied him the praise of diligence and fidelity. Besides these works, he published *Lessons for Youth and Old Age*, 1699, 12mo. He likewise published the second volume of Dr Lightfoot's *Works*, in 1684; and an elaborate edition of Stow's *Survey of London*, 1720, 2 vols. fol.

STUARTS, The. See Scotland and Great Britain.

STUART, Gilbert, an eminent jurist and historian, was born at Edinburgh in the year 1742. He was educated in the public school and in the University of his native city. To the pursuit of jurisprudence he devoted himself with uncommon ardour; but although he had a strong relish for the study of law, he anticipated no delight from its practice, and he was never called to the bar. Of his early progress in this study he exhibited a very conspicuous specimen in a work published without his name; *An Historical Dissertation concerning the Antiquity of the English Constitution*, Edinb., 1768, 8vo. Stuart's Dissertation, distinguished by so much vigour of intellect and maturity of juridical learning, procured him from the university the degree of LL.D., which is very rarely bestowed upon so young a scholar. A second edition, bearing the author's name, was published at London in the year 1771, and he then prefixed a dedication to the Earl of Mansfield. The dedication is dated at London in the month of January 1770; and before this period he had become a regular contributor to the *Monthly Review*, with which he continued his connection from 1768 to 1774. We likewise find him employed as the editor of *An Historical Treatise on the Feudal Law, and the Constitution and Laws of England; with a Commentary on Magna Charta, and necessary Illustrations of many of the English Statutes; in a Course of Lectures read in the University of Dublin, by the late Francis Stoughton Sullivan, LL.D., Royal Professor of the Common Law in that University*, Lond., 1772, 4to. A pseudonymous work, of a very different denomination, has been ascribed to Dr Stuart. It bears the title of *Animadversions on Mr Adam's Latin and English Grammar; being an Exhibition of its Defects, and an Illustration of the Danger of Introducing it into Schools.* By John Richard Busby, Master of Arts, Edinb., 1773, 8vo.

Dr Stuart now undertook the management of *The Edinburgh Magazine and Review*, of which the first number bears the date of November 1773. Smellie was the printer, and Stuart was the principal writer. Lord Hailes, Dr Blacklock, Professor Richardson of Glasgow, Professor Barron of St Andrews, and Smellie, were among the number of the contributors. The work was certainly clever, but much too satirical; and it consequently merely outlived the fifth volume, and expired in August 1776. Notwithstanding the failure of this project, Dr Stuart had displayed so much talent in his principal articles, that his reputation as a man of letters suffered no diminution. He however felt a very painful mortification at the unsuccessful result of his labours; and his mind was so badly regulated that, instead of reflecting on the natural tendency of his own conduct, he continued to cherish a most bitter and indiscriminate resentment. He was still in the early vigour of manhood, and he speedily roused himself to new and greater exertions. After an interval of less than two years, he produced what we are disposed to regard as the best of his works, *A View of Society in Europe, in its Progress from Rudeness to Refinement; or, Inquiries concerning the History of Law, Government, and Manners*," Edinburgh, 1778, 4to. The style of this work, though never languid or feeble, may, however, be considered as deficient in fluency and variety. His periods are, perhaps, too uniformly short. "This brevity," he avers, "is a conspicuous part of oratory, and is consistent with the greatest elevation and dignity. Where Cicero himself is most eloquent, and where the tide of his language is most rapid and powerful, his sentences are concise; and he avoids with care the periodic swell, as cold, artificial, and unnatural. And, indeed, it is to be laid down as a general rule, that where sentences are uniformly long, as in Milton and in Clarendon, there is no eloquence in the composition, and little connection in the argument."—*Edinburgh Magazine and Review*, vol. v., p. 250.

Being disappointed in his expectations regarding the professorship of civil law in Edinburgh, he allowed his embittered spirit to find vent in all his future publications. This spirit is very easily to be discerned in his next publication, *Observations concerning the Public Law and the Constitutional History of Scotland: with occasional Remarks concerning English Antiquity*, Edinb., 1779, 8vo. This publication was speedily followed by *The History of the Establishment of the Reformation of Religion in Scotland*, Lond., 1780, 4to. The work is written with his usual ability, but it cannot be affirmed that such an undertaking was peculiarly adapted to his habits of thinking. He however displays a greater degree of impartiality than could well have been anticipated. Of this work, his next publication may be considered as the sequel: *The History of Scotland, from the Establishment of the Reformation till the death of Queen Mary*, Lond., 1782, 2 vols. 4to. Here the author has made a great, and indeed a splendid effort, to eclipse the reputation of Robertson, whom he both envied and hated. As the one historian considered Mary guilty of some of the foulest crimes laid to her charge, it was almost an obvious consequence that the other should represent her as innocent. The preface to the *History of Scotland* is dated at London on the 1st of March 1782; and soon after this period he undertook the management of the *English Review* in 1783. How long he continued to conduct the *English Review* we are not informed. In 1785 he became the editor of *The Political Herald and Review*. This work, it is believed, only reached a second volume. It is too well known that Stuart's mode of life had been such as to impair his health and strength. With a constitution undermined by disease, and a mind soured by disappointment, he embarked for Leith, and sought a place of rest under the roof of his father, who having become emeritus professor in 1775, was then residing at Musselburgh. The son was labouring under a dropsy, from which the usual operation afforded him a temporary

relief; but all medical aid was ineffectual, and he descended to his grave at the premature age of forty-four. He died on the 13th of August 1786, and his father survived till the 18th of June 1793.

Gilbert Stuart is thus described by a writer who seems to have had some personal knowledge of him: He "was about the middle size, and justly proportioned. His countenance was modest and expressive, sometimes announcing sentiments of glowing friendship, of which he is said to have been truly susceptible; at others, displaying strong indignation against folly and vice, which he had also shown in his writings. With all his ardour for study, he yielded to the love of intemperance, to which, notwithstanding a strong constitution, he fell an early sacrifice."

Stuart, *Gilbert Charles*, sometimes called American Stuart, was an eminent painter, born of Scottish parents at Narraganset, Rhode Island, United States, in 1755. He accompanied a travelling artist, named Alexander, to Scotland, where he resided for some time, but returned again to America in 1773. Having again proceeded to London in 1775, he contrived to support himself by playing as an organist in a church in that city. Meeting with his countryman, Benjamin West, who took him into his studio as his pupil and assistant, his career henceforward was one of prosperity. His life, however, was a scene of change and confusion, caused entirely by his intemperate habits. After painting the portraits of many distinguished men in London, Dublin, and Paris, he returned to America, where he exercised his pencil on portraits of Washington, Jefferson, J. Q. Adams, and many other men of note. He died at Boston July 1828. Stuart is generally recognised to be one of the greatest portrait-painters which America has yet produced.

Stuart, *James*, author of the *Antiquities of Athens*, and frequently, on that account, known as Athenian Stuart, was born in London of poor parents in 1713. He originally assisted Goupy of the Strand, and in 1742 he set out for Rome. After remaining in that city for seven years, industriously engaged in painting, he had proposals made to him by Revett and Gavin Hamilton, to start for Greece on an architectural expedition. Hamilton ultimately declined accompanying them, and Stuart and Revett accordingly set out for Greece in 1751. They remained in that country till about the end of 1753. On returning to England Stuart found more work than he could accomplish. He engaged in the literary portion of the *Antiquities of Athens*, the first volume of which appeared in 1762. The work, on the whole, was a great success. Stuart, by the encouragement which he received got sluggish; and while he executed various designs for noblemen, societies, &c., in Grecian architecture, he allowed the *Antiquities* to slumber in his hand until both head and hand were cold. He died the 2d February 1788. The second volume of this work was edited after his decease by Newton, and published in 1790, and the third by Beverley in 1794.

STUHLWEISSENBURG, a town of Hungary, capital of a county of the same name, on the Csargo, in a marshy region, near the west border of the morass of Sarret, 38 miles S.S.W. of Buda, and about 100 S.E. of Vienna. It is a large and ancient town, with ill paved, irregular streets. The principal building is the Cathedral of St Mary, formerly the place of coronation and burial for the kings of Hungary, and containing many of their tombs. This building is handsome and richly decorated. There are here five other churches, an episcopal palace, county buildings, gymnasium, military academy, and other schools, hospital and theatre. Woollen and linen cloth, hardware, and other articles are manufactured here; and there is an active trade in wine and fruit. On account of the scarcity of good water, several Artesian wells have been bored here. Pop. (1851) 14,971.

STUKELEY, William, an eminent antiquary, descended from an ancient family in Lincolnshire, was born at Holbeach in that county, on the 7th of November 1687. From the free school of his native town he was removed to Corpus Christi College, Cambridge, where he was admitted on the 7th of November 1703. Having chosen the medical profession, he took the degree of M.B. in 1709, and that of M.D. in 1719. He first settled as a practitioner at Boston; but in 1717 he removed to London, and was admitted a fellow of the College of Physicians in 1720. By the recommendation of Dr Mead, he was chosen a fellow of the Royal Society. He contributed to the re-establishment of the Society of Antiquaries, of which he officiated as secretary for many years. In 1726 he left the metropolis, and settled at Grantham in Lincolnshire, where he soon obtained extensive practice. In 1728 he married Frances, the daughter of Robert Williamson, Esq. of Allington, a lady of good family and fortune. Being much afflicted with gout, he found the exercise of his profession very laborious, and therefore meditated a retreat into the church. On the 20th of July 1720, being then in the thirty-third year of his age, he received ordination from Archbishop Wake; and in the ensuing October was presented by the Lord-chancellor King to the living of All-Saints in Stamford. He became a widower in 1737, and, in the course of the following year, married the only daughter of Dr Gale, the learned dean of York. In 1739 the living of Somerby, near Grantham, was bestowed upon him by the Duke of Ancaster. In 1747 the Duke of Montagu presented him to the rectory of St George, Queen Square, and he then vacated his other benefices. He survived till the 3d of March 1765.

Dr Stukeley was a man of varied learning, but was chiefly distinguished by his knowledge of antiquities. His writings are numerous, and partly relate to medical as well as theological subjects; but we shall confine ourselves to an enumeration of the most important or curious of his antiquarian publications.

An Account of a Roman Temple near Graham's Dike, 1720, 4to. *Of the Roman Amphitheatre at Dorchester*, Lond., 1723, 4to. *Itinerarium Curiosum; or, an Account of the Antiquities and remarkable Curiosities in Great Britain*, Lond., 1724, fol.; Lond., 1776, 2 vols. fol. *Stonehenge; a Temple restor'd to the British Druids*, Lond., 1740, fol. *Abury; A Temple of the British Druids: with some others described*, Lond., 1743, fol. *Palæographia Britannica; or, Discourses on Antiquities in Britain*, Lond., 1743–52, 4to. *An Account of Richard of Cirencester*, Lond., 1757, 4to. *The Medallic History of Marcus Aurelius Valerius Carausius, Emperor in Britain*, Lond., 1757–9, 2 vols. 4to.

STURM, Jacques Charles François, the discoverer of the algebraic theorem which bears his name, was born in Geneva in 1803. Originally tutor to the son of Madame de Staël, he subsequently resolved, in conjunction with his school-fellow Colladon, to try his fortune in the French metropolis. Sturm soon made the acquaintance of the foremost mathematicians in the capital, and obtained employment on the *Bulletin Universelle*. On the discovery of his important theorem, namely, the determination of the number of real roots of a numerical equation which are included between given limits, in 23d May 1829, he rapidly rose to fortune and public honours. He was chosen a member of the French Academy in 1836, and was afterwards appointed to succeed Poisson in the chair of Physics at Paris. He presented numerous memoirs to the academy, of which it has been said that an impartial posterity will place them by the side of the finest memoirs of Lagrange. Sturm died on the 18th of December 1855.

Sturm, *Johann*, better known by the name of Sturmius, a learned philologer and rhetorician, was born at Schleiden, near Cologne, on the 1st of October 1507. He afterwards pursued his study at Liege, in the College of St Jerome, and then went to Louvain in 1524. He there spent five years, three in learning and two in teaching.

He set up a printing-press with Rudger Rescius, professor of Greek, and printed several Greek authors. In 1529 he went to Paris, where he was highly esteemed, and read public lectures on the Greek and Latin writers, and on logic. In 1537 he went to Strasburg, and the year following opened a school, which became famous, and by his means obtained of Maximilian II. the privileges of a university in the year 1566. He was very well skilled in polite literature, wrote Latin with great purity, and was an able teacher. His talents were not confined to the school; for he was frequently intrusted with deputations in Germany and foreign countries, and discharged these employments with great honour. He showed extreme charity to the refugees on account of religion: he not only laboured to assist them by his advice and recommendations, but he even impoverished himself to aid them. He died on the 3d of March 1589, in the eighty-second year of his age. He was a learned writer, and published various works, which were found to be useful and important by his contemporaries. One of these was an edition of Cicero, in 9 vols. 8vo. He bestowed much labour in elucidating the rhetorical works of Aristotle, Hermogenes, and Cicero. With the view of improving the system of education, he published several treatises, one of which was frequently reprinted. It is entitled *De Literarum Ludis recte aperiendis liber*, Argent., 1538, 4to. F. A. Hallbauer edited a collection of his tracts under the title *De Institutione Scholastica Opuscula omnia*, Jenæ, 1730, 8vo.

STUTTGART, a town of Germany, capital of the kingdom of Würtemberg, on the Nesenbach, an affluent of the Neckar, 38 miles E.S.E. of Carlsruhe, and 97 S.E. of Frankfort. It occupies a very beautiful situation in a valley closely environed with vine-clad hills, and further off with woody mountains. The old part of the town lies low, and has narrow crooked streets and insignificant houses, mostly built of wood; but the more modern portion, which occupies a loftier position, consists of straight, broad, and regular streets, with large and handsome houses. The place is almost entirely of modern growth, and owes its present prosperity in a very great degree to its being the residence of the court. The principal street occupies the site of the ancient city moat; it is straight and broad. Opposite the royal palace is a large public square; and there are several others of smaller size in different parts of the town. The new palace was begun in 1746 and finished in 1806. It is a large building of freestone, not very fine externally, but splendidly decorated and furnished in the interior. The old palace, which stands to the south-west, is a massive building resembling a feudal castle. It was completed in 1570, and is now occupied by the government offices. This edifice fronts a square, two sides of which are formed by another palace, that of Prince Frederic, the king's son-in-law. In the square stands a large bronze statue of Schiller, by Thorwaldsen; and on its other side is a fine old Gothic Church of the fifteenth and sixteenth centuries. It has a lofty tower, and contains a fine organ, many ancient sculptures, and monuments of many princes of the Würtemberg family. The hospital church is also Gothic; its exterior is clumsy, but the interior is very fine, and contains the grave of Reuchlin, and Danneker's model of his statue of Christ, now at Regensburg. The other churches in the town are modern and of little merit. The *Ständehaus*, where the estates or parliament of the kingdom meet, was built in 1580, but only adapted to its present purpose in 1819. The town-hall, which stands in the market-place in the older part of the town, is a building of the fifteenth century. Stuttgart has also a Museum of Natural History, containing a valuable collection; a public library of 200,000 volumes, and about 3220 MSS., including a very large collection of Bibles; a royal cabinet of medals, containing about 17,000 specimens, besides various other antiquities; a museum of the fine arts, with many fine statues and pictures; a theatre, bazaar, post-office, and other buildings. The educational establishments comprise a gymnasium, military academy, school of art, polytechnic school, and others. There are numerous hospitals, asylums, alms-houses, and other benevolent institutions. A striking feature in this comparatively small town is the number of barracks which it contains. The infantry barracks is one of the largest buildings of the kind in Germany; it can accommodate with ease 3000 men. There are besides cavalry barracks of somewhat less size. The principal manufactures of the town are the making of woollen and cotton cloth, gold, silver, and bronze wares, musical, optical, and philosophical instruments, and the various branches of industry connected with the book trade, which is extensively carried on here. There is also a considerable trade in bark. The town is advantageously situated for commerce, as by means of the Neckar it communicates with the Rhine, and by railways with the principal towns of Germany. In the vicinity of Stuttgart there are some fine gardens and pleasure-grounds; among the rest those of the palace, to which the public are freely admitted. The date of the foundation of the town is not exactly known, and there are no important events connected with its history. Pop. (1858) 51,655.

STYLES. See CHRONOLOGY.

STYLITES, SIMEON, a famous anchoret in the fifth century, who first took up his abode on a column six cubits high, then on a second of twelve cubits, a third of twenty-two, a fourth of thirty-six, and on another of forty cubits, where he thus passed thirty-seven years of his life. The tops of these columns were only three feet in diameter, and were defended by a rail that reached almost to the girdle, but did not permit the votary to lie down. Other solitaries who practised this sort of stupid devotion were known by the name of "Pillar Saints." The faquirs, or devout people of the East, imitate this mode of life to the present day.

STYRIA (Germ. *Steyermark*), DUCHY OF, a province of the Austrian Empire, bounded on the N. by the archduchy of Austria; E. by Hungary; S. by Croatia and Carniola; S.W. and W. by Carinthia and Salzburg. Its form is very irregular. Length, from N. to S. 124 miles; greatest breadth, 112; area, 8646 square miles. Pop. (1857), exclusive of the military, 1,070,747. (See AUSTRIA.)

STYX, a waterfall of Greece, descending from a lofty rock above the town of Nonacris, in the N.E. of Arcadia, and forming a stream that falls into the Crathis. The descriptions given by Homer and Hesiod of the water of the Styx agree with the natural features of this mountain-torrent; and Pausanias states that the passage in which Homer represents Juno as swearing by the Styx seems just as if the poet had the waterfall before his eye. The water was supposed by the Greeks to be poisonous, and to destroy everything that was thrown into it; and there was a report that Alexander the Great was poisoned by the water of the Styx. A similar belief has prevailed in the vicinity down to the present day. In Greek mythology, the Styx was represented as a river of hell, round which it flows nine times. The gods held its waters in such veneration, that to swear by them was reckoned an oath altogether inviolable. If any of the gods had broken this oath, Jupiter obliged them to drink the waters of the Styx, which lulled them for a whole year into a senseless stupidity. It is said that this veneration was shown to the Styx, because it received its name from the nymph Styx, who, with her three daughters, assisted Jupiter in his war against the Titans. Styx was a river which it was necessary for departed shades to pass before they could enter the infernal regions; and it was the office of Charon to ferry them over. Mythological writers have said that the Egyptians framed

both this and some other fables relating to the dead, from certain customs peculiar to their country; that in particular there was, not far from Memphis, a famous burying-place, to which the dead bodies were conveyed in a boat across the Lake Acherusia; and that Charon was a boatman who had long officiated in that service.

SUAKIN, a seaport of Nubia, on an island close to the shore of the Red Sea, N. Lat. 19. 7.; E. Long. 37. 20. Besides the town itself, on the island, there is on the mainland the much larger suburb of El Geyf. The houses are built of blocks of madrepore; and are one or two storeys in height. The town itself has three mosques, and the suburb another. The bay forms a good harbour; and the town is an important trading place between the interior of Africa and the opposite coast of Arabia. From three to four thousand slaves are annually shipped from this port to Arabia. Gold, tobacco, ostrich feathers, ivory, salt, &c., are among the articles of commerce. Suakin is much frequented by pilgrims to Mecca. Pop. 8000.

SUAREZ, Francis, a renowned Jesuit, was born at Grenada on the 5th of January 1548. He belonged to a noble family, and was sent to prosecute the study of law in the University of Salamanca; but when he had finished his course, he was induced to change his destination, and assume the habit of St Ignatius. He at first experienced much difficulty in comprehending the principles of the philosophy which was then taught; but having been placed under the guidance of Rodriguez, he soon began to be distinguished by the uncommon rapidity of his progress, and became one of the most distinguished members of the society. Having taught philosophy at Segovia, he was afterwards employed in teaching theology at Valladolid, Rome, Alcala, and Salamanca. Wherever he taught, his lectures attracted a numerous auditory. He was at length appointed to the first chair of divinity in the university of Coimbra; but, before entering upon his office, he went to Evora and took his doctor's degree. Here his reputation continued to increase. At the instigation of the Pope, he prepared an elaborate work, entitled *Defensio Catholicæ Fidei contra Anglicanæ Sectæ Errores*, Conimbricæ, 1613, fol. This work gave much offence to King James, and was burned at St Paul's by the hands of the hangman. Nor did it receive better treatment from the parliament of Paris; who, by an *arrêt* pronounced on the 26th of June 1614, condemned it to the flames, as containing maxims contrary to the rights of sovereigns. It was ably refuted by Robert Abbot, afterwards bishop of Salisbury. Suarez, having been called to Lisbon for some weighty conference, died there on the 25th of September 1617. An instant before he expired, he said to those who surrounded his bed, "I never knew it was so pleasant to die."

Suarez was a great master of the scholastic philosophy and theology of his age, nor was he a mean or ordinary proficient in jurisprudence. Grotius has described him as the most acute of philosophers and divines. His treatise *De Legibus et Deo Legislatore*, is commended by Sir James Mackintosh, "as exhibiting the most accessible and perspicuous abridgment of the theological philosophy in its latest form." Of this learned Jesuit, the works are very numerous. An edition of them in twenty-three vols. fol. began to be published at Mentz and Lyon in the year 1630. An edition was published at Venice in the year 1740.

SUBIACO (anc. *Sublaqueum*), a town of the Papal states in the Comarca, and 34 miles east of Rome, on a hill near the right bank of the Teverone. It stands in the midst of beautiful scenery; but has itself dark narrow streets, lined with old and gloomy houses. On the top of the hill stands an old castle, which was long a summer residence of the Pope. Subiaco has also a handsome church, containing many works of art; and in the vicinity are the remains of a palace of Nero, and a fine monastery. Pop. 6000.

SUBPŒNA, in *Law*, a writ by which persons are called into chancery, in cases where the common law has provided an ordinary remedy; and the name of it proceeds from the words therein, which charge the party called to appear at the day and place affirmed, "sub pœna centum librarum," &c.

SUCHET. See France.

SU-CHEW, a city of China, in the province of Kiang-su, on the Great Canal, near Lake Tai-hou, 55 miles W.N.W. of Shanghai. Like Venice it is built on islands, and interpenetrated by canals, which are navigable for large vessels. It is surrounded by fortifications, 10 miles in circuit; and beyond these there are four large suburbs. Here are numerous fine temples and other buildings; manufactures of silk, nankeen, and other goods are carried on, and there is an active trade. Su-chew is not only the residence of the richest merchants of China, but a flourishing seat of art and science, taste and beauty, for here are to be seen the most beautiful women in China; and hence it has received the name of the paradise on earth. Pop. 600,000.

SUCKLING, Sir John, an English poet and dramatist, was the son of Sir John Suckling, comptroller of the household to King Charles I., and was born in the year 1608–9. He discovered an uncommon aptitude for the acquiring of languages, insomuch that he is reported to have spoken Latin at five years of age, and to have written it at nine. When he grew up he travelled; but seems to have affected nothing more than the character of a courtier and fine gentleman, which he so far attained that he was allowed to have the peculiar happiness of making everything he did become him. In his travels he made a campaign under the great Gustavus Adolphus; and his loyalty, if not his valour, appeared in the beginning of our civil wars; for, after his return to England, he raised a troop of horse for the king's service, entirely at his own charge, and mounted them so completely and richly that they are said to have cost him L.12,000. This troop, with Sir John at its head, behaved so ill in the engagement with the Scots upon the English borders, in 1639, as to occasion a famous lampoon, composed by Sir John Mennis, which was set to a brisk tune, and much sung by the parliamentarians. This disastrous expedition, and the ridicule that attended it, were supposed to have hastened his death; but he survived till the 7th of May 1641. Some say that he died by his own hand at Paris, and family tradition confirms the report. He was a sprightly wit and an easy versifier, but no great poet. His poems, plays, speeches, tracts, and letters were collected into an octavo volume in the year 1709; and another edition, consisting of selections from his writings, with a life, by Rev. Alfred Suckling, appeared in 1836.

SUDBURY, a market-town and municipal borough of England, Suffolkshire, on the left bank of the Stour, 16 miles S. of Bury St Edmunds, and 54 N.E. of London. It is a neat, clean, and generally well-built town, connected by a bridge across the river, with a suburb, Ballingdon, in Essex. The principal buildings are the town-hall and corn exchange, of modern erection, and three parish churches of older date. The latter are large and handsome, chiefly in the perpendicular style of architecture. One of them, St Gregory's, contains in its chancel the grave of Archbishop Theobald, who was killed by Wat Tyler's mob in 1381. The Dominican friars had a church and priory here, erected in the thirteenth century; but of these few remains are now to be seen. There was also here anciently an establishment of the knights of St John near the bridge, and a Benedictine cell not far off. Sudbury contains places of worship for Independents, Baptists, and Quakers; a grammar school, national, British, and Church of England schools; a theatre, savings bank, hospital, and poor-house. Silk is the principal article manufactured. A considerable trade is carried on; but the navigation of the river is not

Sue.

good, and has been superseded to a large extent by railways. Weekly markets and annual fairs are held in Sudbury. The borough is governed by a mayor, four aldermen, and twelve councillors. It formerly returned two members to Parliament, but was disfranchised for bribery in 1844. Sudbury was one of the first towns in which Edward III. settled the Flemish woollen manufactures, in order to instruct his people in that branch of industry. This trade has now fallen off here, but has been succeeded by the manufacture of silk. Sudbury was the birthplace of the celebrated painter Gainsborough. Pop. 6042.

SUE, Eugène, a popular French novelist, was born at Paris on the 10th of December 1804. He belonged to a family of physicians, who had distinguished themselves in more than one reign of the sovereigns of France. His father was household physician to Napoleon, and the future novelist was presented at the font by the Empress Josephine and her son Eugène Beauharnais. Having received his name from so illustrious a house, it became his care afterwards to do what he could to render it immortal. Sue originally began the family profession, but gave it up in a short while for the more showy career of a military man. After pursuing his adventures both by land and sea for a number of years, he in 1831 returned to Paris, where he found his father dead, and some L.1600 a year awaiting him. He began to spend it with great good-will, and took to writing first as an amusement, and subsequently as a necessity. His first novels were received with neglect, such as *Plick et Plock*, 1831; *Atar-Gull*, 1831; *La Salamandre*, 1832; *La Coucaratcha*, 4 vols., 1832–34; *La Vigie de Koat-Ven*, 4 vols., 1833. Next followed his conspicuous failure, *L'Histoire de la Marine Française*, 5 vols. 1835–37, which provoked the waggish jocularity of some of the naval officers at Toulon, who presented the author with a silver medal to express "the gratitude of the French navy to Eugène Sue for the history he has not written." Numerous romances followed this historical attempt, in which vice, as is usual with French novels, triumphed over virtue. In 1840 M. Sue resolved to try the virtuous novel, and, as a commercial speculation, it had an amazing success. One of the great literary events of Louis Phillippe's reign is described as the publication of Sue's *Mathilde*, in 6 vols., 1841. On this followed in close succession, *Les Mystères de Paris*, 10 vols., 1842; *Le Juif Errant*, 10 vols., 1844–5, all which appeared in the pages of *La Presse*, *Les Debats*, and *Le Constitutionnel*. This literary lion, for such he had now become, was feasted and praised as only Frenchmen can praise and feast. This vicious panderer to the lowest feelings and worst passions of the mob was, to the great mass of the French people, the immortal delineator of manners, and the most exquisite writer which had ever appeared. This virtuous author would not hold his public in suspense, he accordingly gave them *Le Morne au Diable*, 2 vols., 1842; *Martin l'Enfant Trouve*, 12 vols., 1847; *Les Sept Péchés Capitaux*, 16 vols., 1847–49. The *Mystères du Peuple*, 1849-56, was in process of publication when, in 1857, it was condemned, and suppressed as immoral and seditious by the assize court of Paris. This was a timely hint to Sue that his services were no longer needed as the instructor of his age. He afterwards wrote, with a marked decrease of popularity, his *Les Enfans de l'Amour*, 4 vols., 1850; *La Bonne Aventure*, 6 vols. 1851; *Ferdinand Duplessis, ou Memoirs d'un Mari*, 6 vols, 1852. In 1848, Sue, who was an extreme Socialist, was elected a representative of the Assemblée Nationale; but on the election of Napoleon III. he was expelled from the French territory. He retired to Annecy, where he died on the 3d of July 1857.

Suetonius.

SUETONIUS, C. Tranquillus, a celebrated Roman historian, who flourished in the reigns of Trajan and Hadrian. The facts known about his biography are few, and are mainly derived from the letters of Pliny, and from one or two allusions in his own works. He was born about the year A.D. 70, since he calls himself "adolescens" at the period of the false Nero's appearance in Parthia, which was twenty years after the true Nero's death, A.D. 68 (Nero, c. lvii.), and "adolescentulus" in the reign of Domitian (Domit., xii.) His father, C. Suetonius Lenis, was a tribune of the 13th legion, and probably of equestrian rank (*augusticlavius*), and he had been present at the battle of Bedriacum, in which Otho was defeated by Vitellius (Otho, x.) In the face of this direct testimony, it is absurd in Muretus to argue, from a supposed various reading, that the father of the historian was that famous Suetonius Paulinus whose splendid achievements have been recorded by Tacitus.[1] Nor it is possible that Paulinus could have been his grandfather, since Suetonius would otherwise have unquestionably mentioned the fact when he alludes to his grandfather in the Life of Caligula (c. xix.) Why he altered the cognomen Lenis into Tranquillus is uncertain; perhaps merely from the same sense of euphony which induced Melancthon to Græcise his own harsh German patronymic. At one time Suetonius was in the army, and Pliny, to whose friendship and patronage he owed most of his advantages, obtained for him the rank of tribune; this position was, however, unsuited to his studious habits, and at his own request it was transferred to one of his relatives.[2] He also seems to have practised at the bar, for he begs Pliny to procure him a delay in pleading a cause in consequence of an ill-omened dream.[3] But we should infer from the term "scholasticus" which we find applied to him, and from the fact that Suidas[4] only calls him a grammarian, that his *public* appearances as an orator were few, although he may have given private lessons in rhetoric as well as in grammar. He generally lived in Rome or its environs, and his circumstances must have been easy, for he requests Pliny to purchase for him a little estate which had many attractions.[5] The same firm and constant friend obtained for him the *jus trium liberorum*, although, as he had no children, he was not legally entitled to enjoy it: the privilege was so important, that it was only obtained by the exercise of strong court influence.[6] Suetonius was finally elevated to the post of *magister epistolarum*, an office probably founded by Hadrian,[7] which would be likely to give him ample opportunities of private intercourse with the emperor,[8] and a free access to the imperial archives. He lost this office in consequence of an indiscreet familiarity with the Empress Sabina, and Septicius Clarus, the prætorian præfect, with many others, were involved in his disgrace. We can account for this conduct when we are told that Hadrian himself was in the habit of treating his wife like a common servant, and that she was ultimately driven to commit suicide. This example was one which courtiers would not be slow to imitate, but Hadrian resented it as *unauthorized* ("*injussu ejus* familiarius se egerant)."[9] That there was nothing directly *culpable* in the conduct of Suetonius is clear, both from the language of Spartianus, and from the certainty that the moral character of the empress afforded her husband no pretext for the divorce which he so ardently desired. This event took place in the year 119; and although we acquit Suetonius of *guilt*, it is clear that his behaviour must have been notoriously irregular, or it would hardly have reached the ears of Hadrian, who was at that time busily engaged in building the great wall by which he hoped to protect Britain from the incursions of the Picts and Scots. From this time forward

we lose sight of Suetonius, who probably spent the remainder of his life in the composition of his numerous works, and the uninterrupted enjoyment of literary pursuits.

It is difficult to estimate the personal character of Suetonius: except his rudeness to Sabina, we know of no positive facts against him, and Pliny speaks in the highest terms of his learning and uprightness. "Suetonium Tranquillum," he writes to the emperor, "*probissimum, honestissimum*, eruditissimum virum, et mores ejus secutus et studia jampridem, domine, in contubernium assumpsi; tantoque magis diligere cæpi, quanto hunc propius inspexi."[1] On the other hand, it is impossible to acquit him of the grossest and most detestable prurience in his writings. He gloats over the distortions of debauchery, and betrays a hideous familiarity with the arcana of crime. He clearly enjoys the loathsome details of excesses which exhausted the fertility of a vicious vocabulary,[2] or he would not go out of his way to record them with such fatal accuracy. There is something sickening in the manner in which he thinks it necessary to chronicle with the minutest fidelity the merely personal excesses of a series of monsters; and the words "de quibus *singillatim ab exordio* referam"—which preface two chapters wherein he sees fit to plunge us under the Stygian stream of iniquity, which even the vilest of emperors thought it necessary to conceal on an inaccessible rock—are unmatched for their philosophic indifference.

It is no excuse to say that he is merely recording facts, and that the record was necessary and desirable for the warning of mankind.[3] When we have paid Suetonius the very questionable compliment of St Jerome, that he wrote as freely as the emperors lived, we have said all that can be said in his apology. But there are some facts so horrible, that as their commission is an insult to humanity, so the narrative of them is an unpardonable injury. We hold with Tacitus, "Ostendi debent scelera, *abscondi flagitia*." It is true that we find in the highest and holiest histories a record of the most fearful crimes, but the *manner* of the record makes all the difference. In Tacitus, nay, even in the Holy Scriptures, we find proofs sufficiently deadly of human depravity; but they are narrated only with horror and reluctance. Quintilian's dictum, that "historia scribitur ad narrandum non ad probandum," though it has been taken as the motto of an historical school, may serve to excuse the cold and naked analysis of Suetonius, but could never be adopted by men whose powers of moral indignation have been unweakened by familiarity with vice. It is unjust to compare Suetonius and Tacitus in their account of the same disgraceful enormities. Tacitus alludes to them, indeed, but only in such a way as would make the blush of honest shame burn on every cheek; Suetonius lingers over them with a gloating curiosity, which makes him share their guiltiness. Tacitus writes to visit the offenders with the vengeance of posthumous execration; Suetonius perseveringly degrades himself into an incentive of jaded sensuality. Of him, as of writers like Spartianus[4] and Lampridius, we are forced to say, "*parum abest a docente qui talia narrat;*" and we agree with Muretus, that the biography of the emperors is a course of reading "ruinous to youths, and dangerous even to men of full years."[5]

As an historian, Suetonius ranks very low. "He was a man of great learning, and did not write badly; but he had no survey of his subject, nor any historical talent. His description of the time in which he himself lived is even worse than those of previous periods, in which he had the works of others which he could follow; and this circumstance is the best evidence that he had no vocation to write history. His history is written in the form of biographies, and this idea is quite right; but he had no plan: he wanders about from one subject to another, in consequence of which his biographies are without any definite character."[6] For chronology he is nearly worthless, and he was incompetent to form any distinct or profound conception of those whose lives he wrote. He heaps together a loose and incoherent heap of separate details, from which we must judge for ourselves. No doubt he was accurate, impartial, and laborious, and was in no hurry to publish his writings[7] until he had carefully elaborated them; but he must be regarded, not as an historian, but as an "anecdotier," a very good name applied to him by Laharpe. In spite of the pains which he took to collect information from every possible source—tradition, conversations, documents, memoirs, inscriptions—we should find ourselves very much at a loss for anything like history, if we had nothing to guide us but his scandalous gossip. Linguet, in the *Révolutions Romaines*, went so far as to say, that no fact need be believed if Suetonius was the only authority for it; but Krause[8] and others have sufficiently defended him from the charge of wilfully perverting truth, although he occasionally admits an incredible calumny.

Suetonius is valuable as the commentator and supplement of Tacitus. It is doubtful whether the *Vitæ Cæsarum* or the *Annales* were written first, but Niebuhr thinks it certain that the work of Suetonius was published early in his life, and that it would not have been so unsatisfactory as it often is, if he had been able to avail himself of the guidance of Tacitus.

Napoleon[9] once remarked, that Tacitus did not explain how it was that the emperors, monsters as they were, continued the idols of the people. This enigma is solved by Suetonius, who ruthlessly pulls up the curtain which hides the dark interior into which Tacitus would not condescend to intrude. The people, as Montesquieu has observed, did not hate those in whom they saw a magnified reflection of their own baseness, and at whose hands they received the spoils of wealthy families and fertile provinces. In supplying us with the facts that were requisite for a complete understanding of a deeply interesting, though a deeply degraded period, Suetonius has rendered a service which almost makes us forget his slugglish sensibilities, in admiration for the interest of his communications, and the graphic simplicity of his style.

Suetonius was a voluminous writer. Besides the *Vitæ XII. Cæsarum*, and the treatises, *De Illustribus Grammaticis*, and *De Claris Rhetoribus*, the extant lives of Terence, Horace, Lucan, Juvenal, Persius, and Pliny the Elder, pass under his name; and Suidas attributes to him a long list of other works of which only small fragments exist, and the names of which are hardly worth recording. He was long a favourite author, and the editions of his works are very numerous; before the year 1500 there were no less than fifteen editions, of which the oldest with a date is, Romæ, 1470. Others are—Casaubon, Paris, 1610; Schild., 1647; Burmaum, 1736; and Baumgarten-Krusius, ed. Nase., Paris, 1828. There is an expurgated French translation by Duteil., 1699; and English translations by Philemon Holland, 1606; and S. Thomson, 1796. (F. W. F.)

SUEUR, LE. See PAINTING.

SUEVI, the name given by the Romans to a large section of the people of ancient Germany. The meaning of the name is unknown; and it cannot be determined, with

any approach to certainty, whether it is of Teutonic, Celtic, or Slavonian origin. A similar obscurity hangs over the people themselves. According to the accounts of Cæsar, they dwelt on the east bank of the Rhine, about the modern Baden; but Tacitus places them further to the north-east; and Strabo asserts, that in his time they occupied the country between the Rhine and the Elbe, and even stretched beyond the latter river. The name was probably a general one, including many distinct tribes, such as the Semnones, Longobardi, Chatti, &c.; and as Germany became better known to the Romans, the general appellation was dropped, and the several tribes designated by their particular names. Towards the end of the third century we find the name again restricted to the district to which Cæsar applied it; and from this use of the term has come the modern *Swabia*, *Swabians*, &c.

SUEZ, a seaport-town of Egypt, situated at the head of the Gulf of Suez, the western and longer of the two arms in which the Red Sea terminates,—76 miles E. of Cairo, in Lat. 29. 57. 30. N., Long. 32. 31. 30. E. It is a small town, having a stationary population of only about 1600, but is of importance as being one of the stations on the overland line of route to India. The streets are unpaved, and houses are in general poorly built. The only respectable building in the place is a large and handsome hotel recently erected by the Pasha. The town is protected on three sides by a wall mounting a few cannon. It has a good quay, but only boats of not more than 60 tons can come up to the town, larger vessels having to anchor in the roadstead about two miles off. The country around Suez is a perfect desert, no fresh water nor any kind of verdure being to be seen, and hence water and all kinds of provisions have to be brought to it from a great distance.

SUEZ, *Gulf of*. See RED SEA.

SUEZ, *Isthmus of*, a neck of land connecting the two continents of Asia and Africa, and separating the Red Sea from the Mediterranean. Its breadth between the two seas is 90 miles, from the Gulf of Pelusium to that of Suez. The connection of the Mediterranean with the Red Sea by means of a canal has long been a very desirable object, and even as early as the time of the Pharoahs, several centuries before the Christian era, such a canal was constructed, extending from the Nile near Belbeis to the Gulf of Suez. (See EGYPT.) In recent times Napoleon projected a canal across the isthmus, and predicted that the execution of this great work would promote the prosperity and ensure the safety of the Turkish empire. Since the overland route was established, the importance of such a work has been deeply felt, and in 1852 M. F. de Lesseps, a French engineer, conceived the idea of forming a joint-stock company for cutting a ship-canal across the isthmus. In 1854 he received a firman from Mohammed Said, the viceroy of Egypt, conferring upon him the exclusive privilege of forming a company for that purpose. He then proceeded to Constantinople to obtain the adhesion of the Porte, and at first it is said that the Sultan was favourable to the scheme, but he deferred giving his sanction to it at the instance, it is said, of Lord Stratford de Redcliffe, the British ambassador, who wished to communicate with his government. In the summer of 1855 M. de Lesseps came to England for the purpose of giving information on the subject of his scheme. The same year a commission of eminent engineers of various countries was appointed to make an examination of the proposed route. The report drawn up by them was to the effect "that the direct canal between Pelusium and Suez was the only solution of the problem, and that there existed no other practical method of joining the Red Sea with the Mediterranean; that the execution of this maritime canal was easy, and its success certain; and that the two harbours required to be constructed, as Suez and Pelusium presented no difficulties but such as were of an ordinary character." A few days after the reports of the commission, on 5th January 1856, the charter of concession was granted by the Viceroy of Egypt. According to it the works to be executed are—1. A canal navigable by large vessels between Suez and Pelusium; 2. A canal of irrigation adapted to the river traffic of the Nile, and connecting that river with the Suez Canal. 3. Two branches for irrigation and supply, striking out of the preceding canal in the directions respectively of Suez and Pelusium. These works to be completed within six years, and four-fifths of the workmen employed to be Egyptians; Lake Témsah to be converted into an inland harbour fit for vessels of the highest tonnage; a harbour of refuge to be constructed at the entrance of the maritime canal into the Gulf of Pelusium; and the necessary improvements to be made in the port and roadstead of Suez. The Egyptian government to have a claim of 15 per cent. on the net profits of each year. It is farther provided that the canal shall always remain open as a neutral passage to every merchant-ship; that the maximum toll for passage shall be 10 francs per ton on ships and per head on passengers; and that the provisions of this charter shall be in force for ninety-nine years after the opening of the canal.

The isthmus from Pelusium to Suez forms a longitudinal depression. It is believed that at one time the two seas were united, and even now a considerable portion of the soil is below the level of the two seas. There are three of these depressions or basins,—the Bitter Lakes, Lake Témsah, and Lake Menzaleh. The basin of the Bitter Lakes extends over an area of 81,612 acres, and is altogether dry. Lake Témsah is midway between the two seas, forming, as it were, the centre of the isthmus. It covers about 5000 acres, and it is said that at very little cost it might be made into a large and safe inland harbour. On the north-west mouth of the isthmus, and separated from the Mediterranean by a narrow strip of land which the waves overleap in rough weather, is Lake Menzaleh, which communicates with the Mediterranean. The rest of the isthmus has an elevation of from 5 to 8 feet above the level of the two seas, with the exception of two inconsiderable ridges, the Serapeum and El Guisr,—the former having a medium height of 30, the latter of 45 feet. The cutting in the latter of these will extend over about 5 miles. In November 1858 the subscription was opened, and by the end of the month the entire capital of L.8,000,000 was subscribed for; and the company was definitely constituted on the 5th of January 1859. The Ship Canal is to be 90 miles in length, 330 feet wide at the water-line, and its bottom 20 feet below low water-level in the Mediterranean. The present port of Suez is to be improved and deepened, and a harbour is to be formed in the Gulf of Pelusium. Lake Témsah is to be formed into an inland harbour, communicating with the Nile by means of a canal 80 feet wide on the water-line, and about 22 feet deep.

We have here followed principally the account of M. de Lesseps, but it is evident that, in such an undertaking, there are difficulties to contend with that do not seem to have been sufficiently taken into account. The works employing many thousands of men are to be carried on in a sandy desert many miles from a spot where a drop of water or a morsel of food can be obtained; while the canal, when completed, will always be in danger of being injured by drifting sand. From the nature of the Gulf of Pelusium, a harbour can only be formed here by means of piers carried out for several miles, while the immense quantity of sand and mud carried down by the Nile, constantly drifting about on this coast, will render it liable to be blocked up by the formation of bars.

A railway has been constructed from Alexandria to Cairo, and a portion of the continuation to Suez is now open.

SUFEID KOH, or the WHITE MOUNTAIN, a range in Afghanistan, running from E. to W., parallel to the Hindoo Koosh, to the south of the Valley of the Cabool, about N. Lat. 23. 50.; E. Lon. from 69. 30. to 71. 16. It is chiefly of primary formation, and consists of three parallel chains, the two lower of which are covered with pine-forests; while the highest is rocky and precipitous, rising above the line of perpetual snow. The culminating point of the range is 14,100 feet above the sea.

SUFFOLK, a maritime and agricultural county, in the eastern district of England, is bounded on the N. by Norfolk, W. by Cambridgeshire, S. by Essex, and E. by the German Ocean. Its length in a direct line from east to west is 56 miles, its breadth from north to south 32. It has nearly 50 miles of sea-coast on the eastern side. The area is 1481 square miles. It contains 947,681 statute acres, and 499 parishes. It is in the sees of Norwich and Ely, and in the Norfolk circuit.

Suffolk presents a gently undulating and diversified surface, but there is not an eminence worthy of particular mention in the county, and, excepting the Fens in the Mildenhall district, is not low. The woods are of small extent, and are not generally of luxuriant quality. The streams are numerous, though by no means large. The principal rivers are the Orwell, Gipping, Deben, Yare, Alde, Blyth, and Lark. There are also the Waveney, Little Ouse, and Stour; but these are border rivers, the two former separating the county from Norfolk, and the latter dividing it from Essex. There are a great number of fine springs and rivulets intersecting almost every part of the county. The turnpike roads in every part of the county are excellent, and so are most of the cross-roads. The Eastern Counties, the Eastern Union, and the East Suffolk Railways, run the entire length of the county. In the summer season sea-bathing attracts a considerable number of visitors to the shore at Lowestoft, Southwold, Aldeburgh, and Felixstowe, where every accommodation for such visitors is provided. The soil is so exceedingly variable, that it is difficult to define the localities of each. The heavy land district constitutes what is known as central Suffolk. The eastern Sands, extending from the mouth of the Deben to Yarmouth, is very light, and much of the district, from Beyton to Mildenhall, and from Newmarket to Brandon, consists of a blowing sand on a light chalky clay. The Fen district occupies the extreme north-west corner of the county, and is of very small extent. The quantity of pasture-land is much reduced. Formerly Suffolk sent large quantities of butter to the London market, now both butter and cheese are imported to supply the demand and consumption in the county itself. The rotation and manner of cultivation in the *heavy* land district is—first year, fallow, tares, beet, or turnips; second year, barley; third year, half clover, half peas, or beans alternately; fourth year, wheat. There is much variation in the course of cropping among the small farmers, but on the best cultivated farms this may be taken as the general course. On the *light* land a different course of management is adopted, but it is generally farmed on the four-course system. Thorough draining is much practised in the county. Beet-root has in some measure superseded the growth of carrots. Sainfoin and trefoil are cultivated in the sand district between Thetford and Newmarket. Flax has attracted much attention, but has made but little progress. Lucerne is grown on a small scale, and chicory has also been introduced. A few hops are cultivated, but only in two or three places in the county.

Suffolk takes a high rank as an agricultural county, but of late years a much smaller proportion of its population than formerly has been dependent upon agriculture for their subsistence. At the census in 1851, the returns relating to occupations refer to *individuals*, whilst those for 1811, 1821, and 1831 refer to *families*. It is not easy, therefore, to exhibit the proportion which the agricultural, commercial, and miscellaneous bore to each other at each of the decennial periods; but a gradual increase in the number of persons employed in trades, manufactures, and handicraft, has been going on in this county during the last quarter of a century. In 1851 the returns relating to those employed in agriculture and connected with land were—land proprietors, 423; farmers, 5637; farm bailiffs, 581; farm-servants (indoor), 645; agricultural labourers (outdoor), 42,783.

The draught-horses peculiar to the county are known by the name of Suffolk punches. They are excellent workers, are in great demand, and sell at high prices. Suffolk cows are generally considered to fill the pail better than any other kind. On the light soils extensive breeding flocks of sheep are kept, generally Down ewes, a little cross with the Norfolk to increase their size. There are but few Leicester flocks, and fewer still of pure Norfolk.

The net rental of landed property in Suffolk is estimated at L.912,062. The property is much divided, and there are no estates so large as to create a decided political preponderance; and it is said that there is in Suffolk a larger number of proprietors occupying their own lands than in any other county. On the heavy lands, farms seldom exceed 300 acres in extent, and are generally much smaller. On the light lands they vary from 300 to 1500. There are but few large farms, though there are many large farmers, men holding several farms, but more than half the farms in Suffolk range between 50 and 300 acres.

The following peers derive their titles from places in this county:—Earls of Suffolk, Orford, Euston, and Stradbroke, Viscount Brome, and Barons Rendlesham and Worlingham. The Dukes of Norfolk, Grafton, and Hamilton and Brandon; the Marquises of Hertford and Bristol; Lords Thurlow, Calthorpe, Huntingfield, and Henniker, also have seats in the county.

There are but few manufactures in the county; for although the cloth trade, introduced by the Flemings, at one time flourished, and nearly every labourer's wife was engaged at her spinning-wheel, the occupation has now entirely died out. Agricultural implements are perhaps more extensively manufactured in this than in any other county in England. Stays are made on a large scale at Ipswich. Silk winding and straw-plaiting give employment to large numbers at Sudbury, Lavenham and Hadleigh. A few are employed in the manufacture of lace, and a smaller number in the preparation of flax. Along the coast there is a great number of fishermen, and at Lowestoft many vessels are equipped. The herring fishery is an important one to that district. The fish are dried in houses erected on purpose in the town. At an earlier period of the year the same persons are engaged in the mackerel fishing, and the fish are transmitted by rail to the London market.

The population of this county at the six decennial periods of enumeration was found to amount in 1801 to 214,404; in 1811 to 233,963; in 1821 to 271,541; in 1831 to 296,317; in 1841 to 315,073; and in 1851 to 337,215. At the census in 1851 the males numbered 166,308, and the females, 170,907.

The number of inhabited houses in 1851 was 69,282; the uninhabited were 3107; and those building, 449. The annual value of the real property of the county, as assessed for the purposes of the property-tax in the year 1813, was L.1,127,404; in 1851, it was L.1,834,252. The annual value of real property rated to the poor was, in 1850, L.1,366,648.

The towns of this county containing more than 2000 inhabitants, with their population in 1851, were the following:—Ipswich, 32,914; Bury St Edmunds, 13,900; Lowestoft, 6781; Sudbury, 6043; Woodbridge, 5161; Beccles,

Suffolk. 4398; Mildenhall, 4374; Bungay, 3841; Stowmarket, 3306; Hadleigh, 3716; Halesworth, 2662; Long Melford, 2587; Eye, 2587; Framlingham, 2450; Southwold, 2109; Gorleston, a suburb to Yarmouth in Norfolk, and, by the Reform Bill, a part of that borough, 3999.

On looking at returns as to the social condition of the people in Suffolk, some curious facts present themselves for notice. Only 40 per cent. of the population are attendant upon the services of the Church of England; but 86 per cent. of the marriages in the county are celebrated according to the rites of the Establishment. The births are 1 in 32 of the population, and 8 per cent. of the births are classed as illegitimate. The deaths are 1 in 51 of the population, the proportion in all England being 1 in 46, and in Norfolk 1 in 48. The criminal returns exhibit a great increase of crime during the century. In 1801 the criminals were 51 in each 100,000 of the population, and in 1821 they were 93, in 1841, 157; and in 1851 the proportion was 168. The population increased 56 per cent.; crime more than 300 per cent. in the half-century. Pauperism is the plague spot of the county. In 1851, of every 10,000 persons 153 were paupers; whilst in Great Britain only 65 in every 10,000 were so classed. One out of every 12 persons in this county is a pauper, and the average cost of relief during the five years ending 1852 was L.142,688 per annum. The educational returns of this agricultural district are almost as discouraging. In 1851 there were 143 parishes, nearly one-third of the entire number of parishes in the county, in which, if there was a school, it was only a dame's school; 90 of these were entirely without a school. In the hundreds of Hoxne and Resbridge only 8 per cent. of the males attended school; and in a large number of the schools throughout the county the average time of a child's attendance is less than 2 years. Out of 1219 indoor paupers in Suffolk 10 only could read and write well; nearly 80 per cent. of the felons are without education, and 46 per cent. of the men and 52 per cent. of the women who are married are unable to sign their names to the marriage registers. In 1851 there were 20 literary and mechanics' institutes, having 2689 males and 119 females as members. The libraries contained 33,296 volumes. The attendance upon religious worship at the same period was found to range from 58 per cent. in the Hundred of Resbridge to 27 per cent. in the Hundred of Mutford. There were 895 places of worship, with 239,403 sittings.

Amongst the antiquities of the county, the foremost place must be given to the Roman castle at Burgh, the walls of which are still standing. There are several churches in Suffolk, portions of which lay claim to Saxon antiquity, as the Tower of Flixton, near Bungay. Norman architecture is of very frequent occurrence in the churches of the county. Several of these also display magnificent wooden roofs which exhibit a combination of boldness, picturesque effect, and geometrical skill. Of ancient monastic buildings, in which Suffolk was once so prolific, the remains are but few. The gateways of Bury Abbey attest the grandeur of this wealthy establishment, and at Butley, Sibton, Herringfleet, Bungay, and Leiston are more or less picturesque remains of former monastic splendour. Of castellated architecture, Orford, with its polygonal keep 90 feet in height; Framlingham, a mere shell of a proud fortress; Bungay Castle, with its massive ruins, as well as those of Wingfield and Mettingham, recall the stern magnificence of feudal times. Suffolk is especially rich in examples of domestic architecture. Helmingham, Hengrave, Melford, Kentwell, Parham, Flixton, Wenham, and Roos Halls are fine monuments of the taste, splendour, and hospitality of our wealthy ancestors.

The civil government of the county is peculiar. There are four sessional divisions in the county, named after their respective chief towns, Beccles, Woodbridge, Ipswich, and Bury. Each of these divisions has from time out of mind been considered a county by itself. Beccles has its own sessions, levies its own rate, repairs its own bridges, and pays the whole of its own charges; and Bury, Ipswich, and Woodbridge divisions do the same. Three boroughs, Bury St Edmunds, Ipswich, and Sudbury, have separate commissions of the peace and courts of quarter sessions. There are county gaols at Ipswich and Bury St Edmunds, a county-house of correction at Beccles, and borough prisons at Ipswich and Sudbury. The county is divided into twenty-one hundreds, besides the liberty of the borough of Ipswich, and is also sub-divided into the Geldable portion and the liberties of St Etheldred, St Edmund, and Duke of Norfolk. The liberty of St Edmund formerly returned a grand jury at the assizes distinct from that returned for the rest of the county; that privilege was abolished in 1837, and the assizes have since that period been held in the spring at Bury St Edmunds, and in the summer at Ipswich.

Suffolk returned sixteen members to Parliament prior to the passing of the Reform Bill, but Aldborough and Dunwich were disfranchised by that Act, and Eye reduced to one member. Sudbury has since been deprived of its privilege, on the ground of corruption. The county is divided, for electoral purposes, into two divisions, the eastern and the western. Each division returns two members. The polling places for the eastern division of the county are—Ipswich, Needham, Woodbridge, Framlingham, Saxmundham, Halesworth, Beccles, and Lowestoft. For the western division the places for polling are—Bury St Edmunds, Lavenham, Stowmarket, Wickham Brook, Mildenhall, and Hadleigh. Two members are also returned for each of the boroughs of Ipswich and Bury St Edmunds.

Sugar. SUGAR. Referring to CHEMISTRY (vi., 515–17) for the composition and chemical relations of sugar, we propose in the present article to give a brief technological view of the subject. Sugar, in one or other of its varieties, is widely diffused, and imparts sweetness to the juices of many vegetables. The practice of sweetening food is older than the knowledge of sugar. The ancients used honey for the purpose; and when the sweet produce of the cane became known it was called *mel arundinaceum*. In the first century, Dioscorides refers to the canes of India and of Arabia Felix as producing honey, and applies to it the term σακχαρον, or sugar, which Pliny refers to as being used only in medicine. Sugar was not known in northern Europe, at least as an article of food, until the time of the crusades. The sugar-cane was introduced into Cyprus from Asia, and was noticed in A.D. 1148 as being extensively cultivated in that island. It was transplanted from Cyprus to Madeira, and thence, in 1506, to the West Indies. The sugar-cane is said to have been also cultivated on the coasts of Andalusia before the invasion of the Arabs, who seem to have introduced the method of boiling down the juice for the production of sugar. The refining of raw sugar is of later date, and is referred to Venice. The refining of sugar was commenced in England about 1544; but *loaves of sugar* are spoken of as being sold in Scotland so early as 1329. There was a refinery in Dresden in 1597. Sugar-candy is noticed in the *Alchemia* of *Libavius* in 1595, and this is probably the form in which sugar was known to the ancients. The general introduction of tea and coffee caused a great demand for sugar, before which, and so late as the end of the seventeenth century, syrup and honey were in use among the poorer classes of Germany. In 1747, Margraaf discovered cane-sugar in the roots of many plants, especially in beet-root; but no attempt was made to manufacture that variety of sugar on an extensive scale until the time of Napoleon, who, in attempting to ruin the colonial trade of Great Britain, excluded our merchant-ships from the conti-

nent, and, to supply the demand for sugar, offered premiums for its manufacture from beet-root. Much skill and ingenuity were exercised in the manufacture, which is still extensively carried on in countries where the richer juice of the cane is excluded from competition by heavy imposts.

The sugar-cane (*Saccharum officinarum*) is a perennial plant, belonging to the family of the grasses. It varies in height from 6 to 15 feet, and upwards, and in diameter from $1\frac{1}{2}$ to 2 inches. Its stalk is knotty, with a leaf and an inner joint at each knot. The roots are slender, and nearly cylindrical, about a foot in length, furnished with a few short fibres.[1] The joints of the stalk or cane may vary in number from 40 to 60, and in the Brazilian cane they are as many as 80. The Otaheite cane has fewer joints, and they are further apart. Every joint contains a bud, which encloses the germ of a new cane. "The joints of the cane," as Mr Porter remarks in his work on the sugar-cane, (1843), "may be considered as concentric circles, the centre of which is always occupied by a point, which, expanding into a circle itself, is replaced by a new point,—circles which, rising successively one upon the other, enlarge and arrive in a given time at their greatest diameter." The first joint requires 4 or 5 months for its complete growth, during which 15 or 20 joints spring from it in succession, the decay of the leaf indicating the maturity of each joint; and when the leaves of the first two or three joints have withered, there are 12 or 15 leaves at the top, arranged like a fan. The last joint is called the *arrow;* it is 4 or 5 feet in length, and is terminated by a panicle of sterile flowers. The period of flowering is usually delayed by cultivation, new joints being formed instead. The sugar-cane requires a moist, nutritive soil, and a tropical or sub-tropical climate. It is propagated by slips or pieces of the stem with buds on them, and it requires from 12 to 16 months to arrive at maturity. The leaves fall off before flowering, and the stem becomes of a straw-yellow colour. The plantation should be managed so that the canes may ripen in succession. The land, unless naturally rich, requires abundance of manure, but saline matter should be avoided, since common salt, chloride of potassium, and muriate of ammonia, form non-crystallisable compounds with the sugar. One equivalent of common salt, for example, = 60, will combine with two equivalents of sugar = 342, and thus cause a loss of sugar $6\frac{1}{4}$ times greater than the weight of the salt in the compound. Beet-root sugar factories situate near the sea-shore have experienced great losses from this cause, which also operates to some extent on the windward coast of Barbadoes. After the cane harvest, the roots strike again and produce a fresh crop, but in about six years they must be removed: this period, however, is subject to variation in different places. The canes should be cut in dry weather: they should have a smooth, brittle skin, considerable weight, greyish pith, and a sweet, glutinous juice. The developed buds which form the secondary stole of the plant that has been cut are named *rattoons*, and they are *first*, *second*, or *third*, &c., according to the age of the parent root. They diminish every year in thickness and length of joint, and are said to yield a richer juice and to produce finer sugar than the original plant. The canes should be cut close to the stole, for this gives vigour to the rattoons, and, moreover, the lowest joint contains the richest juice. The cane-top, with one or two joints of the cane, must be cut off and rejected, as the juice of those parts is watery. The canes are tied up in bundles and sent to the crushing-mill, the amount of work done by this regulating the quantity of canes to be cut; for if the cut canes are kept many hours, they will ferment and spoil. The cane-mill usually consists of three massive cast-iron rollers, about 24 inches in external diameter, with projecting rims to prevent the canes from spreading over the sides, arranged horizontally, two below and one above and between: they are worked by means of toothed wheels attached to the axles. The canes are passed down an inclined plane between the first lower and the top roller, and, being crushed between them, are guided by plates between the top roller and the second lower roller, where the crushing is completed. The juice passes into a channel below, and thence to a reservoir. The first pair of rollers crushes the cane, and the second pair expresses the juice, and turns the crushed cane down a trough out of the mill. The first lower roller is usually grooved. In order to obtain the largest proportion of juice, the rollers must be set very close together, and revolve slowly under steam-power. It is stated that when the power was wind, only from 50 to 56 per cent. of the juice was obtained; animal-power gave 58·5; water-power, 61·8; and steam, 70 per cent. In general, however, the average of steam is not superior to that of water. From 12 to 14 tons of good ripe cane produce about 1500 gallons of juice, which are required for making one hogshead of sugar. The crushed cane known as *cane-straw*, *begasse*, or *cane-trash*, is used as fuel in evaporating the juice; it contains at least 18 per cent. of cane-juice. The opinion has been repeatedly expressed that the cane-trash should be returned to the land as manure, and, if spread over the spaces between the cane-roots, it would also serve to mitigate the effects of severe drought. Coals can be sent to the colonies from Great Britain at a cheap rate to supply the demand for fuel.

The juice of the cane is a solution of sugar in water, with traces of albumen, of gum, and of a peculiar substance resembling gluten, or vegetable gelatine; also a minute proportion of cerosin, and of a green vegetable wax. The mineral ingredients resemble those of other plants and vegetable juices, and consist of the sulphates of lime and of potash, chlorides of potassium and of sodium, phosphate of lime, silica, &c. The juice has usually a yellowish colour, but is sometimes colourless, and greyish globules suspended in it render it turbid. It has an agreeable but rather insipid taste, and a peculiar balsamic odour. It contains from 17 to 20 per cent. of crystalline cane-sugar; but the planter does not obtain more than $7\frac{1}{2}$ per cent. There is a loss of sugar in the mode employed of expressing the juice from the cane; and, secondly, a loss arising from the chemical change due to exposure to the air, whereby the crystalline sugar becomes degraded into mucilaginous or non-crystalline sugar, commonly called *molasses*. Indeed, did space permit, it would be easy to show that the loss to the planter commences in an imperfect system of agriculture, the ground being worked by hand-hoeing instead of deep ploughing, and from a frequent absence of agricultural and manufacturing machinery of improved construction.

The exposure of the juice to the air of a tropical climate, even for half an hour, would cause fermentation to set in; lime is therefore immediately added for the purpose of neutralizing the acid, and rendering some of the soluble impurities insoluble. The old method of clarification, or defecation of the juice, is by heating it in iron pans or *teaches*, arranged together in a row, and heated by one common fire. The juice-reservoir below the crushing-mill supplies the largest pan, the fifth in the row, and farthest from the fire, with juice. The milk of lime, or *temper*, as it is called, is equal to about $\frac{1}{800}$th of the weight of the juice, but the proportion varies with the quality of the juice, and the effect of the heat, which should not exceed 140°, is to

[1] There are three species of cane recognised by the cultivator:—1. The *Creole* cane, with dark green leaves and a thin knotty stem; it is indigenous in India. 2. The *Batavian* or *Striped* cane; it has a dense foliage, and is covered with purple stripes. 3. The *Otaheite* cane, which is the most luxuriant and juicy, and is cultivated in the West Indies and South America.

coagulate the albuminous portions of the juice, which rise to the surface in the form of scum. This is removed by skimming, and the juice is passed through the other four teaches, and evaporated at increasing temperatures until the sugar will crystallize out on cooling. Scum collects on the surface of each teache, and a greal deal of it is nearly pure sugar decomposed by the heat; it is passed into the molasses cistern, and is used for making rum. The teaches diminish in size as the juice diminishes in volume, and it is ladled by hand from one teache to another, thereby leading to further deterioration by exposure to the atmosphere. The syrup is passed from the last, or *skipping teache*, to the coolers usually by means of shoots, and it is known when the *granulating* point has been attained by taking a portion of the syrup upon the thumb, and placing the forefinger upon it, separating them so as to draw out a thread, and if it extend to the length of about an half-inch, the sugar is judged to be sufficiently boiled. This trial by the *touch* is thought to have given the name of *teache* or *tayche* to the pans, the term being sometimes restricted to the last or hottest pan. The coolers are shallow, open vessels of wood, in which, in the course of twenty-four hours, the sugar *grains*, or forms into a soft mass of crystals, embedded in molasses. The temperature in the coolers is rendered equable by stirring up the mass from time to time with iron rods. The contents of the coolers are removed to hogsheads, or *potting-casks*, placed on an open framework in the curing-house. The bottom of each cask is bored with holes, an inch in diameter, each hole containing a plantain stalk, or a crushed cane, long enough to reach to the top of the cask. The soft sugar is placed in these casks, and the molasses gradually drain away through the spongy stalks into a cistern lined with lead, forming the molasses reservoir. It may take from two to six weeks before the sugar is sufficiently dry for shipment; and there is a further drainage of molasses in the hold of the vessel, promoted by the deliquescent salts absorbing the damp air, and entailing a further loss of sugar, said to amount on an average to 12 per cent.

Such is the old system of manufacturing sugar, which, we regret, is not yet altogether abandoned in our colonies. Under this system it has been calculated that from every 1000 parts sugar-cane, from 60 to 80 parts raw sugar, and from 25 to 30 of molasses, are obtained; while, according to chemical analysis, the yield should be from 180 to 200 parts of crystallized sugar. Mr Kerr states, that of the 1500 gallons of juice required for a hogshead of sugar, netting 15 cwt. in the English market, the planter does not get a return of more than 6 per cent. of moist Muscovado sugar, and that of very inferior quality.

In proceeding to notice the more important of the improvements which have been suggested, and in many cases adopted, for improving the manufacture of raw sugar, we may state that the objects had in view have been the protection of the juice from fermentation, and its concentration with as little agitation and exposure to the air, and at as low a temperature as possible. Dr Mitchell proposed to dip the canes into hot water as soon as they are cut, for the purpose of coagulating the albumen, and preventing it from passing into the juice, and also to destroy the vitality of the glutinous fermenting matter. M. Payen recommends sulphurous acid or bi-sulphite of lime to be used instead of milk of lime. The French have also invented a contrivance for raising the juice from the crushing-mills to the clarifying vessels with but little agitation, by means of an apparatus called a *monte-jus;* in which steam acting on the surface of the liquor forces it up a pipe into the clarifier. This vessel, too, instead of being a naked copper, exposed to the fire, is surrounded by a cast-iron jacket, and steam being admitted into the space thus formed, a moderate and regulated temperature can be commanded. The bottom of the pan is furnished with a plug, containing two or three holes, one for disposing of the clear liquor, and another, and larger one, for passing off the thick scum and sediment. The juice is clarified at a temperature of 176°; particles which rise to the surface are skimmed off, and milk of lime is added in quantities just sufficient to neutralize the acid, and this is regulated by the frequent use of litmus-paper. When the scum on the surface begins to crack, the steam is shut off, and the whole is left for fifteen or twenty minutes, during which time the lighter impurities will have risen to the surface, and the heavier ones will have subsided. A hole in the plug, 3 or 4 inches above the bottom, is thrown open, and the liquor, which should be pale and clear, allowed to flow out; the heavy matters and the scum are passed through the larger opening into a cistern, and then placed in bags, and the juice expressed. The clarified juice still contains matters in suspension, which are removed by passing through fine copper-wire sieves, or flannel-bag filters, from which the filtered liquor is passed through a bed of bone-black, by means of which vegetable colouring matter is more or less removed, together with any excess of lime, and also mineral salts, originally present in the juice. The filtered liquor is next concentrated in open pans, heated by means of steam-pipes to about 25° to 28° Beaumé. The further concentration of the juice is completed in the vacuum-pan, as in the refining of sugar. There is also another contrivance for preparing the juice for the vacuum-pan. A series of straight copper pipes, placed one above the other, with the ends fixed in cast-iron boxes, or united by curved end pieces, is placed so as to receive the waste steam of the vacuum-pan, and over this arrangement of pipes thus heated, the weak juice is made to fall in a multitude of drops; so that while condensing the steam within, the juice sends off a considerable portion of vapour, and falls in a more concentrated state into a vessel below, from which it can be pumped up into the vacuum-pan.

As the vacuum-pan is no longer restricted to the refining of sugar, it may be noticed in this place in connection with the manufacture of the raw product. It depends for its action on the principle that liquids boil at temperatures dependent on the pressures they have to sustain. Thus water, under a pressure of 30 inches barometer, boils, that is, becomes rapidly converted into steam at 212° F., whereas water *in vacuo* will boil at about 80°. The vacuum-pan was patented by Howard in 1812; it consists, in its improved modern form, of a copper pan with a cast-iron jacket, within which steam is admitted for heating the pan, while within the pan, and corresponding to its curvature, is a worm or coil of copper pipe, through which steam is passed for boiling the juice. The pan is covered by a copper dome, fitting to it air-tight. In order to preserve a vacuum, or at any rate a greatly reduced pressure within the pan, the steam, as fast as it is generated by the boiling of the juice, is pumped out into a condenser, and condensed by the injection of cold water, or by the trickling of weak juice over a system of condensing pipes, as above described. In order to withdraw and examine the juice during the boiling, without disturbing the vacuum, a cylinder passes from one side of the domed top down into the liquor, which cylinder contains a piston called a *proof-stick*, furnished with a notch or receptacle, which becomes filled with sugar on plunging it down the cylinder, and can be withdrawn to a sufficient extent to bring the sample to the outside. A thermometer passes through an air-tight collar for indicating the temperature, and there is a barometer or vacuum-gauge for showing the internal pressure. There is also a measuring vessel of about 35 gallons, for regulating the quantity of juice admitted into the pan. There is also an overflow vessel for catching any liquor that may boil over from the pan. There are also peep-glasses in the domed top, one opposite to the other, so that, on looking through one, sufficient light

Sugar. passes through the other to show how the boiling is going on within. The bottom of the pan is a gun-metal saucer, ground into a socket, and on lowering this by means of a lever, the sugar can be run out of the pan. In connection with the vacuum-pan is also an expansion vessel for reducing the pressure of the steam to the point required within the pan. The heat employed for evaporating the weak syrup is from 180° to 190°; when the syrup begins to granulate the temperature is lowered to 160°, and just before the evaporation is completed, the temperature is lowered to 145°, the lowest temperature at which proof-sugar will boil under a pressure of 3 inches below a perfect vacuum. When the attendant finds by drawing out a thread against the light that crystals are beginning to form, he lets in another measure full of syrup into the pan, and continues the operation until the whole charge has been admitted. The crystals first formed seem to act as nuclei to the next charge. A large pan, 8 feet in diameter, for example, will boil 80 tons of sugar in 24 hours; but in smaller pans the skip or panful of concentrated sugar may be made in from 1½ to 2½ hours from the commencement of the boiling. Fine grained sugar requires a larger measure of syrup at each charge than the coarse. The concentrated juice, or *proof-sugar*, as it is called, consists of innumerable small crystals floating in syrup, and it is passed out of the pan at 145°, not into a cooler, as in the old process with the teache, but into a *heater* or copper pan, with an iron steam-jacket, raised to 180°, the temperature best adapted to the forming and hardening of the crystals. During this time the sugar is stirred with wooden oars to prevent granulation; it is ladled or run out into buckets or scoops, and so poured into moulds or small inverted cones, which are perforated at the point, but at first the hole is stopped with paper, and so they are left until the following morning at a temperature of about 100°, when the holes are opened and the temperature maintained for 3 or 4 days, during which time the process of *liquoring* is performed, that is, a saturated solution of pure sugar is poured into the top or wide part of the moulds, and this filtering through the mass carries with it the rest, or much of the colouring matter. The moulds rest with their points in pots or jars, which receive the drainings. When properly drained the sugar is turned out of the moulds in the form of loaves, which being trimmed to shapes, are dried in a hot room, and are then ready for the market. In this way, sugar, equal to refined, can be produced from the canes at one operation; indeed the work of the refiner in England is chiefly to remove the defects occasioned by the imperfection of the planter's apparatus: in fact, raw sugar, as generally supplied to the public, is a very impure product in consequence of defects in the manufacture which tend to lessen its sweetness, impart a coarse flavour, injure its colour, and render its solution milky or muddy. But in addition to chemical impurities, there are mechanical ones, such as earths, vegetable matters, and insects, the last of which may produce a well-known disease in the hands of the grocer.

The improved methods of manufacture which we have pointed out have been to a certain extent adopted, or are being gradually introduced. In Java, Cuba, and other places, where improved machinery has been introduced, an increase of from 30 to 40 per cent. on the quantity of sugar produced has been effected, while the market value has risen from 5s. to 10s. per cwt.

The various qualities of raw sugar imported into this country will be noticed presently; but it will be convenient first to review briefly the operations of the refiner. The cases, bags, and hogsheads of sugar are made to discharge their contents on the floor, and the casks are inverted over a steam-jet pipe, which quickly removes all the sugar that adheres to the staves. The sugar is passed through a sieve to break up the lumps, and water is added, and the solution quickly effected by the assistance of steam, which is made to blow up through a perforated pipe placed at the bottom of the pan; whence the melting pans are sometimes called *blow-up cisterns*. Even at this early stage it was recommended by the late Mr Finzel to substitute a vacuum-pan for the blow-up cistern, by which means the solution is said to be effected with greater rapidity, while exposure to air and high temperature are avoided. It has been found, however, in practice, that the impure sugars have so strong a tendency to froth up, that the vacuum-pan is constantly boiling over, so that the plan has been abandoned. While the sugar is being dissolved in the blow-up cistern, a small quantity of blood and some lime-water are added, to clarify the solution and neutralize the acid. The solution is kept in motion by a mechanical stirrer, or by two or three men with oars. The quantity of blood is not more than about ½ per cent., and its action is assisted by from 3 to 6 per cent. of powdered animal charcoal. The temperature is kept for a short time below 168°, at which the albumen of the blood coagulates, after which steam is fully admitted and the solution made to boil. The albumen being dispersed through the solution and then coagulating, forms a net which entangles the mechanical impurities, and rises with the charcoal in the form of a thick compact scum, which is removed. The liquor has been partly decolorised by the action of the charcoal, but it still contains impurities in suspension coated with albumen. The liquor is therefore passed through bag filters or long bags, from which it passes through charcoal beds, which, in the course of 15 or 20 hours, decolorise a quantity of syrup containing four times as much sugar as there is charcoal in the filters. The liquor is now passed into the vacuum-pan, and is concentrated to the density of 42° or 43° B. at a temperature varying from 230° to 240°. In this condition the sugar is held in solution by the high temperature, and when allowed to cool, rapid crystallization takes place, producing that fine sparkling grain which characterizes loaf-sugar. It is necessary, however, to transfer the liquor to the moulds at a certain temperature, just as the crystals have begun to form, and this is regulated in the vessel below the vacuum-pan into which the liquor is received, and from which a number of men fill their scoops and charge the moulds. The saccharine mass falls into the moulds with a sound as of wet sand, showing the formation of crystals in the mass. The moulds are of iron, coated with varnish or glaze, or painted. Galvanized iron moulds have been introduced, but they do not give to the surface of the loaf so good a texture as the ordinary iron moulds. The holes in the points of the moulds are stopped up during the filling, which is performed on the lowest floor, and they are raised by an endless chain or band, called a *mould-carrier*, to a floor above. The sugar is frequently stirred to prevent it from crystallizing at the sides, and to promote the formation of a compact net-work of small crystals enclosing the mother liquor or saturated solution, which is impure and coloured, while the crystals are pure and colourless. The liquid portion is somewhat viscid, and drains off with difficulty, although assisted by a temperature of 75° and upwards. When the plugs are removed, the draining is allowed to go on for 24 hours. The first syrup that drains off into pots or troughs placed to receive it is called *green* syrup; the after syrups are called *seconds* and *drips*, and are more valuable, because stronger and of better colour. The syrups are passed through funnels and pipes into their proper cistern, the different syrups being kept apart for re-boiling. After the sugar has set, the face is cut out with a trowel, and the scrapings, with other similar sugar material, is formed with water into a *magma* or pasty mass, which is poured into the several moulds for the purpose of removing the colouring matter. After this, nearly saturated solutions of refined or other white or fine sugars are applied cold to the surfaces in small quantities by means of a ladle

or a nose-pipe, the last in succession being the finest. By this means the coloured syrup is completely removed by the passing through of the pale or colourless syrups, and a coating of pure sugar is given to the grains, so that after having passed through the stove the sugar has lost its hygrometric quality, and remains permanent in the air.

The process of *claying*, as it is called, has the same object as the above, and may be used instead of, or in conjunction with it. White pottery clay, washed, to separate soluble matters, is made into a thin paste, and placed on the sugar in the mould, in a cavity formed by loosening and scooping out the sugar. It is also usual first to remove the sugar from the mould, and take away the solid crust formed at the point. The action of claying is as follows:—The water which separates drives the molasses before it, and becoming itself a saturated solution of sugar, sinks through the loaf, expels the mother liquor, and thus gets rid of the colouring matter. The syrup which drains off is termed *clayed syrup*. When the sugar is removed from the moulds, the point is usually knocked off, and a new top afterwards produced, by turning between crooked knives, and then the loaves are dried in a hot room at 77°, which is gradually raised to 122°.

The above methods of cleaning the sugar are tedious, and various modes of quickening the process have been tried; such as the action of compressed air on the surface of the mass; the production of a partial vacuum below the moulds (known as the *pneumatic* process); and thirdly, the *centrifugal* process; this has been tried in two ways. 1. The moulds, with their contents, were set in a circular machine, and whirled round with great velocity. This dangerous plan, however, has not come into use, at least not in Great Britain. 2. The sugar is run in a pasty state into the wire-basket, or perforated plate vessel of a *hydro-extractor*, which, revolving at the rate of several hundred turns per minute, during a period of from 3 to 15 minutes, according to the quality of the charge, a dry granular sugar is thus produced fit for the market. When the plan was first introduced by Mr Finzel, the product consisted of large beautiful crystals of pure sugar, which were for a time in favour; but the very perfection of the crystalline structure, rendering this sugar less soluble in the same time than an equal weight of a coarser raw sugar, it was declared not to sweeten so well, and it did not maintain the position it deserved. The plan, however, has since been modified: the apparatus has been simplified, and the granular syrups being put into the perforated cylinder, the latter is made to revolve from 1200 to 1500 times a minute during a space of five minutes, the result is a clean, granular, sparkling, light-coloured moist sugar, for which there is now a great demand in London. The syrups whirled out of the extractor during the process are boiled down with other syrups, and again passed through the machine. The centrifugal machine has been introduced into the colonies with advantage to the planter, and the marked improvement of his product. We may also mention, that the superior variety of treacle known as *golden syrup* is obtained by passing the treacle once through a charcoal filter.

Refined sugar, of the first quality, is prepared in small moulds, and the various syrups which drain off from it during the cleansing produce several kinds of what are called *bastard sugars*. Some of these syrups produce sugar too soft for loaf, but furnish a superior quality of moist sugar. Others are run into large bastard moulds, and are crystallized at a higher temperature in proportion as they are impure. A small first quality mould will contain about 30 lb. weight of wet granulated sugar, from which about 10 lb. of green syrup will drain off, and if the remaining 20 lb. be dried without claying, the weight will be 17 lb., but if clayed only 11 lb.; but the sugar is of the first quality. A bastard mould will contain 60 lb. of granulated sugar of the second quality, from which 25 lb. of molasses will drain off, leaving 35 lb. of unclayed moist sugar, or 32 lb. when dry; but if this be clayed and dried it will produce 17 lb. of second quality loaf-sugar. The time occupied in refining varies from 8 to 10 days, but for the inferior qualities longer. What is called *stamped* sugar is prepared from the inferior qualities, by grating the moist soft lump, passing the flour through a sieve, and, while moist, stamping it in layers in a first quality mould, from which it is removed and dried.

The large crystals of sugar known as *sugar-candy* are prepared chiefly in Holland and Belgium, from syrup boiled over an open fire, and set aside to crystallize in a vessel in which strings are stretched, to serve as nuclei to the crystals. In the course of six or eight days the crystallization is complete, and the vessel, which is contracted towards the bottom, is inverted, when, after breaking up the surface, the syrup drains off, and the crystals are removed and dried. The usual crystalline form is a six-sided prism, commonly flattened, and terminated irregularly. A solution of sugar, saturated at 230°, forms, in cooling, a granular mass, or *tablet;* but when rapidly boiled until it acquires a tendency to a vitreous fracture on cooling, or when sugar is fused at about 280°, or from that to 320°, so that a portion *feathers* or concretes on being thrown upon a cold surface, it may be poured out upon a marble slab, and will cool into an amorphous mass. Such is *barley-sugar*, so called from the sugar having been formerly concentrated by rapidly boiling in barley-water or sweet wort. It is usually sold in sticks, to which a spiral twist has been given while hot. This vitreous transparent substance deteriorates by keeping. It becomes opaque first on the surface, and then throughout the mass, passing in fact into the crystalline condition; heat is given out during the change. Confectioners add a little vinegar or tartaric acid to the sugar, which retards, if it does not altogether prevent, the opacity. The show-sticks resembling barley-sugar in grocers' windows are made of coloured glass.

The sugar-refiner receives most of the sugars of commerce into his establishment, and it will be well to enumerate the principal varieties of them here. West Indian and other American raw sugars are known as *Muscovado*, from the Spanish, or rather Portuguese word *mascabado*, "more advanced." These are made marketable by being crystallized and cleared of molasses, without any attempt to dry or decolorise them. They form the favourite *scale* or grocery sugars of this country, the muscovado of Jamaica being preferred. There is, however, an important exception in the case of Cuba, three-fourths of the sugar from that island being clayed. Clayed sugar is not so large or well defined in its crystals as muscovado. The removal of the coating of syrup from the surface of its crystals gives it a grey and less pleasing shade or complexion than muscovado, which, when well made, is bright yellow or straw-coloured. The clayed sugars, therefore, are not used for grocery sale. What is called *white clayed* is that portion which forms the upper part of the mould in the process of claying; it is whiter or further removed from brown than ordinary clayed. Clayed sugars are commonly stronger, that is, they yield a larger percentage of refined sugar and less of the lower products than muscovado. The sugars of St Croix are much admired. The sugars of Porto-Rico and Barbadoes are esteemed; but the softness and quantity of *foot*, as the wet side of the contents of the cask is called, in the case of Barbadoes sugar, is an objection. The sugars of Brazil are usually clayed, and are sold as *white clayed* and *brown clayed*, the latter being nearer the apex of the mould. The Mauritius produces two-thirds as much sugar as all our West Indian colonies together. The sugar is subjected to a process analogous to claying; that is, it is washed with a surface application of concentrated cane-

Sugar.

juice, which percolates through the mass as the water does in claying. Such sugar is spoken of as *claircé;* it is much esteemed by the refiners of France and of the United Kingdom. There is an inferior class of sugars (analogous to refinery bastards), known as *syrup sugars*, prepared from the molasses of the foregoing varieties, and from that obtained from lower kinds. The sugars of the British East Indies are made by various processes, and are of various qualities, as indicated by the names *Khaur*, *Goor*, *Jagery*, the two former belonging to Bengal, the last to Madras. Some sugars made by European refiners in Hindostan are named after the factories where they are worked, such as *Cossipore*, *Ballykhal*, &c. The sugars of Java are mostly clayed. They are well adapted for refining, and are chiefly used in Holland. The Philippine Islands produce *Manilla* sugar; it is a strong brown raw material, adapted for refining. Much of it is unclayed, and under the names of *Taal*, *Zebu*, &c., finds its way to the Australian and British markets. It is converted into yellow crushed sugar. In addition to these *tropical* sugars there are occasional importations of brown sugar in cakes or loaves (*Rapaduros*). Such sugars are made in small establishments, and are moulded often without parting with the molasses. Attempts have also been made to introduce cane-juice in a concentrated or inspissated state for the use of the refiners, but without much success. The *Melado* of Cuba is of this kind. The sugars imported into the British markets are distinguished as *British colonial*, *foreign*, and *beet*, the first being the produce of our own colonies, the last of the continent of Europe. *Maple sugar* is never imported except for presents. *Date sugar* is largely used by the refiners. *Beet raw sugar* is imported from France by the refiner, but requires to be used with caution on account of its peculiar flavour.

The packages in which sugar is made up are as varied as the sources of supply. West India muscovados are sent over in *hogsheads* (hhds.), *tierces*, (trs.), and *barrels* (brls.) The average net weights of the hogsheads are 10 and 18 cwts. respectively, those of Porto-Rico being the smallest, those of Jamaica the largest; of the tierces, 7 and 10 cwts., and of the barrels, 2 cwts. The clayed sugar of Cuba, called *Havannah* sugar, from the name of the principal port of shipment, is packed in boxes of about 4 cwt. It is the produce chiefly of the north side of the island, the southern side furnishing more muscovado or hogshead sugar. Much of the Brazil crop is packed in cases or chests of from 12 to 18 cwt.; but the more convenient and economical form of *bags* is superseding the unwieldy packages; the bag weighs about 160 lb. Mauritius sugar is shipped in *mats*, or bags covered with strong reed or cane matting, of about the same weight as the Brazil bags. East India sugar is supplied in bags of rather less than 2 cwt., that of Manilla in mats of from 50 to 150 lb., and that of Java in *baskets* or *kanasters* of from 5 to 6 cwt. The tares allowed on these several packages by the customs and by merchants vary in different places, the merchants' or market tare differing at different ports of the same country.

In the year 1843 the consumption of sugar in the United Kingdom was 202,400 tons; in the year 1859 it was 457,500 tons. In the year 1858 the quantities of unrefined sugar imported into the United Kingdom amounted to 9,010,813 cwts., of the computed real value of L.12,322,405. Of this quantity there were entered for home consumption 8,746,934 cwt. In the same year were also imported of refined sugar and sugar-candy 386,839 cwts., of cane-juice 56,418 cwts., and molasses 775,657 cwts., of which quantities there were entered for home consumption respectively, 257,339 cwts., 57,361 cwts., and 819,226 cwts., the last number including 17,553 cwt. delivered duty free for use in distilleries. The import of the refined sugar was of the computed real value of L.753,681, and of the molasses L.391,787. Raw sugar is entered as of first quality, equal to white clayed; second quality, not equal to white but equal to brown clayed; and third quality, not equal to brown clayed. Of the whole quantity of unrefined sugar imported into the United Kingdom in 1858, rather more than one-third, or 3,628,912 cwts., were from foreign ports, the remainder from British possessions. Of refined sugar and sugar-candy in the same year, 204 cwt. were from British possessions, and 386,635 cwt. of foreign, 326 cwt. of British, and 255,914 cwt. of foreign respectively. The duty on the unrefined sugar entered for home consumption amounted to L.5,848,170. Sugar, whether the produce of British or foreign possessions, being now subject to the same rate of duty, the custom-house entries have ceased to distinguish them, except as the port of shipment serves to indicate their origin. The average price for the year was 29s. 7d. per cwt.

On the continent of Europe the beet-root (*Beta vulgaris*) is cultivated on account of its saccharine juice being available for the manufacture of sugar. There are many varieties of this plant, such as the *large field beet*, the *disette* of the French, and the *mangel-wurzel* of the Germans. In this variety the flesh, skin, and leaf-stalk are white, the bulb is nearly cylindrical, protrudes much from the ground, and weighs 25 lb. and upwards. There is a sub-variety of a reddish colour, known as *long red mangels;* another variety of beet is represented by the *White Silesian;* it is somewhat pear-shaped, with a white flesh and skin, and occasionally rose-red rings in the flesh. Its largest roots do not exceed 5 lb. It abounds in sugar, and the juice is more free from salts and other injurious ingredients, so that it is a favourite with the sugar manufacturers. The three sub-varieties of the White Silesian are distinguished by the colour of the ring presented by a cross-section of the crown close to the bulb. The first is the *collet rose*, with a rose-red ring; the second the *collet vert*, with a green ring; the third the *collet jaune*, with a yellow ring. There is a third group of beet-root known as the *globular*, of which the *yellow globe mangel-wurzel*, or *Castelnaudary beet* is the type. It is pear-shaped, approaching to globular, with the skin flesh-yellow, or passing on into orange, yellowish-green leaf-stalks, and a soft and juicy flesh. It grows to a much larger size than the Silesian, and four sub-varieties of it are recognised. There is a softer variety than the Silesian, known as the *Siberian beet;* it is of a flattened pear-shaped form, with a white or occasionally rose-red flesh; the bulb grows almost entirely out of the soil, which is a disadvantage, since the part exposed to the action of the sun contains less sugar than the covered portion. All the varieties of beet tend to change their colour, and to become red in the skin and slightly rosy in the flesh; they do not, apparently, differ in chemical composition, although some are better adapted to the manufacture of sugar than others. The collet rose is said to contain the richest and purest juice and is most prized, but the *Quedlinburg beet* is preferred in North Germany; it is thought to keep better than the Silesian, and its juice to be less acted on by the air. The sugar of the beet is identical with that of the cane; it gradually increases in quantity until the beet is ripe, and by good cultivation, the percentage of sugar may nearly equal that of the sugar-cane. When the flower-stalk begins to form, the percentage of sugar declines; and when the seed is mature, it is almost nothing. Good beet contains, on an average, 10 per cent. of sugar, 3 of pectin, soluble salts, &c., and 83 per cent. of water, thus making 96 of juice, the remaining 4 parts consisting of albumen, woody fibre, and insoluble salts. The juice ferments like that of the sugar-cane, but mannite is produced at the expense of the sugar, and a kind of mucus is formed, which is precipitated by alcohol, and resembles gum-arabic. Beet will grow almost anywhere in the temperate zone, and upon all kinds

of soil, but a light rich loam inclining to clay rather than sand is best. Care should be taken in the application of manure, especially of the nitrogenous kind, lest the juice be rendered impure, and the proportion of fermenting azotised matter be increased. The beet-roots may be kept for some months in what are called *silos*, or shallow ditches dug in the sandy soil, protected from the air by a thatch, and built into trunks of wood in the mass, to serve as ventilating apertures. But there is danger of the sugar passing into the non-crystalline variety. The leaf-stalks and root are removed as soon as the plant is gathered; the former penetrate somewhat deeply into the bulb, and form the *heart;* this contains very little sugar, but a large proportion of salts, especially nitrates.

When the roots are to be used in the manufacture of sugar, the bruised, decayed, and mouldy parts should be cut away, or the juice may be injured. The bulbs are washed in a large revolving drum, formed of laths or bars of wood partly immersed in water; this gets rid of sand and earth. The axis of the drum is somewhat inclined; the bulbs are fed in at the upper end and pass slowly down to the lower, where they are raised by a scoop and thrown upon a lattice frame. They then pass through a rasping or grating machine, which tears open the cells containing the saccharine juice, and reduces the bulbs to pulp. This machine consists of a drum, the surface of which is thickly studded with teeth, against which the bulbs are pressed, while the drum rotates, and a stream of water plays against them, to prevent them from being clogged. The drum makes 700 or 800 revolutions per minute, and reduces from 300 to 350 cwt. of bulbs to pulp every day while it is in action. The pulp passes into a cistern below the rasp, and is immediately placed in bags of woollen cloth or hemp, and is pressed by means of a hydraulic press. The bags are separated from each other by means of metal plates, or hurdles of plaited willow twigs. After the pressing, from 15 to 20 per cent. of juice remains in the pulp. To recover a portion of this the bags are dipped in water containing 1000th part of tannin in solution, to check fermentation, when the bags swell up to their former bulk, and are again pressed. The juice is collected into a reservoir. The table at which the bags are filled is furnished with a gutter leading to the juice-reservoir, and in some cases the first pressure is made at this table by means of a small hand-press, which expresses 30 to 40 per cent. of the juice. The waste pulp or *husk* still contains a small proportion of sugar, and is used as food for cattle, mixed with other kinds of fodder. There is also a loss of sugar during the rasping and pressing, in consequence of exposure to the air, and some of the finer particles of the pulp find their way into the juice. Hence an attempt has been made to obtain the juice by maceration, such as cutting the bulbs into thin slices, and digesting them repeatedly in warm water; but the objection is to the great dilution of the juice by this means. Attempts have also been made to dry the beet-root as soon as it is harvested, so as to get rid of 83 per cent. of water; but the expense of fuel is an objection, although the method of manufacturing sugar from *cossettes*, as the dried fragments are called, is occasionally adopted; but here, again, in proceeding to the manufacture, water, or lime and water, must be added.

As soon as the beet-root juice is obtained, it is raised to the temperature of 140°, and the defecation is conducted by means of hydrate of lime. In order to clear the liquor, an excess of lime is used, and this is got rid of by means of ammonia alum, whereby sulphate of lime is formed, and, the alumina set free, assists the clarification. Pectic acid may also be employed to get rid of the lime, but there is an objection to sulphuric acid which was formerly used, for this converts some of the crystallizable sugar into glucose. The liquor is filtered through charcoal-beds, evaporated at a steam-heat in an open vessel to 25° B., filtered again, and then passed into the vacuum-pan. In evaporating the syrup, various forms of apparatus are in use, some of which take the place of the vacuum-pan, of which kind we may mention the evaporating cone of Lembeck, consisting of a double conical envelope about 16 feet high, heated by steam of the pressure of four or five atmospheres, while the syrup is distributed over the interior by means of a six- or eight-way-funnel, and in descending is divided and distributed by means of hollow conical segments, toothed at the lower edge. The exterior surface of the cone also receives a supply of the syrup which is to be evaporated, and as the syrup descends it increases in strength, and passes by small channels into a trough leading to a cistern. By means of a ball-cock arrangement the syrup is made to flow quicker or slower, according to the rate of evaporation.

The workmen have several kinds of tests for ascertaining the degree of concentration of the syrup. The *preuve au filet*, or *string-test* already referred to in the manufacture of raw sugar, consists in taking a drop of syrup between the finger and thumb, and if, on suddenly separating them, it draw out into a thread, the syrup is judged to be sufficiently concentrated; if the thread break and curl up into a little hook, the evaporation is said to have been carried to the *preuve au crochet*, of which there are two kinds, the weak and the strong. In making sugar-candy there is the *preuve au soufflé*, or bubble-test, in which a man dips a skimmer into the syrup, and removing it, holds it upright, and blows forcibly through the holes so as to form bubbles of syrup on the other side: if a number of bubbles are blown away, the proof is said to be *soufflé fort;* if only a few, *soufflé leger*. In making barley-sugar, &c., the proofs are *le petit cassé*, *le grand cassé*, and *le cassé sur le doigt*. In the first, the moist finger is dipped into the syrup, next into cold water; the sugar is then rolled up into a ball, and this, on being thrown to the ground, splits and loses its shape. In the second proof, the ball is so brittle as to fly to pieces by this treatment, and in the third it solidifies and becomes brittle on the finger. According to M. Payen, the foregoing tests depend upon the following temperatures and percentages of sugar:—

Tests.	Temperature.	100 parts contain	
	Fahr.	Sugar.	Water.
Filet	228·2°	85	15
Crochet leger	230·9	87	13
„ fort	233·6	88	12
Soufflé leger	240 8	90	10
„ fort	249·8	92	8
Cassé petit	251·6	92·67	7·33
„ grand	263·3	95·75	4·25
„ sur le doigt	270·5	96·55	3·45

There are certain points to be attended to in the defecation and clarification of the syrup, or the evaporation will not be successful. If there has been a deficiency of lime, the syrup will froth and foam in the boiling, to remedy which a lump of butter is thrown into the syrup, which spreads over the surface and lubricates the bubbles. If there has been an excess of lime the syrup will not boil, especially if much oxalate of potash be present in the beet. When the syrup is sufficiently concentrated, it is drawn off into coolers or heaters, as the case may be, then passed into moulds, where its treatment resembles that of cane-sugar.

We have referred to an excess of lime being injurious, and it is so chiefly in the mode of getting rid of it. Sugar unites with lime without changing its properties, and may be recovered with little or no loss. This fact has led to several plans for economising the manufacture of beet-root sugar; an excess of lime is employed for the purpose of converting the whole of the sugar into saccharate of lime; and then, after defecation and evaporation, the sugar is re-

Sugar.

covered by saturating the lime with carbonic acid, obtained by the combustion of coke and charcoal. The advantages are, great saving in animal charcoal, and the protection of the juice from deteriorating influences.

The secondary products of the manufacture consist of the pulp, as already noticed, while the molasses contain the non-crystalline sugar, various salts, organic matters, gum or mucus, which imparts a nauseous taste; it is occasionally mixed with the refuse pulp, and is given to cattle, or is used in the production of alcohol. The scum, the bone-black, &c., are used as manure.

Although, as already stated, Napoleon I. endeavoured to encourage the manufacture of beet-root sugar in France, it declined after his fall; but in 1825 it revived again. In 1827–8 France produced 4000 tons of beet-sugar; in 1837–8, the production had increased to 39,000 tons; and in 1857–8 to 150,000 tons. In 1858–9 it was 130,000 tons. The French duties, as well as those in Belgium, are charged on the density of the juice as measured by the areometer.

In Germany the sugar-beet manufacture dates from about 1835. In 1858–9 the Zollverein worked up 36,668,557 cwt. of roots. There were 250 refineries in the Zollverein in 1859, of which number 221 were in Prussia. Up to 1853 the customs calculated 20 cwt. of roots as being equal to 1 cwt. of raw sugar. Since that date 15 cwt., and now even 12½ cwt. of roots are considered equal to 1 cwt. of sugar. The present duty is about 3 thalers 22 silbergroschen per cwt., and that from cane as used in the inland refineries 5 thalers. In the Austrian empire the quantity of beet-root worked up in 1859 was 16,042,248 cwt. Here also the system of protection is adopted in favour of beet-sugar.

In Belgium the quantity of sugar produced in 1859 was 18,000 tons. Here, too, there is a protective duty. It is stated that in Russia from 30,000 to 40,000 tons are produced annually.

Another source of sugar is the maple (*Acer saccharinum*), the sweet juice of which supplies the natives of the United States and Canada with a considerable proportion of their sugar. The juice is collected in February and March, when the sap is most abundant, for which purpose two holes are bored on the south side of the tree, 4 or 5 inches apart, and 18 or 20 inches from the ground. They are made to slope upwards, and not to penetrate more than half-an-inch into the white bark or splint of the stem. Wooden pipes are put into the holes thus formed, and the juice is allowed to flow during about six weeks into wooden troughs, from which it is removed in cans to reservoirs which supply the boiling pans, which are of the capacity of from 13 to 15 gallons. The juice must be removed from the troughs every two or three days, or it will ferment. The boilers are heated over a brisk fire; the scum is removed as it forms, and fresh juice is added to supply the loss from evaporation. The syrup is strained through a woollen cloth, boiled rapidly down in a second pan, cooled, and poured into moulds to crystallize. After the syrup has drained off, the resulting sugar is dry in the grain, of pure taste, and about equal to raw colonial sugar. There is a pleasant maple flavour belonging to this sugar; it finds a ready sale in the United States in the form of small, well-proportioned, square-sided cakes. In good seasons a tree will yield from 3 to 9½ lb. of sugar, and we have seen it stated that one sugar orchard has yielded on an average as much as 6 lb. per tree for 80 years. According to a recent calculation, as much as 27,000 tons of maple sugar are produced in the United States in one year.

Attempts have been made to manufacture sugar from the stems of Indian corn, from the common gourd, and from various kinds of palm. From the last-named source, a juice charged with cane-sugar is known in India as *toddy*, when fermented and distilled *arrack*; but by the evaporation of the toddy, the sugar known as *jagery* is obtained. The ryots or peasants of India cultivate the sugar-cane, express the juice, boil it down to a thick syrup, which, under the name of *goor*, is sold to the goldars, who produce the solid product. Other sources of sugar have been proposed, such as chesnuts, the fruit of the *Cactus Opuntia*, and a species of wild daffodil, *Asphodelus*.

The Chinese and African sugar-canes, known as the *sorgho* and *imphee* (*Holcus saccharatus*), are the names of gramineous sugar-bearing plants or millets: they were introduced to European notice in 1786 by Professor Pietro Arduino, of Florence, who attempted to introduce the imphee from Caffreland into Italy, but did not succeed. In 1851 the Count de Montigny, the French consul at Shanghai, sent home some seeds of the *Holcus saccharatus*; and about the same time Mr Leonard Wray called attention to the same plant as cultivated by the Zooloo Caffres, not for the purpose of manufacturing sugar therefrom, but for chewing and sucking the stalks. He discovered no less than sixteen kinds of imphee of various degrees of saccharine richness. The plant, however, has been cultivated as a source of sugar in China and Japan from time immemorial, and flourishes most on light sandy soils, and calcareous soils, but particularly on alluvial deposits. It has a tall straight stalk, 16 or 18 feet high, with knots or nodes at intervals, from which spring alternately long spreading, tapering, and drooping leaves. The outer coating of the stalk is smooth and siliceous, like the stalks of maize, and becomes harder as the plant approaches maturity. The seed is formed on the tuft at the top. The soft green pulp undergoes a change of colour as the plant ripens, becoming violet, then brown, and lastly purple, almost black. In this state the maximum of sugar is obtained. The *bagasse* or crushed stalks should, as in the case of the ordinary sugar-cane, be returned to the soil as manure. The sorgho has been introduced into the United States of America (*Sorgho and Imphee, the Chinese and African sugar-canes*, by Henry S. Olcott, New York, 1857). Various accounts have been given of its productiveness. A sample grown near Washington yielded nearly 14 per cent. of dry saccharine matter. Mr Wray's plants yielded 16 per cent.; some results are as low as 10, and others as high as 23 per cent. It is stated that an English acre of imphee will, if the circumstances be favourable, yield 2 tons and upwards of dry sugar; but Mr Wray does not estimate the average crop at more than 1½ tons.

The canes are cut as close to the ground as possible, the leaves are stripped off and the tuft removed, and they are carted to the mill as fast as they can be ground. After the crushing, the juice is immediately transferred to the boiler, and heated to about 180° Fahr., an infusion of nut-galls being added. The syrup is then raised to the boiling point, when the fire is suddenly checked, to allow the scum to rise to the surface and be skimmed off, when the heat is again urged until it granulates on cooling. The after-treatment of the sugar has no novelty requiring notice.

The sorgho and the imphee have been introduced into the West Indies, but they are not equal to the canes previously cultivated there. In the United States of America, however, where frosts are destructive to the ordinary sugar-cane, the new plants appear likely to be valuable. In 1857, according to Mr Olcott, 50,000 acres were under cultivation; but unfortunately this gives no information respecting the use of the imphee as a sugar-bearing plant, since much of the seed was sown for the sake of the green crops.

In this brief notice of a vast subject, our attention has been chiefly occupied with technological details. The subject may be profitably viewed from other points of view, such as the political, the commercial, the botanical, the chemical, and even the physiological. For informa-

tion under these heads the reader is referred to other parts of this work, and also to the following books and memoirs selected from the literature of the subject. Porter *On the Sugar-Cane*, 2d ed., 1843; Wray's *Practical Sugar Planter*, 1848; Evans's *Sugar Planter's Manual*, 1847; Kerr, *Cultivation of the Sugar-Cane*, &c., 1851; Knapp's *Technology*, English translation, vol. iii.; Scoffern, *Manufacture of Sugar in the Colonies*, 1849; Leon, *Art of Manufacturing and Refining Sugar*, 1850. There are also articles of importance in M'Culloch's *Commercial Dictionary;* Ure's *Dictionary of Arts*, &c.; Tomlinson's *Cyclopædia of Useful Arts*, &c. The manufacture of beet-root sugar is given at considerable length in Dumas's *Traite de Chimie appliquée aux Arts*, tome vi.; Payen's *Chimie Industrielle*, 1851; Dureau *De la Fabrication du Sucre de Betterave*, 1858. We have also to acknowledge the considerable assistance we have received in this article from manuscript information placed at our disposal by an eminent firm in Liverpool. Also to the Messrs Fairrie, the well-known sugar-refiners of Whitechapel, London, who allowed us to inspect their works, and furnished some interesting particulars for the purposes of this article. (C. T.)

SUHARUNPORE, a town of British India, capital of a district of the same name, in the N.W. provinces, 1007 miles N.W. of Calcutta, on the small river Dumoulao, about a mile from the Doab Canal. It stands in an open, level, and fertile region; and is surrounded by numerous groves of palms, mangoes, and other trees, which, as they display indications of care and intelligence not common in India, contribute, along with the many British residences in the environs, to give the place a very pleasant appearance, and to render it one of the handsomest English stations in the country. It has a fort, a military cantonment, and a government depôt. Here also is a botanic garden, formed in 1817, and now in a flourishing condition, and very tastefully laid out. Pop. (1848) 37,968. The district, which lies between the Ganges and the Jumna, the former dividing it from Gurhwal and Bignour on the east, and the latter from Serhond on the west, is bounded on the north by Dehra Dhoon, and on the south by Mozuffurnuggur. Its length is about 68 miles, its breadth 60, and its area 2165 square miles. The surface is very uniform, sloping gradually downwards from the Sewalik Hills in the north, and is only broken by ridges of low sand-hills parallel to the Ganges and Jumna. It is drained by small rivers flowing southwards, and falling into one or other of the great ones which bound the district. Owing to the high latitude and the elevation of the country, the climate is cooler than that of most parts of India, and there is a great range of temperature in the course of the year. The land produces wheat, barley, oats, pulse, and other vegetables, rice, cotton, indigo, and maize. Irrigation is carried on by means of the Doab Canal, which derives its water from the Jumna. Suharunpore was ceded to the British in 1803. Pop. 801,325.

SUHL, a town of the Prussian monarchy, in the province of Saxony, government and 30 miles S.W. of Erfurt, on the Aue or Lauter. It has several churches, a school, hospital, workhouse, and public offices. In the neighbouring country there are many iron forges, and mills for boring and polishing the metal. Suhl is a centre of the manufacture of arms, and of all sorts of hardware. Woollen and linen cloth, especially fustian, are also made here. Pop. 8892.

SUHM, PETER FREDERIK VON, one of the most laborious writers of Denmark, was born at Copenhagen on the 18th of October 1728. He is said to have read nearly all his father's library, consisting of some 1500 volumes, before he entered college in 1746. He began the study of jurisprudence, but soon turned aside from the law, even when the brightest prospects in that profession were luring him on, to pursue his literary tastes. He began by studying northern history and antiquities; and with that purpose he visited Norway, and remained there from 1751 to 1765. His best writings are—*Odin, or the Mythology of Northern Paganism*, 1771; the *Critical History of Denmark*, 4 vols., 1774–81; and the *History of Denmark*, 7 vols., 1782. He likewise wrote *Idylls* and *Tales* with grace and spirit. These will be found in his *Samlade Skrifter*, 16 vols., 1788–99. His benevolence was as conspicuous a feature of his character as his immense literary industry. His great library, consisting of 100,000 volumes, he threw open to the public, and he consented that it should be united to the royal library a short time before his death, which took place on the 7th September 1798.

SUICIDE, the crime of self-murder, or the person who commits it. Some crimes are peculiar to certain stages of society, some to certain nations. Suicide is one of those crimes which we are led to believe not common among savage nations. The first instances recorded of it in the Jewish history are those of Saul and Ahitophel; for we do not think the death of Samson a proper example. We have no reason to suppose that it became common among the Jews till their wars with the Romans, when multitudes slaughtered themselves that they might not fall alive into the hands of their enemies. Among the Greeks this crime was forbidden by Pythagoras, as we learn from Athenæus, by Socrates and Aristotle, and by the Theban and Athenian laws. In the earliest ages of the Roman republic it was seldom committed; but when luxury and the Epicurean and Stoical philosophy had corrupted the simplicity and virtue of the Roman character, they then began to seek shelter in suicide from their misfortunes or the effects of their own vices. The religious principles of the Brahmins of India led them to admire suicide on particular occasions as honourable. Accustomed to abstinence, mortification, and the contempt of death, they considered it as a mark of weakness of mind to submit to the infirmities of old age. A custom similar to this prevailed among many nations on the continent of America. When a chief died, a certain number of his wives, of his favourites, and of his slaves were put to death, and interred together with him, that he might appear with the same dignity in his future station, and be waited upon by the same attendants. This persuasion was so deeply rooted, that many of their retainers offered themselves as victims. A like custom prevails among many of the negro nations in Africa. The tribes of of Scandinavia, which worshipped Odin, the "father of slaughter," were taught, that dying in the field of battle was the most glorious event that could befall them. This was a maxim suited to a warlike nation. In order to establish it more firmly in the mind, all were excluded from Odin's feast of heroes who died a natural death. In Asgard stood the hall of Odin, where, seated on a throne, he received the souls of his departed heroes. This place was called *Valhalla*, signifying "the hall of those who died by violence." Natural death being thus deemed inglorious, and punished with exclusion from Valhalla, the paradise of Odin, he who could not enjoy death in the field of battle was led to seek it by his own hands, when sickness or old age began to assail him. In such a nation suicide must have been very common. Among the numerous Norse legends there are many picturesque instances of suicide. Beowulph's father, for example, is represented by the old scald as gathering his attendants around him by the seashore, to witness his embarkation for the other world. After arranging round him all the spoils of war which he had gained during his life, his money and his weapons, the old hero lay down by the root of the mast: the sails were set and the helm set fair, and the lonely old man in the lonely ship stood out to sea, and was never heard of more. As suicide prevailed much in the decline of the Roman Empire, when luxury, licentiousness, profligacy, and false philosophy pervaded the world, so it continued to prevail even after

Christianity was established. The Romans, when they became converts to Christianity, did not renounce their ancient prejudices and false opinions, but blended them with the new religion which they embraced. The Gothic nations, also, who subverted the Roman Empire, while they received the Christian religion, adhered to many of their former opinions and manners. Among other criminal practices which were retained by the Romans and their conquerors, that of suicide was one; but the principles from which it proceeded were explained so as to appear more agreeable to the new system which they had espoused. It was committed either to secure from the danger of apostacy, to procure the honour of martyrdom, or to preserve the crown of virginity.

Mercier says, that at Paris it was the lower ranks who were most commonly guilty of it; that it was mostly committed in garrets or hired lodgings; and that it proceeded from poverty and oppression. A great many, he says, wrote letters to the magistrates before their death. Dr Moore's correspondent from Geneva informed him that, from the year 1777 to 1787, more than 100 suicides were committed in Geneva; that two-thirds of these unfortunate persons were men; that few of the clerical order have been known to commit it; and that it is not so much the end of an immoral, irreligious, dissipated life, as the effect of melancholy and poverty. Quetelet, in commenting on the proportion of suicides annually committed throughout the world, gives the following:—Russia, 1 to 49,182 inhabitants; Austria, 1 to 20,900; France, 1 to 18,000; State of Pennsylvania, 1 to 15,875; Prussia, 1 to 14,404; city of Baltimore, 1 to 13,656; Boston, 1 to 12,500; New York, 1 to 7797.

The statistics of the registrar-general of England and Wales give the following results:—Upwards of 1000 persons in England and Wales seek refuge from suffering by suicidal death every year. The quinquennium, from 1852 to 1856, gives a total of 5415 suicides, of which 1182 were committed in 1856, and 1076 in 1855. The number returned is probably less by one-tenth than the number ascertained to have occurred. Of the suicides included in the registrar's tables, 3886 were males, and 1529 females, making an average annual mortality of 8·51 of the former and 32·5 of the latter sex in every million persons living from 10 years and upwards of each sex respectively. The maximum is attained in the decennium 45–55; and then there is a steady decline until the decennium, 85–95. It would seem that the greatest tendency to suicide in this country is manifested in the male sex, from the 55th to the 65th year; in the female, from the 65th to the 75th year; and that in both sexes the tendency to suicide is greater during middle age and the decline of life than during early life and adolescence.

The returns of 1838–9 indicate that the tendency to suicide is greatest during middle age and the decline of life. In the quinquennium already mentioned, 19 males and 14 females destroyed themselves at 10 years of age; 348 males and 273 females at 15; 547 males and 244 females at 25; 726 males and 272 females at 35; 940 males and 346 females at 45; 778 males and 219 females at 55; 410 males and 135 females at 65; 127 males and 28 females at 75; and 9 males with 5 females at 85 years of age. The modes of suicide are various, and adapted to all tastes. There were 10 suicides on railroads, 13 by self-precipitation down the shafts of mines, 1424 by mechanical injuries of all kinds, 561 by chemical injuries, such as fire and poison, and 3212 by suspension of the respiration. It is strange and almost incredible that, while the apothecary's shop offers so many easy methods of terminating existence, yet in England the vulgar death of hanging, or strangulation, is preferred both by males and females. With males, cutting the throat ranks next; drowning, third; and poisoning, fourth: with females, the order is strangulation, drowning, poisoning, and cutting of throats. Females resort to the rope and to steel less frequently than men; they prefer the bowl and the water. Among poisons, females very judiciously choose opium, and its preparations, as the favourite agent of destruction; next come arsenic and oxalic acid, two clumsy and barbarous means, because slow and torturing. Women use essential oil of almonds more than pure prussic acid. Ten different forms of poison are used by males, and 17 by females; even nitric acid, camphor, and phosphorus have been used, and one female took the deadly cyanide of potassium as her sleeping potion. It may be deduced from the extant statistics, that the annual average number of suicides occurring in England and Wales, in every 100,000 of the population in the five years 1852–56, was 5·81; and the annual average proportion per cent. to the total number of deaths from all causes, 0·26. There is no doubt that many more suicides are committed, but that these are hushed up for obvious reasons, owing particularly to the peculiar and almost superstitious abhorrence of suicide in this country. In Geneva, for example, the annual average of suicide to the mortality from all causes is as high as 1·21 per cent., and in this canton the suicides took place at a far earlier period of life. In Geneva, the maximum is reached at 30 years of age, in England not till 55; in the one country it occurs in early life, in the other when life has begun to decline. In Paris the maximum is also attained, as in Geneva, at 30 years; but the maximum of suicides in Paris coincides with that of females but not of male suicides, the greatest number of the latter occurring from 30 to 40. The excess of early suicides in Paris (from 20 to 30 years) has led to much inquiry among psychologists. The number of suicides is invariably greater among males than females, who have fewer of the struggles of life to sustain. Suicides by hanging, and suicides by cut-throat, are more numerous in France by twice and thrice respectively than in England; poisoning is also more common, in the rate of seven to four; asphyxia, or suffocation by carbonic acid gas (the charcoal process), and suicides by falls from elevated places, appear peculiar to France, Geneva, and Sardinia. (See *Journal of Psychological Medicine for* 1859.) John Stuart Mill, who is decidedly opposed to legislative interference with the sale of poisons, as exerting over the subject an entirely unnecessary degree of state surveillance, has nevertheless the following remarks:—"When there is not a certainty," he remarks, "but only a danger of mischief, no one but the person himself can judge of the sufficiency of the motive which may prompt him to incur the risk [of buying poison, *e.g.*;] in this case, therefore (unless he is a child, or delirious, or in some state of excitement or absorption incompatible with the full use of the reflecting faculty), he ought, I conceive, to be only warned of the danger, not forcibly prevented from exposing himself to it." (On *Liberty*, p. 173.) Buckle, a somewhat hasty theorist, regards suicide as a common and constant phenomenon, and tries to show the folly of law-givers thinking that by their enactments they can diminish suicide. Preventive measures, however, have been recently tried in London with success; and Plutarch acquaints us that an unaccountable passion for suicide seized the Milesian virgins, from indulging which they could not be prevented by the tears and entreaties of parents and friends; but what persuasion and entreaty could not effect was accomplished by very different means. A decree was issued, "that the body of every young woman who hanged herself should be dragged naked through the streets by the same rope with which she had committed the deed." This wise edict put a complete stop to the extraordinary phrenzy, and suicide was no longer committed by the virgins of Miletus.

Buckle justly remarks, farther on in his *History of Civilization*, vol. i., "that suicide is merely the product of the

general condition of society, and that the individual felon only carries into effect what is a necessary consequence of preceding circumstances. In a given state of society a certain number of persons must put an end to their own life." He remarks again—"We are able to predict within a small limit of error the number of voluntary deaths for each ensuing period, supposing, of course, that the social circumstances do not undergo any marked change."

As suicide was deemed criminal by the most illustrious and virtuous of the Greek philosophers, it was considered as a crime by the laws, and treated with ignominy. By the law of Thebes suicides were to have no honours paid to their memory. The Athenian law ordained the hand which committed the deed to be cut off, and burned apart from the rest of the body. The body was not buried with the usual solemnities, but was ignominiously thrown into some pit. In Cea and Massilia (the ancient *Marseille*), it was considered as a crime against the state; and it was, therefore, necessary for those who wished to destroy themselves to obtain permission from the magistrates.

In the early part of the Roman history there seems to have been seldom occasion for framing any laws against suicide. The only instance recorded occurs in the reign of Tarquinius Priscus. The soldiers who were appointed to make drains and common sewers, thinking themselves disgraced by such servile offices, put themselves to death in great numbers. The king ordered the bodies of all the self-murderers to be exposed on crosses, and this put an effectual stop to the practice. In Justinian's Pandects there is a law, by which it was enacted, "that if persons accused, or who had been found guilty, of any crime, should make away with themselves, their effects should be confiscated." But this punishment only took place when confiscation of goods happened to be the penalty appointed by the law for the crime of which the self-murderer was accused or found guilty, and was not inflicted for suicide committed in any other circumstances.

It was decreed in the sixth century, that no commemoration should be made in the eucharist for such as destroyed themselves; neither should their bodies be carried out to burial with psalms, nor have the usual service read over them. This ecclesiastical law continued till the Reformation, when it was admitted into the statute law of England. As an additional punishment, however, confiscation of land and goods seems to have been adopted from the Danes, as we learn from Bracton. At present the punishment consists in confiscating all the personal property of a *felo de se* for the use of the crown, and in excluding his body from Christian burial.

SUIDAS, a Greek lexicographer, is supposed by Fabricius to have lived during the latter part of the eleventh century; but other writers are disposed to believe that he must have belonged to a more recent period. His country and his personal history are alike unknown. From authors of various denominations he compiled an ample dictionary, which, with all its imperfections, has been found a most valuable repository of ancient erudition; and no scholar, intimately acquainted with the Greek language and literature, is unacquainted with the *Lexicon* of Suidas. The first edition, which is very elegantly printed, was published by Demetrius Chalcondylus, Mediol., 1499, fol. He had access to several manuscripts. The text of Aldus has some appearance of being derived from a different source, Venet., 1514, fol. A third edition, with various interpolations, followed after a longer interval, Basil, 1544, fol. It was succeeded by the Latin version of Wolfius, Basil, 1564, fol.; Basil., 1581, fol. An edition of the Greek text, accompanied with a Latin version, was published by Æmilius Portus, Colon. Allobrog., 1619, 2 tom. fol. A splendid and valuable edition was at length produced by Küster, Cantab., 1705, 3 tom. fol. Here the version of Portus has received innumerable corrections; and from the collation of manuscripts, as well as by the aid of his own critical sagacity, he effected a great reformation of the text. The text of Suidas was afterwards illustrated by many other writers, particularly by Toup, *Emendationes in Suidam*, Lond., 1760–6, 3 tom. 8vo, Oxon., 1790, 4 tom. 8vo. The labours of these learned men prepared the way for a most valuable edition, published under the following title: *Suidæ Lexicon post Ludolphum Kusterum ad codices manuscriptos recensuit* Thomas Gaisford, S.T.P. Ædis Christi Decanus, necnon Græcæ Linguæ Professor Regius, Oxon., 1834, 3 tom. fol. The third volume is very thin, and merely includes three Indices. Bernhardt published an edition founded on Gaisford's in 1834 and 1853; and Bekker has recently issued an edition of Suidas in 1854.

SULLA. See Roman History, §§ 26, 27.

SULLY, Maximilien de Bethune, Duke of, was born at Rosny on the 13th of December 1560, and died at Villebon on the 22d of December 1640. His name is so conspicuous in the public annals of France, that a mere outline of his personal history would require an ample allotment of space. He participated in the fortunes of Henry IV., and rendered him the most important services in the cabinet as well as the field. He was grand-master of the artillery, and superintendent of the finances. Rigidly attentive to the interest of the king, he had no disposition to neglect his own; and in the course of a long life he accumulated an immense fortune, of which he laid the foundation by his marriage with Anne de Courtenay, a rich heiress. He was remarkable for his decision of character and bluntness of manners; and in spite of all the allurements presented to him, he steadily adhered to the Protestant faith. The Memoirs of Sully furnish some of the most curious and valuable materials for the history of that eventful era.

SULMONA, a town of Naples, in the province of Abruzzo Ultra II., in a fertile valley, 24 miles S.S.W. of Chieti. The valley is drained by the Sagittariæ, an affluent of the Pescara, and forms an important pass across the Apennines. The town itself is old and gloomy; it is surrounded by walls, and it contains a fine cathedral, numerous other churches, monasteries and nunneries, and a town-hall in the cinque cento style. Dyeing, papermaking, the manufacture of catgut and of sausages, are carried on; and the town has long been celebrated for its confectionary. There are some remains of an ancient aqueduct with pointed arches. The ancient Sulmo, the birthplace of Ovid, stood near Sulmona. Pop. 9200.

SULPHUR. See Chemistry.

SULPICIA, a Roman poetess, who lived under the reign of Domitian, and has been so much admired as to be termed the Roman Sappho. We have nothing, however, left of her writings but a satire, or rather the fragment of one, ascribed to this poetess, written against Domitian, who published a decree for the banishment of philosophers from Rome. This satire is to be found in Scaliger's *Appendix Virgiliana*, and in other collections. It was separately published, with elaborate annotations by C. G. Schwartz, Altorf., 1721, 8vo; Hamb., 1819, 4to. She is mentioned by Martial and Sidonius Apollinaris; and is said to have addressed a poem on conjugal love to her husband Calenus, a Roman knight.

SULPICIUS, Severus, an ecclesiastical writer, was born in Aquitania about the year 363 A.D. His father was a man of superior rank. Having received a suitable education, the son applied himself to the practice of the law, and distinguished himself by his learning and eloquence. He married a rich wife, and was thus placed in a state of greater independence. He chiefly resided at Toulouse, and at *Eluso* or *Elusio*, near Carcassonne. The death of his wife weaned his affections from the world, and he is

Sulzer.

supposed to have devoted himself to an ecclesiastical, if not a monastic life. He had recourse to the instructions of Martin bishop of Tours, whose life he has written; and he likewise contracted a friendship with Paulinus bishop of Nola. The invasion of the Vandals impelled him to seek a place of refuge at Marseille, where he entered a monastery, and is supposed to have died about the year 410. His principal work is his *Historia Sacra*, brought down from the creation of the world to his own time, and written in a style superior to the standard of that declining age of Latinity. He has with propriety been designated the "Christian Sallust." The first edition was published by Flacius Illyricus, Basil. [1556] 8vo. Various editions of his works subsequently appeared; some of which were illustrated by the notes of Sigonius, Vorstius, Horn, and Le Clerc. A more elaborate edition was undertaken by De Prato, Veronæ, 1741–54, 2 tom. 4to. He promised a third volume, which, however, did not make its appearance.

SULZER, Johann Georg, a philosophical writer of distinction, was born at Winterthur, in the canton of Zürich, on the 16th of October 1720. He was the youngest of twenty-five children. At the age of sixteen, when he went to the University of Zürich, he had not the smallest notion of the sciences or of elegant literature, and consequently no taste for study. The first incident that developed in him a hidden germ of philosophical genius, was his meeting with Wolf's *Metaphysics*. This was the birth of his taste for science; but he wanted a guide. The clergyman with whom he lodged was an ignorant man; and the academical prelections were, as yet, above the reach of his comprehension. On the other hand, a sedentary life was not suitable to his taste; and a sociable turn of mind often led him into company, where he lost much time in frivolous amusements, yet without corrupting his morals. Who that observed him at this period, says Formey in his *Eloge*, would have thought that Sulzer would one day be numbered among the most knowing and wise men of his time? John Gessner, who became an eminent naturalist, rendered Sulzer's inclination to study triumphant over his passion for amusement and company. Animated by the counsels and example of this fellow-student, he applied himself to philosophy and mathematics with great ardour, and resumed the pursuit of Greek literature and the oriental languages. He was settled as a pastor in a rural district. In 1741, he published *Moral Contemplations on the Works of Nature;* and in the following year an *Account of a Journey through the Alps*, which showed at the same time his knowledge of natural history, and the taste and sensibility with which he surveyed the beauties of nature, and the grandeur and goodness of its Author. He afterwards became private tutor to a young gentleman at Magdeburg. This procured him the acquaintance of Euler, Maupertuis, and Sack, which opened to his merit the path of preferment, and advanced him successively to the place of mathematical professor in the Gymnasium of Berlin in 1747, and to that of member of the Royal Academy in 1750. In this last quality he distinguished himself in a very eminent manner, enriched the class of speculative philosophy with a great number of excellent memoirs, and was justly considered as one of the first-rate metaphysicians in Germany. But his genius was not confined to this branch of science. His *Universal Theory of the Fine Arts* is a valuable production. A profound knowledge of the arts and sciences, and a perfect acquaintance with true taste, are eminently displayed in this work, and will secure to its author a permanent and distinguished rank in the republic of letters. The first volume of this excellent work was published in 1771, and the second in 1774. His *Remarks on the Philosophical Essays of Hume* is a work of real merit, which does justice to the acuteness, while it often detects the sophistry, of the Scottish philosopher. The moral character of Sulzer was amiable and virtuous; sociability and benevolence were its characteristic features.

Sumarokov || Sumatra.

SUMAROKOV. See Russia.

SUMATRA, a large island in the East Indian Archipelago, stretching from N.W. to S.E.; between 5. 45. N. and 5. 55. S. Lat.; 95. 20., and 106. 5. E. Long.; and separated from the Malay peninsula by the Straits of Malacca on the N.E. It is bounded on the E. by the Java Sea; S. by the narrow Strait of Sunda, separating it from Java; S.W. and W. by the Indian Ocean; and N. by the Bay of Bengal. Its length is more than 900 miles; its average breadth in the southern part, 210, but in the northern, 140 miles; and its area is estimated at 160,000 square miles. It is thus second only to Borneo in size among the islands of Asia.

Surface and mountains.

Along the south-western coast of Sumatra there extends a mountain-chain, rising steeply in some places at a distance of only two miles from the sea; the north-eastern portion, on the other hand, spreads out into vast unbroken plains, very little above the level of the sea. The island is thus divided generally, according to the character of its surface, into two parts, a mountainous and a level one, by a line passing through its centre in the direction of its length. And the mountainous region itself consists of three distinct parts; the southern, the central, and the northern. The southern mountainous region is formed by two chief ranges, and covers a tract of ground about 100 miles in length by 40 in breadth. The mountains rise abruptly from the shore of the Strait of Sunda, which washes the southern extremity of the island; and from the three promontories of Tanjong Toca, Tanjong Kamantara, and Flat Point, which enclose the two bays of Lampong and Samangka, three separate chains take their origin and unite into one above the head of Samangka Bay. This chain stretches north-west parallel and close to the coast, which is here lined by a series of lofty hills and narrow glens, which are sterile and thinly peopled. Much more elevated than this is the other range, which runs parallel to this, considerably further inland. Between these two chains lies a lofty tableland, undulating and hilly in its surface, and containing several large lakes. The principal summits in this southern portion of the Sumatran Mountains are Raja Bassa, about 16,000 feet, and Keyzer's Peak, about 5000 feet high. The central part of the mountainous district both contains all the loftiest summits of Sumatra, and stretches over a greater breadth of the island than either of the others. It is, however, further away from the coast, for the mountains rarely approach nearer than 20 miles to the sea, and in some places recede as far back as 30. They are separated from the sea by a plain tract, sloping very gradually up to their foot, from which they rise pretty abruptly, and in some places precipitously. The mountains themselves in this region have been very little explored. They seem to form three, and in some places even more parallel ranges. Many of the peaks are volcanoes, some of which are still active. The chief of them are the following:—Derupo, in S. Lat. 3° 52′, 10,440 feet high; Indrapura, S. Lat. 1° 34′, 12,140 feet; Talang, S. Lat. 1°, 8480 feet; Merapi, S. Lat. 0° 24′, 9700 feet; Singallang, S. Lat. 0° 28′, 10,150 feet; and Ophir, N. Lat. 0° 12′, 9500 feet. All of these, except the two last, are volcanoes; and all except Talang have the crater at some distance below the summit. Besides these, Sumatra contains about 15 other volcanoes, generally from 6000 to 7000 feet in height. In the midst of this mountainous region there are many valleys and lakes, surrounded with rich and fertile tracts, which are frequently well cultivated. One of the most remarkable of these districts is Menangcabau, which lies between Mount Talang and the equator. It is a broken and hilly tableland, about 50 miles each way, and enclosed on all sides with high mountains. The lowest part of it is occupied by the Lake of Sinkara, and the whole is well cultivated, densely inhabited, and

Sumatra.

dotted with towns and villages. The central mountain region may be considered to terminate at Tapanooly Bay, about N. Lat. 1° 40′. North of this lies the third or northern region, extending to the extremity of the island. It consists of three or four parallel ranges, which occupy a breadth of about 25 miles, and are separated from the ocean by a plain 10 or 12 miles broad. Their general height is less than the mountains further south; but there are some considerably elevated peaks, such as Loesa, 11,150 feet high; Abong-Abong, 10,350 feet; and Queen's Mountain, 6900 feet. These mountains are almost all covered with dense forests. The eastern range here is the loftiest, and forms the water-shed of the island. The chain terminates at Acheen Point, the northern extremity of the island; but there is also a hilly tract that stretches eastward along the north coast as far as Diamond Point, at the entrance of the Straits of Malacca.

Valleys and plains.

The eastern part of Sumatra, forming probably the greater part of the whole island, from Diamond Point in the north to Tanjong Toca in the south, is occupied by an immense plain of a very uniform character, except along the coast, where there is some variety. It is but slightly elevated above the sea-level, and a large portion of its seaward margin, occupying the centre, from Rakan River to Lucepara Point, is so low as to be laid under water at spring-tides, and thus to be converted periodically into a vast swamp. Behind this, the land gradually rises; and the more northerly and southerly regions seem both to be sufficiently elevated to escape the danger of inundation. Another important plain in Sumatra lies on the west coast between the sea and the central part of the mountains. This region is better known than any other part of the island, as it has been for two centuries the seat of several European settlements. It is a low and somewhat uneven tract, intersected by numerous swamps, which in some places form islands and peninsulas of considerable size. There are no important valleys in Sumatra. Those that descend laterally from the mountains are in almost all cases very narrow and steep, so as to afford but an ungenial soil and few attractions to the husbandman. The longitudinal valleys and plateaus among the mountains are of greater size and fertility. Some of these have been already noticed. Another stretches for about 100 miles from the peak of Merapi, northwards to that of Lubu Raja. These mountain-valleys are the chief seats of the native population, but they are as yet but little known to Europeans.

Lakes and rivers.

In the mountain region there are several lakes, but most of them are of small size. The most important are Sinkara, which is 12 miles long by 4 wide; Dano, which is of smaller size, 1500 feet above the sea; Eik Daho, said to be 4000 feet high; and St George's Lake. Numerous rivers flow from the mountains towards the south-west, but those which take this direction are for the most part of small size. The largest is the Sinkel, which has a course of more than 100 miles, and receives from the right the Sikeri. It enters the sea about N. Lat. 2° 15′. Proceeding southwards along the coast we pass in succession the mouths of the Batang Tara, Tabuyong, Indrapura, Spov, and Kataun, besides many others of smaller size. The eastern part of the island is watered by more considerable streams. Of these the largest is the Palembang, which rises by numerous branches in the southern mountains, between 2° 30′ and 5° S. Lat. The principal of these upper branches is that known at first as the Ayer Musi, but lower down in its course as the Tatong. All the other branches unite with this near the town of Palembang, where they form a river more than a mile wide, which bears the name of Palembang down to the sea. It is navigable for boats 250 miles above its mouths, and it falls into the Strait of Banca, forming a delta about 24 miles broad, south of the Palembang. The largest river is the Talan Booang; and north of it there are the Jambi, flowing from St George's Lake; the Indragiri, the Kampar, the Siak, the Rakan, the Assahan, the Batu Bhara, and the Delli, all flowing in more or less tortuous courses from the mountains down to the sea, many of them forming considerable estuaries, and being navigable for some distance. There are no considerable inlets of the sea along the coasts of Sumatra.

Capes and islands.

The southern extremity of the island is formed as has been already stated, of three capes, which enclose two small bays, in which there are several good roadsteads. Along the whole length of the south-west coast there are no considerable headlands; but there is a series of islands extending in a line parallel to the shore at some distance from it. There are, beginning at the south, Engano, South Poggy, North Poggy, Sepora, Sebeeroo, Batoe, Nias, and Hog Island. The two capes which form the northern termination of the island are Acheen Head and Diamond Point; the former at the western and the latter at the eastern extremity of the steep rugged coast, which has been called the coast of Pedir, about 150 miles in length. The chief headlands on the eastern coast are Perhabean Point at the mouth of the Rakan; Jaboeng Point, at that of the Jambi; and Cape Lucepara, at the southern entrance of the Strait of Banca. Off this coast lie the Islands of Rupat, separated from Sumatra by the strait of the same name; those of Baccalisse, Padang, and Rankan, all lying together and separated from Sumatra by the Brewer's Strait; and that of Banca separated by the Strait of Banca from the main island. In general it may be said that the south-west and north coasts of Sumatra are rocky, and in some places steep; while the north-east coast is low, and lined for the most part with shoals and sand-banks.

Climate.

As Sumatra lies directly beneath the equator, the climate is very warm; but it is remarkable that, on the sea-level near the shore, the heats are more moderate than in other countries within the tropics. At the most sultry hour in the afternoon the thermometer fluctuates between 82 and 85 degrees: it seldom rises above 86 in the shade, and at sun-rise it is usually as low as 70. Very dense fogs frequently prevail in the mountainous regions. The island is subject to the monsoons, and as, during their prevalence, the mountains arrest all the vapours with which they are charged, the island, at least its southern portion, is almost incessantly deluged with rain. The climate of the northern portion is not so moist, probably on account of the vicinity of the Malay peninsula. Besides the monsoons, which vary every six months, there is a daily variation in the winds, which blow from the sea to the land during so many hours of each day, and during the night in the opposite direction, from the land to the sea. Thunder and lightning prevail in Sumatra, especially during the north-west monsoon, when the explosions are extremely violent; and waterspouts are also frequent along the west coast. The island is unfortunately subject to earthquakes, which often prove most destructive. In the marshes and flats along the coasts, the climate of Sumatra has been found very insalubrious by the Europeans; but amid the mountains of the interior the native inhabitants seem to find it healthy, and they attain frequently to a great longevity.

Soil and produce.

The soil has been celebrated for its fertility; and it certainly produces a most luxuriant vegetation. Of the greater part of the island but little is known, as it is covered with impenetrable forests; but wherever it has been explored the soil seems to consist of a stiff, reddish clay, covered with a layer of black mould, of no considerable depth. From this there springs a strong and perpetual verdure of rank grass, brushwood, or timber trees, according as the country has remained for a longer or shorter period uncultivated; and this forest or jungle, as there is but a scanty population, affords abundant cover for wild beasts of the most ferocious kind by which the country is infested. Many of the plants

Sumatra. and trees that compose the forests of Sumatra are remarkable for their gigantic size. Few of the trees are under 100 feet in height, and many of them are nearly twice as much; while the gigantic creepers and parasites, and the enormous flowers of some of the plants are, if possible, still more astonishing. The most important article of cultivation is rice, which is exported in considerable quantities from Acheen to India. Maize, yams, potatoes, peas, beans, and other vegetables are also raised. The cocoa-nut tree is one of the most valuable productions, furnishing an article of food which is in almost universal use. There are also large plantations of the betel-nut tree and the bamboo; the latter growing thick into an impenetrable mass, is used in the fortification of villages. The sago-tree also flourishes, and there is a great variety of palms. Capsicum pepper, turmeric, ginger, coriander and cummin seed, are raised in the gardens of the natives. Pepper is grown here in large quantities. The plant appears to flourish in any of the different soils that are found in this island, and it is a great article of commerce. The pepper plants, which are in even rows, running parallel and at right angles with each other, present a fine contrast to the wild scenes of nature which surround them. The camphor-tree, which grows in the northern parts of the island, is valued for its juice, which is an article of trade, and sells at a high price. The benzoin is produced from a tree which grows in the same district, as also does the tree that yields cassia. Cotton is also produced, and forms an article of export. Various other shrubs and plants are cultivated, and are converted by the natives to many useful purposes. Hemp is extensively cultivated, not however for the purpose of making ropes, but to procure an intoxicating liquor called *bang*, which the natives smoke in pipes along with tobacco. Plantations of the latter plant are met with in almost every district; and there is a variety of other creeping plants, which are manufactured into twine, thread, and other articles of the same nature. No country in the world is more distinguished than Sumatra for the variety of fine fruits with which it abounds, and which are the spontaneous produce of the earth. The most remarkable are the mangustin, which is produced in abundance, and which for delicacy and flavour holds pre-eminence over all the Indian fruits; the pine-apple, which, though not indigenous, grows in great plenty with ordinary culture; the orange, which is in great perfection and variety; the shadock of the West Indies, which is here very fine, and is distinguished into the white and the red. Limes and lemons abound; as also the bread-fruit; the jack-fruit; the mango, a rich high-flavoured fruit of the plum kind; the papaw, a fruit substantial and wholesome, like a smooth sort of melon, but not very highly flavoured; the pomegranate, the tamarind, nuts and almonds of different kinds, besides various other fruits of which the names are scarcely known in Europe. Owing to the equable temperature that prevails throughout the year, there is a perpetual succession of shrubs and flowers, which diffuse a pleasant fragrance, and are, many of them, used in medicine, or in affording useful dyes. The castor-oil plant is found in abundance, especially near the seashore; also the caoutchouc or India-rubber plant, the indigo plant, and several others.

Animals. The zoology of Sumatra is distinguished by some of the most remarkable animals in nature. The shelter afforded by its vast forests or tracts of jungle is most favourable to the breed of wild animals, which abound throughout the island. Numerous herds of elephants range over the forests, and are pursued and killed for their teeth; they are extremely destructive to the plantations of the natives, which they trample down by merely walking through the grounds, and thus obliterating all traces of cultivation. The rhinoceros, both the single and the double horned, is also a native of the woods. Of beasts of prey the tiger is the most remarkable. It grows to an enormous size, and its strength is so prodigious that it is able to drag into the woods the largest prey, and by a stroke of the fore-paw will break the leg of a horse or buffalo. Whole villages are sometimes depopulated by these animals, and great numbers of inhabitants lose their lives. When a tiger enters a village, these ignorant people prepare rice and fruits as an offering to the animal, conceiving that he will be pleased with these hospitable attentions, and pass on without doing them any harm. Tigers are occasionally caught in traps, which are ingeniously contrived in the form of a cage with falling doors, into which the beast is enticed, and is then enclosed; or a large beam of timber is so placed as to fall on its back and crush him. Another expedient is to entice it to ascend a plank, which being nearly balanced, is weighed down by it when it is past the centre, so that it falls upon sharp stakes prepared below. The natives sometimes contrive to poison tigers. The bear is common; it is small and black, and climbs the cocoa-trees, feeding upon the tender part or cabbage. Two species of deer are found in the forests, and the monkey tribes are innumerable. Here are also sloths, squirrels, civet-cats, tiger-cats, porcupines, hedgehogs, armadillos, bats of all kinds, alligators in the rivers, which are also haunted by the hippopotamus, guanas, chameleons, flying lizards, tortoises, and turtle. Among the domesticated animals the most useful is the buffalo, which also exists in a wild state, and is remarkably strong and active. This animal supplies the inhabitants with milk, butter, and beef. Black cattle exist on the island, but in no great numbers, except on the northern coast, where they are employed in agriculture. The breed of horses is small, but they are well made and hardy. The sheep are also a small breed; the other animals are the goat and the hog, both domestic and wild; the otter, the cat, the rat, and the dog. Frogs, toads, and reptiles of every kind, abound in the swamps; and the noise which they make on the approach of rain is tremendous. Among the poisonous serpents is the viper; and the hooded snake is sometimes found in the country. The boa-constrictor is also to be met with, and sometimes grows to the length of 30 feet, and is of proportionate bulk and strength. The surrounding seas abound in fish. Among these are the duyong, a large sea-animal of the order mammalia; besides sharks, skates, the muræna gymnotus, rock cod, mullet, the flying-fish, and many others. Of birds there is a great variety, for besides common fowls, which are abundant, the island contains peacocks, eagles, vultures, kites and crows, jackdaws, kingfishers, the rhinoceros bird, remarkable for its horn, the stork, the snipe, coot, plover, pigeons, quails, starlings, swallows, minas, parrots, parroquets, geese, ducks, teal, &c. The Sumatran pheasant is a bird of great magnificence and beauty, perhaps the finest that the island contains. Sumatra may be said literally to swarm with insects, many of which are extremely annoying and destructive. These consist of cockroaches, crickets, flies of all sorts, mosquitoes, scorpions, and centipedes. Ants exist in immense numbers and varieties. Bees are also numerous, but the honey is of an inferior quality.

Minerals. Gold is a production for which Sumatra was once famed, and it is still found in considerable quantities chiefly in the mountains surrounding Menangcabau, but also in some other places. Copper exists in the northern part of the mountain region; but though it is plentiful, and in some places contains gold, it is only worked to a very small extent. In the country of Menangcabau iron ore is collected, smelted, and formed into metal, and there are indications of its existence in other parts of the island. Tin is one of the great mineral products of the island. It chiefly abounds in the neighbourhood of Palembang, on the east coast; but in many other parts its existence is indicated, and particularly in the neighbourhood of Bencoolen. Sulphur

Sumatra.

may be gathered in any quantity near the volcanoes; arsenic is also found, and is an article of traffic; and saltpetre is procured, and is used by the natives for making gunpowder. Coal exists in various parts, and is washed down to the coast in floods; but it is not esteemed good, being found near the surface of the earth. Mineral and hot springs are discovered in many districts.

Inhabitants.

The majority of the present inhabitants of the island belong to one race; though there are various portions of them distinguished by peculiar characteristics, and hence sometimes considered as separate nations. But the differences are not very considerable; and the languages that are spoken may all be considered as dialects of one common tongue. The people may be designated, in general, Malays, and are commonly divided into the following five tribes or nations:—1. The Acheenese, who occupy the extreme north of the island, and probably, on account of their mixture with Hindoo immigrants, differ considerably from the other tribes, being darker in complexion, taller, and stouter, but still retaining the general character of the Malay race. 2. The Battas, who occupy the country from sea to sea, between the Acheenese and Menangcabau, or from the river Senkel to the Tabuyong. They are of smaller stature and fairer complexion than the former, and live in a very rude and savage condition. 3. The Malays proper, occupying the valley of Menangcabau (which is said to have been the original cradle of the race), and the whole of the eastern plain from the Rakan to the Masuse. 4. The Rejangs or Sumatrans, who inhabit the west coast from the Tabuyong southwards to the Padang Guchi, a race of men small in size, but well formed, and bearing some resemblance to the Chinese. 5. The Lampangs, occupying the mountains and plains in the extreme south of the island, a race which resembles very strongly the Chinese, and whose language differs considerably from that of any other tribe. Besides these nations, who form the majority of the population, there are two other races who live in a very savage state, wandering in the woods with little intercourse with the others. These are the Orang Kuba and the Orang Gugu; and it is not certain whether or not these represent an aboriginal race of inhabitants. In respect of civilisation the people of Menangcabau and those of Acheen are the furthest advanced of all the Sumatran tribes. The Battas have made considerable progress in some respects, but they retain the custom of cannibalism, in the case of criminals and prisoners of war, with circumstances of peculiar atrocity and cruelty.

Manufactures.

There are some branches of industry which are prosecuted in Sumatra with a large measure of skill and success. The Malays about Palembang build very excellent boats. The Battas erect good substantial houses; and though their farming implements are very rude, they are not only successful in agriculture, but carry on a system of irrigation which is very extensive and ingenious. But the chief seat of manufacturing industry is Menangcabau, where iron and steel are wrought to a high degree of perfection; and the blades of *krises* or daggers made here are celebrated throughout the East Indies. In this district iron has been worked from time immemorial; and an extensive manufactory of coarse pottery, near the banks of the lake, supplies not only Padang, but Bencoolen, with that useful article. The Sumatrans are entire strangers to the art of painting and drawing. In cane and basket work they are particularly neat and expert, as well as in mats, of which some kinds are much prized for their extreme fineness, and for the beauty and taste of the borders with which they are ornamented. They excel also in the manufacture of silk and cotton cloths of varied colours, chiefly for domestic use. Their apparatus for weaving is, however, of the rudest description, and renders their progress tedious. The women are expert at embroidery, the gold and silver thread for which is procured from China, as well as their needles. Gunpowder is manufactured in various parts of the island, chiefly among the people of Menangcabau, the Battas, and Acheenese, among whom, as they are frequently at war, it is an article in great request. It is not, however, well made, being imperfectly granulated, and often hastily prepared for immediate use. Different kinds of earthenware are manufactured in the island. The manufacture of filagree is here carried to the greatest perfection. There is no manufacture in any part of the world that has been more justly admired and celebrated than the fine gold and silver filagree of Sumatra; this is the work of the Malays, to whose superior taste and industry many of the monuments of art which remain are ascribed. This manufacture is in universal use in the country; and its fineness and beauty form a singular contrast to the coarseness of the tools which are employed in the workmanship, and which are rudely and inartificially formed by the goldsmith from any old iron that he can pick up. A piece of iron hoop as a wire-drawing instrument, an old hammer-head stuck in a block as an anvil, and two old nails tied together as a pair of compasses, are the chief instruments. They have no bellows, but blow the fire with their mouths through a reed. They are very inexpert at polishing the plain parts, but in other respects nothing can exceed the extraordinary delicacy of the Malay work. They are extremely skilful in manufacturing fishing-nets and springs for catching birds.

Religion.

The Malays and a part of the Sumatrans proper are Mohammedans; the other tribes, in as far as they exhibit any traces of religion at all, are heathens. Mohammedanism seems to have superseded in this country the Buddhist doctrines, which prevailed here at an early period; but it has never made much progress among the tribes in the interior, owing probably, among other reasons, to the immense numbers of swine, which constitute an important part of the wealth of these people, as well as a favourite article of food. The Battas have a religious system and an influential priesthood, but they worship no idol.

Language.

The Malay language, which is understood to be the original language in the peninsula of Malacca, has extended itself through all these Asiatic islands, and has become the common tongue in this part of the globe. It is spoken everywhere along the coasts of Sumatra. It also prevails in the inland country of Menangcabau, and is understood in almost every part of the island. From the smoothness and sweetness of its sound, it has been called the Italian of the East. Their writing is in the Arabic character, very little corrupted; owing to which, and the adoption of the Mohammedan religion, a great number of Arabic words are incorporated with the Malay. The Battas have an ancient and peculiar mode of writing, from the bottom upwards; but of their books in this character little is known, and they seem to be of no great value.

Divisions.

In a political point of view, Sumatra is divided between the native independent states and the Dutch possessions. Of the former, the largest is Acheen, occupying the whole northern part of the island. (See Acheen.) It is governed by a sultan, who had formerly under him many subject-princes; but most of these have now become independent. On the east coast lies the state of Siak, which is also governed by a sultan, and has a capital of the same name at the mouth of the Siak river. The country of the Battas forms three independent states,—Sinamora, Bato-Seling-Dong, and Butar. Its principal town is Baroos, on the west coast. Of less size and importance are the states of Indrapura, Passaman, and Jambi, the two former on the west and the latter on the east coast. The rest of the island belongs to the Dutch. Their possessions form six governments, besides two others, which comprise the smaller islands adjacent to Sumatra. The governments are:—1. Sumatra on the west coast, from the equator to 1° 55′ S. Lat., including the district of Menangcabau. The capi-

Sumatra.

tal is Padang. 2. Bencoolen, to the south of the former, and likewise on the west coast, with a capital of the same name. 3. Lampong, occupying the southern extremity of the island. 4. Palembang, north of the preceding, on the east coast, including the town and river of the same name. 5. Indragiri, still further north, extending to the southern entrance of the Straits of Malacca; and 6. Assahan, the most northerly of all the governments on the east coast. Besides these there is the government of Banca, consisting of the island of that name, and that of Rhio, comprising the smaller islands lying south of the Malay peninsula. The extent and population of these various divisions of Sumatra are exhibited in the following table:—

	Square Miles.	Pop. (1857).
Dutch Possessions:—		
Sumatra	46,628	1,499,271
Indragiri	14,327	
Assahan	5,382	
Bencoolen	9,643	112,542
Lampong	10,067	82,974
Palembang	54,216	467,685
Native States:—		
Acheen		600,000
Battas		1,200,000
Other tribes		550,000
Total population.........about		4,512,472

The Dutch are continually by slow degrees enlarging their power and possessions in this island, and year by year are making encroachments on the independent states.

Commerce and navigation.

The trade of Sumatra is carried on chiefly with the neighbouring East Indian countries. The island affords many productions which are exported, especially pepper, gold-dust, camphor, nutmegs, cloves, mace, benzoin, gutta-percha, copper, tin, sulphur, coral, &c., which are generally brought down by the natives to the seaports, and there exchanged for goods of Indian or European manufacture. Besides cotton, muslin, and silk, opium and salt are imported from India; porcelain, hardware, gold thread, and other articles from China; striped cotton cloth, arms, and spices from Java, Celebes, and other islands of the East Indies; and silver, steel, cutlery, broad-cloth, &c., from Europe. There is a considerable trade between this island and Java and Madura, carried on chiefly in native, but partly also in European vessels. In 1854 there entered at the principal ports of Sumatra, from those in Java and Madura, 964 vessels, tonnage 44,446; and there cleared for these ports 871 vessels, tonnage 39,056.

History.

Of the early history of this island we know next to nothing. Mohammedanism is said to have been first introduced in the thirteenth century, when the Arabians were in the habit of undertaking voyages to the East Indies and to China. About the end of the twelfth century the Malays began to spread themselves from their original seats in Sumatra over the peninsula of Malacca and the Sunda Islands, where they continued to be the dominant race until the fourteenth century. When the Portuguese landed here in 1509, they found that the ancient Malay kingdom of Menangcabau had been dissolved; but there was a powerful monarch ruling over Acheen, who endeavoured to exclude the strangers from his country. In 1575 the Portuguese shipping in the harbour of Acheen was destroyed by the natives, and in 1582 an attempt which they made to gain possession of the town proved quite unsuccessful. No permanent settlement was made on the island till 1600, when the Dutch established a factory at Pulo Chinko, on the west coast. The kingdom of Acheen had by this time begun to decline in power, being distracted by internal wars and discords. The success of the Dutch was at first greatly promoted here, as in the other parts of the East Indies, by the fact that they arrived at a time when the natives were bitterly and justly exasperated against the Portuguese, on account of the oppression and cruelty which they in many cases exhibited, and to which the conduct of the new comers afforded a favourable contrast. But it soon appeared that the commercial eagerness of the Dutch was no less grasping and aggressive than had been the Portuguese lust of plunder and conquest. They rapidly increased the number of their factories and settlements, founding one at Padang in 1649, at Palembang in 1664, and in many other parts of the island, and securing to themselves the monopoly of the profitable trade in pepper.

The English followed the Dutch in this island, and founded a colony at Bencoolen in 1685; but they never made so much progress here as their rivals. In 1811, the Dutch settlements in the East Indies fell into the hands of the British; Holland having been at that time annexed by Napoleon to France. But by the peace of 1816 these colonies were restored to the Dutch, who have since retained them. In 1824, they exchanged the settlement of Malacca for the British colony of Bencoolen. A singular war which took place subsequently in Sumatra led to a material extension of the Dutch possessions. It was occasioned by a religious sect called Padries, who first made their appearance here about the beginning of the century. Their principles were at first harmless enough, being simply abstinence from gambling, smoking opium, and drinking intoxicating liquors; and, for about eighteen years they flourished in peace. But about 1815, a society of this sect was formed for the purpose of spreading their doctrines and practices by force; and this speedily roused resistance and opposition. The Malays and Battas made common cause against the Padries; and for a long time a fierce struggle was carried on, which devastated Menangcabau and the neighbouring regions. At length the assistance of the Dutch was called in against the Padries, and with their help the sect was entirely put down. The indirect results of this war were the annexation of Menangcabau to the Dutch possessions in 1835, and the opening up to them of the Batta country, from which foreigners had previously been excluded.

Sumbawa.

SUMBAWA, an island in the East Indian Archipelago, lying between S. Lat. 8. and 9., E. Long. 116. 50., and 119. 10.; bounded on the N. by the Java Sea; E. by the Strait of Sappi, which separates it from Comodo and Flores; S. by the Indian Ocean; and W. by the Strait of Allass, which separates it from Lombok. Length, about 180 miles; breadth from 20 to 50; area, estimated at 7200 square miles. Its form is irregular, and it is almost divided into two by the deep Bay of Sallee, near the middle of the north coast. Along the southern shore a mountain-range stretches from end to end of the island, with a great depression about the middle, opposite the Bay of Sallee. The rest of the island is for the most part hilly, and level plains only occur in a few places, chiefly at the head of the numerous bays which indent the northern coast, and along the Straits of Sappi on the east. One of the most remarkable peaks in the island is the volcano of Tumbora, near the mouth of the Bay of Sallee; it rises to the height of 9000 feet, and there was in 1815 a most terrible eruption, which caused a fearful devastation in the island, and was heard to the distance of 840 miles. Another eruption, much less destructive, occurred in 1836. The soil of Sumbawa is exceedingly fertile. It produces rice, tobacco, teak, and other kinds of timber, &c. Gold-dust and pearls are obtained here. The horses of the island are of a very good breed, and are exported in large numbers. Buffaloes, deer, and swine abound in the island. Sumbawa is divided into six native states, governed by rajahs, all of whom acknowledge the supremacy of the Dutch, who have a small establishment at Bima on the north coast. This town and Sumbawa, also on the north coast, are the only places where there is any intercourse with other countries; but at

these an active trade is carried on in the exportation of native produce, and importations of opium, Indian and European goods.

SUMBULPORE, a district of British India, presidency of Bengal, lying between N. Lat. 21. and 22. 5., E. Long. 83. 6. and 84. 51.; bounded on the N. by the native states of Ryghar and Gangpoor, E. by those of Bonei and Bombra, S. by those of Sonepoor and Patna, and W. by those of Phooljee, Sarunghur, and Burghur. Length, 112 miles; breadth, 60; area, 4693 square miles. It is watered by the Mahanuddy, which divides it into two unequal parts; the eastern portion being mountainous and covered with forests, the western and northern, low and level. The soil of the lower ground is alluvial and rich, producing in abundance and of good quality, rice, wheat, and sugar-canes. It is believed that indigo and opium might also be raised here. The forests afford a rich supply of teak. The most important minerals of the district are diamonds and gold; the former are said to be the finest in the world. The capital of the district is a town of the same name, on the Mahanuddy, containing a fort, several pagodas, and other buildings. There is little or no trade, although the river is navigable. The climate of the town is very fatal to Europeans. Population of the district estimated at 274,000.

SUMMER, the name of one of the seasons of the year, being one of the quarters when the year is divided into four quarters, or one-half when the year is divided only into two, summer and winter. In the former case, summer is the quarter during which, in northern climates, the sun is passing through the three signs Cancer, Leo, Virgo, or from the time of the greatest declination, till the sun again comes to the equinoctial, or has no declination; which is from about the 21st of June till about the 22d of September. In the latter case, summer contains the six warmer months, while the sun is on one side of the equinoctial; and winter the other six months, when the sun is on the other side.

SUMPTUARY LAWS (*Leges Sumptuariæ*), are laws made to restrain luxury. Most ages and nations have had some such laws. Political writers have been much divided in opinion with respect to their utility. Montesquieu observes that luxury is necessary in monarchies, as in France, but ruinous to democracies, as in Holland. With regard to England, whose government is compounded of both species, it may still be a dubious question, says Blackstone, how far private luxury is a public evil, and as such cognisable by public laws.

SUN. See Astronomy.

SUNDERLAND, a large and rapidly-growing seaport-town on the north-east coast of England, in the county of Durham, 268 miles from London. The municipal boundary embraces an area of 1684 acres, and includes the parish of Sunderland-near-the-Sea, the townships of Bishopwearmouth, and Bishopwearmouth Panns, part of the parish of Monkwearmouth, and the township of Monkwearmouth Shore. The River Wear, after running through the centre of the borough, falls into the sea. The first authentic evidence of the existence of Sunderland as a place of maritime commerce is found in a charter granted by Hugh Pudsey, bishop of Durham, in the end of the twelfth century; and there are records extant showing that in the year 674 a monastery was founded at Monkwearmouth, in which the Venerable Bede was educated, and spent the greatest part of his life. The town contains a number of fine streets, the principal of which is the High Street, which extends for nearly one mile from east to west. Throughout the older part of the town, the houses are much crowded together, and to the defective state of the sanitary arrangements in that quarter may be mainly attributed the great ravages committed by cholera, which first broke out in this country at the port of Sunderland in 1832. In 1849 the cholera again visited the town, but since that time many local improvements have been projected and completed. In 1855, a commencement was made with a system of thorough draining of the entire borough, and in March 1860 the works were finished, 52 miles of sewers having been formed at a cost of L.51,000. From September 1854 to April 1860, 75 new streets were laid out; and during the same period 1280 houses were erected. To afford the means of healthful recreation for the inhabitants, 14 acres of land on Building Hill—a picturesque eminence within the borough—were purchased for L.2000, and L.3250 (including a grant of L.750 from Government) were expended in laying out and beautifying the place for a public park and pleasure-ground. Under the new burial acts, 3 cemeteries have been formed outside the borough boundaries, the extent of ground thus enclosed being 54 acres, and the total cost L.37,000. Three public bathing and washing establishments have been set on foot, under the provisions of the Baths and Washhouses Act 1846, the cost of the whole being L.12,750. A water company has also been formed, and, at an outlay of nearly L.160,000, works have been erected which supply daily to Sunderland and South Shields fully one million and a half gallons of water, pumped from the sand underlying magnesian limestone. One of the greatest objects of interest in Sunderland is the well-known iron bridge which crosses the Wear, and connects Monkwearmouth with the south bank of the river. It consists of a single arch of 236 feet in span, having a height of upwards of 100 feet from the surface of the river at low water to the centre of the arch, which enables vessels of 400 tons burden to pass under by merely lowering their topgallant masts. This remarkable structure was finished in the year 1796, having cost L.33,400, of which L.30,000 was subscribed by one of its designers, Rowland Burdon, Esq., then member of Parliament for the county of Durham. In 1856 it was found necessary to strengthen and widen the bridge, as well as to improve its approaches; and the town council having obtained the necessary parliamentary powers, the renovation of the fabric was commenced in the following year, according to plans furnished by Robert Stephenson, Esq., civil engineer. The improved bridge was opened in 1859, the total cost of the alterations having been L.40,000, the repayment of which is provided for by tolls, from which foot-passengers, by a resolution of the town council, are exempted. The leading feature of Mr Stephenson's design was the throwing across of three great tubular girders, one on each side of the east and west ribs, and another in the centre. The cast-iron rings of the original bridge were replaced in the new one, with malleable iron lattice-work. The harbour at the mouth of the river is enclosed by two piers, the north pier, extending 1000 feet, and the south pier 1800 feet. On the north pier there is a lighthouse, which, in 1841, on the lengthening of the pier, was removed a distance of nearly 500 feet without taking down the masonry. The depth of water on the bar varying from 18 to 21 feet at ordinary tides, vessels of a large size can enter and leave the harbour. Docks have also been formed on the north and south sides of the river. Wearmouth Dock, on the north, can accommodate 80 sail of vessels. It was constructed at a cost of L.120,000, and is now the property of the North Eastern Railway Company. Sunderland Docks, on the south side of the harbour, were constructed at a cost of L.720,000. They can accommodate 350 sail of vessels, and have an outlet to the sea independent of the river. This outlet is of great service to large ships, the depth of water at its mouth being greater than that on the bar at the harbour's mouth. Sunderland docks were opened in 1850; in 1859 they passed from the hands of the company that was formed for their construction to the Commissioners of the River Wear, who that

year obtained an act of Parliament authorizing them to purchase the docks. Ship-building, the export of coals and lime, glass-making, the manufacture of anchors and chains, of ropes and sails, and earthenware goods, are the principal industrial features of Sunderland. On the 1st of January 1860, the number of vessels belonging to the port was 1004, representing an aggregate of 232,261 tons. In 1836, the number of vessels that sailed from the port was 994, with an aggregate of 153,415 tons. In 1859, the number of vessels that left the port had increased to 10,736, and the tonnage to 1,712,928. In 1836, the total exports of coal amounted to 971,190 tons; in 1859, the coal exports had reached 2,633,232 tons. Several hundred sailing vessels belonging to the port are solely employed in the coal trade, but this branch of the shipping interest is threatened with gradual extinction, the screw-steamers belonging to the port carrying in the aggregate half a million tons of coals to the London market in the course of twelve months. The custom-house duty paid at Sunderland in 1859 was L.99,115; the expenses of the establishment were L.7721. The port is defended by three batteries, near to the most important of which is the barracks, with quarters for 300 men. Ship-building is carried on to a great extent on the Wear. In 1859, a year of great depression in that branch of trade, 100 vessels were launched at Sunderland, with a total tonnage of 37,184, and an average per vessel of 371 tons. The total value of the vessels built during a year of average briskness in business, when fitted out for sea and ready to receive their cargoes, is three quarters of a million sterling. The glass trade is also of considerable importance. Of window-glass, 6240 tons are manufactured on an average in the year; and 23 millions of bottles are produced in the same period. There are seven firms carrying on both these departments of glass manufacture, and the total annual value of the window-glass and bottles produced by the 1700 hands whom they employ is nearly a quarter of a million sterling. There are a number of charitable institutions in the town, one of which, the Orphan Asylum, opened in 1860, is patronised by her Majesty Queen Victoria, who contributed 100 guineas to its funds. This asylum was founded for the children of deceased mariners of the port, and is principally maintained from the proceeds of the sale of land on the Town Moor for dock and railway purposes. There are several literary institutions in Sunderland; and a museum, with the nucleus of a free library attached, has been established by the town council. There are 2 handsome theatres, with accommodation for 3500 persons. The town is connected by railway with Newcastle-on-Tyne, which is 13 miles north-west of Sunderland; altogether, there are 4 railway termini in the borough. The municipal government is vested in a mayor, 14 aldermen, and 42 councillors, elected by 7 wards. The borough returns 2 members to Parliament. In 1841 the population was 56,607; in 1851 it was 63,897.

SUNIUM, a promontory and demus of ancient Attica, forming the southern extremity of that country. The promontory, which rises steeply from the sea to a great height, was crowned with a temple to Athens, the tutelary deity of Athens. This temple is now in ruins, but many of its columns are still standing, and have given to the promontory its modern name of Cape Colonna. Sunium was fortified in the nineteenth year of the Peloponnesian war, in order to protect the corn-ships in their passage to Athens with supplies, and from that time onwards it was considered one of the chief fortresses of Attica.

SUPERIOR, LAKE. See CANADA.

SUPERLATIVE, in *Grammar*, one of the degrees of comparison, being that inflection of adjectives that serves to augment and heighten their signification. It shows the quality of the thing denoted to be in the highest degree.

SUPPER. See THEOLOGY.

SURAT, a town of British India, capital of a collectorate of the same name, in the presidency of Bombay, on the left bank of the Taptee, 150 miles N. of Bombay, and 130 S. of Ahmedabad. Its form is semicircular, and its circuit is about six miles. It is defended by a small castle on the shore of the river, and by a wall with bastions and battlements. The town is not very prepossessing in its appearance, having narrow, crooked streets, lined with lofty houses, which have frames of timber filled in with brick. Besides the castle, the chief buildings in the town are the Protestant Church, Mosque, Mahometan College, and two Parsee fire-temples. The English cemetery contains many tombs of former governors of Surat, and others; there are also a Dutch cemetery of considerable interest, and a *dukhma*, or Parsee burial-place. The palace of the Nawab of Surat is a plain, unattractive building, remarkable for nothing but for a fine collection of Arabic and Persian MSS. which it contains. Surat has also some ruins of the abodes of the ancient nobility. Outside the walls is the site of the old French factory, now quite deserted; as also is the Dutch factory, which was once the best building about the town. The prosperity which Surat enjoyed in the latter part of last century,—when its bazaars were stored with all sorts of merchandise, and crowded with men of all nations; when its river was filled with shipping, and its streets with the bustle of life,—has quite passed away. Bombay has far outstripped its rival, and withdrawn from it all its foreign commerce; so that its only trade now consists in the exportation of cotton and grain to the less fertile regions of Concass. But, as it is the station of a large number of the British forces, and also of many of the civil officials, it is still a place of some importance, and contains a large proportion of British residents. The inundations of the Taptee have on several occasions been so great as to inflict much damage on the town, but since the last of these, in 1837, some steps have been taken to defend the town against them, and by the construction of a canal in connection with the river, the risk of their recurrence has been lessened. The first mention of Surat in history occurs in 1530, when it was taken and sacked by the Portuguese, but, as it was then a place of considerable size, it must have been in existence for some time previously. In 1612, permission was given to the English to establish a factory here, and the whole possessions of the East India Company were placed under the governor and council of Surat from 1567 to 1692, when the seat of government was transferred to Bombay, on account of its growing importance. In 1664, Surat was plundered by the Mahrattas under Sevajee, but the English factory was successfully defended against their attacks. During the first half of the eighteenth century, Surat was in a state of great confusion between various conflicting powers. At length, in 1759, the Bombay government, in order to put an end to the disorder, took possession of the castle, and in conjunction with the native Nawab exercised the government for forty years. On the death of the latter, in 1799, the British, at the request of the inhabitants, assumed the entire government, which they have since exercised. Pop. (1847) 95,000. The district of Surat has an area of 1629 square miles, and a population of 492,684.

SURGERY.

THE term *Surgery*, or *Chirurgery*, from χειρ, *the hand*, and εργον, *work*, originally signified, as its derivation implies, the manual procedure, by means of instruments or not, directed towards the repair of injury and the cure of disease; in contradistinction to the practice of *medicine*, denoting the treatment of disease by the administration of drugs, or other substances supposed to be of a sanative tendency. Such a meagre description applied but too justly to surgery in its infancy, and still more after its separation from its twin-sister medicine, in the twelfth century. When its practice was denounced by the Council of Tours as derogatory to the dignity of the sacred office of the priesthood, and beneath the attention of all men of learning, the term chirurgery, in its most literal interpretation, was quite sufficient to comprehend the duties of the degraded and uninformed surgeon, who had become a mere mechanic, attached to and completely dependent on the learned and philosophic physician. But the matured progress of the healing art has, fortunately for science and humanity, rendered such a definition of surgery in these days utterly untenable. Its complete separation from medicine would now be attended with the utmost difficulty; nor is it desirable that the attempt should be made, because its success, however partial and imperfect, would be most hurtful to both. They are now, and it is to be hoped will ever remain, one and inseparable. Their principles are the same throughout, and the exercise of their different branches requires the same fundamental knowledge; but their details are so numerous and intricate as to render it most difficult, if not impossible, for any one individual to cultivate all with equal success. The consequence has been, that while the theory and principles of physic and surgery remain united, as constituting one and the same science, the practical parts are now frequently separated into distinct professions, each person adopting that department most congenial to his pursuits, and for the management of which he conceives himself best qualified. The separation however is not that of acquirements, but merely of practice. It should never be forgotten, that the physician, before he can be either accomplished or successful in his profession, must be intimate with the principles, if not with the practice of surgery. And most certainly no one can ever lay just claim even to the title of surgeon, far less hope for eminence or success, unless he be equally qualified to assume both the appellation and the employment of the physician.

Many and laboured have been the attempts to define surgery according to its present state, so as to prevent interference with the department of physic. This example we will not follow. The arrangement as to what is medical, and what surgical, must in a great measure depend on custom, not on fixed and permanent rules. The paths of the practical surgeon and physician are distinct, but in their course they must often cross each other; and these collisions, so far from being avoided, ought rather to be sought, as probable sources of mutual benefit, so long as those enlightened feelings are entertained, and that honourable conduct pursued, which ought ever to distinguish the followers of a liberal, useful, and learned profession.

The limits allotted to this article not permitting us to enter into the details of surgery, we must content ourselves with a sketch of its history, and with some account of its improved condition as it is at present practised.

Origin. That surgery is as old as man himself, that it was coeval with his fallen state, there can be little doubt. The fall entailed the frequent reception of injuries by external violence; and to assuage their pain and remove their inconvenience, the ingenuity and contrivance of the sufferer were powerfully excited. Thus it would seem, that as to antiquity of origin, surgery must take precedence of medicine. And after wars and dissensions began to prevail, and wounds and injuries became both more frequent and more deadly, it is most probable that to these the practitioners of the healing art alone directed their attention, before the nature of disease began to be understood, or its cure was supposed to be within the reach of human means.

Early Egyptians. As to the state of surgery among the early Egyptians, we know but little, except that it was customary, in the time of Joseph, to embalm the dead; a process which appertains closely to both medicine and surgery. There are some grounds, however, for suspecting that they were more conversant with surgery than is generally supposed; for it is said that on "the ruined walls of the renowned temples of ancient Thebes, basso-relievos have been found, displaying surgical operations, and instruments not far different from some in use in modern times." Their medical practice, entirely founded on incantation and astrology, was sufficiently simple. They divided the body into thirty-six parts, believing in an equal number of demons, to whom those parts were intrusted, and to invoke whose aid in sickness was the principal duty of the physician, each spirit being called upon to cure his own peculiar portion.

Jews. Among the Jews, the operation of circumcision was performed, no doubt skilfully and dexterously, though with rude implements, by the priesthood, an order which, for many ages, and in many climes, conjoined the cure of the body with that of the soul.

Greeks. The earliest notice of this art is from the ancient Greeks, who, it is probable, had derived their medical traditions from the Egyptians. They considered medicine to be of divine origin; and its first professors, as they inform us, were no less personages than gods and sons of gods.

Medicine and surgery, at their origin, were conjoined; and both continued to be practised indiscriminately, until separated by the Arabian school. Their complete estrangement occurred, as we have already stated, about the middle of the twelfth century. At first, surgery chiefly occupied the attention of the ancient leech, as the more certain and more obviously useful branch of his profession; but ultimately it became very secondary to medicine when dignified by philosophy and priestcraft.

Chiron. Chiron the Centaur, born in Thessaly, is presumed to have been the father of surgery, celebrated for skilfully applying soothing herbs to wounds and bruises. But his fame is somewhat endangered by that of Æsculapius, the son of Apollo, by some held to be the pupil of Chiron, by others, his predecessor and superior. **Æsculapius.** Æsculapius is supposed to have been deified, on account of his skill, about fifty years before the Trojan war. His very existence however has been questioned. Apollo was the original god of physic among the early Greeks; but he appears to have resigned in favour of Æsculapius, whose temples became the depositories of medical and surgical knowledge; more particularly those of Epidaurus, Cnidos, Cos, and Pergamus.

Podalirius and Machaon, B. C. 1192. Certain it is, according to the testimony of Celsus, that Æsculapius is the most ancient authority in surgery. His immediate descendants, two sons, Podalirius and Machaon, have been immortalized by Homer. They followed Agamemnon to the Trojan war, and there their services were so highly valued as to secure them a not unconspicuous niche among the heroes of the Iliad. Of the two, Machaon seems to have been the more distinguished. When he is wounded by Paris, the whole army is represented as interested in

his recovery. Even the stern Achilles inquires anxiously after "the wounded offspring of the healing god;" and the valiant Nestor, to whose care he is intrusted, is exhorted to unwonted exertion in his behalf; "for a leech who, like him, knows how to cut out darts, and relieve the smarting of wounds by soothing unguents, is to armies more in value than many other heroes." Podalirius enjoys the distinction of being reputed the first of phlebotomists, and probably the most successful, from his time to this; having opened a vein in either arm of the king of Caria's daughter, who had been severely injured by a fall from the house-top, having, after her recovery, been rewarded with the hand of the fair princess, and having been presented by her munificent father with the Chersonese as her dowry. As to medicine, they seem to have been either ignorant, or in no great repute; for, on the breaking out of pestilence in the Grecian camp, Homer neglects them entirely, and applies at once to Apollo. And even their surgical attainments, for which they are celebrated by him, seem to have extended no farther than to the simple extraction of darts and other offensive weapons, the checking of hæmorrhage by styptics or pressure, and the application of lenitive salves. The poet takes notice of his warriors sustaining fracture of the bones; but in such emergencies he adopts the same course as in the pestilence, and invokes the aid of the nonprofessional deities; from which circumstance we may infer, that in those days surgery had made but little advancement.

Asclepiades.

For upwards of 600 years after the Trojan war, there are scarcely any accounts of medicine and surgery. They seem to have remained strangely stationary during the whole of that period. Their practice was confined to the Asclepiades, or reputed descendants of Æsculapius; whose lore was orally communicated from father to son in that family, until they received an extraordinary impulse from the great Hippocrates, himself a branch of the family, and said to have been the fifteenth in lineal descent from the deified founder. The Asclepiades, in the course of their monopoly, established three schools of medicine, at Rhodes, at Cnidos, and at Cos. The last gave Hippocrates to the world, and thus attained a proud and enduring pre-eminence.

Pythagoras, B. C. 600.

Pythagoras was the first who brought philosophy to bear upon the practice of the healing art, and led the way in raising it to the dignity of a science. Democritus, the happy sage, likewise turned his attention to medicine as a branch of general philosophy, and pursued it zealously. He lived in terms of friendship with Hippocrates, by whom he was held in great respect. By Pythagoras a school at Crotona was founded, about the time of Tarquinius Superbus, espousing doctrines somewhat different from those of Cos and Cnidos. It produced Damocedes, a contemporary of Pythagoras, who seems to have practised in Athens, an honoured and successful surgeon. By Polycrates, king of Samos, he was presented with two talents of gold for having cured him of a troublesome distemper. He was afterwards taken captive by the Persians. Their king, Darius, was intrusted to his care for a dislocated ancle, as well as the queen, Atossa, for a cancer of the breast; and he was soon loaded with honour and wealth on account of his wonderful cures, performed after the Egyptian physicians, previously in attendance, had signally failed.

Damocedes.

But we cannot suppose such men as Damocedes and the Asclepiades to have attained any great proficiency in surgery; for the touch of a dead body was interdicted as a profanation both by Jew and Greek, and consequently they must have been almost entirely ignorant of anatomy. They may have understood something of the skeleton, from their practice amongst fractures and dislocations; and they may have formed some general idea of the viscera, from researches in comparative anatomy, and from instruction by the Egyptians, whose practice in embalming afforded ampler scope for observation. But the minute structure of the human body must have been to them a profound mystery. And, knowing that anatomy is, was, and ever must be, the foundation of true surgical knowledge, we cannot evade the conviction that surgery, though occasionally successful and honoured in ancient times, must have been nothing more than a rude, imperfect, and uncertain art. The practice of its professors seems to have been extremely limited, consisting of little more than the binding up of wounds, and the staunching of hæmorrhage by styptics and the cautery; the extraction of darts and other missiles from the wounds which they had inflicted; phlebotomy, both general and local; and cupping by scarification. Whether they practised the capital operations or not, we are not informed; but it is probable that their comparative ignorance of anatomy effectually deterred them from any extensive division of the soft parts, as extremely hazardous and uncertain.

Hippocrates, B. C. 400.

Hippocrates, born in the 80th Olympiad, upwards of 400 years before the Christian era, did more for medicine and surgery than all who had preceded him; and indeed few of those who have succeeded him have been of equal service to the profession. He soon freed medicine in a great measure from the absurdities with which ignorance and superstition had invested it; and through a long, honoured, and glorious life he set a splendid example of persevering industry, philosophical research, and high moral worth. His fame soon raised the Coan school far above its rivals. Though his anatomical knowledge seems little better than a blending of ingenuity with error, yet he appears to have had some indistinct notions of the circulation of the blood; but Dr Pitcairne, in his "Solutio Problematis de Inventoribus," has sufficiently evinced that he was very far from anticipating the great discovery of Harvey. With all his deficiencies, and notwithstanding all the disadvantages under which he laboured, so correct was his observation, and so faithful his chronicling of disease, that many of his descriptions may be fairly inserted in our modern nosologies. Though his attention was chiefly directed towards the improvement and promotion of physic, now begirt with philosophy, and studied as a science, and though his practice was principally confined to the treatment of internal disease, yet he was not wholly inattentive to surgery. And his practice seems to have been tolerably bold and decisive; for, in regard to external disease, it was with him a maxim, that "when medicine failed, recourse should be had to the knife, and when the knife was unsuccessful, to fire;" a substance of which all the ancient doctors seem to have been particularly fond, from Prometheus downwards. Hippocrates employed it not only in a variety of diseases, but in various forms. Sometimes he applied red-hot irons to the part; sometimes he raised a conflagration on it, and of it, by a piece of wood dipped in boiling oil, or by burning a roll of flax after the manner of the modern moxa. He also made use of tents and issues, as more gentle means of counter-irritation. He seems to have performed the capital operations with boldness and success, excepting lithotomy, the practice of which appears to have been confined to a few who made it their exclusive study. He however recommends the removal of calculus, large and firmly lodged in the kidney, by incision; adding, probably in apology for the daring of the procedure, that otherwise there are no hopes of a cure, and that the disease must prove fatal. He reduced dislocations, and set fractures, but clumsily and cruelly; extracted the fœtus with forceps when necessary; and both used and abused the trepan, employing it not only in depression and other accidents of the cranium, but also in cases of headach, and other affections to which the operation was inapplicable. In cases of empyema and hydrothorax, after ascertaining by percussion that fluid was present in the cavity of the chest, he did not hesitate to make an incision between the ribs; and having allowed part of the fluid to escape, he placed a tent in the wound, and by withdrawing it regularly once a day, the whole was ulti-

Surgery. mately evacuated. He seems to have been perfectly acquainted with tetanus and spontaneous gangrene; observing, that even minute wounds of tendinous parts, as the fingers and toes, sometimes produce convulsions which terminate fatally; and that black spots on the feet frequently increase to extensive gangrene and incurable mortifications. Some of his practices have been long and justly exploded, some have been successfully continued, and others have, after disuse, been revived as modern inventions. For example, his method of ascertaining the presence or absence of fluid in the chest was by percussion, and applying the ear to the part, thus anticipating the use of the modern stethoscope. One of his modes of counter-irritation, we have seen, was by burning flax on the part, as in the modern moxa; and he strongly recommends the production of eschars on the back and breast in the earlier stages of pulmonary disease, thus anticipating the supposed valuable discoveries of a celebrated modern charlatan. His writings are elegant, and well repay a careful perusal. By them he made posterity his debtor; his contemporaries were not insensible to his merits, and endeavoured to reward them during his life. The inhabitants of Argos voted him a statue of gold; he was more than once crowned by the Athenians, and, though a stranger, was initiated into the most sacred mysteries of their religion, the highest distinction which they could confer; after his death, universal and almost divine honours were paid to his memory; temples were erected to him, and his altars covered with offerings.

We have already seen that surgery had long been stationary before the time of Hippocrates; and it made but little advancement during many succeeding generations. The Asclepiades had confined the knowledge of medicine among themselves; Hippocrates, however, gave oral instructions in anatomy and the art of healing, and thus disclosed its mysteries to the world. But few of his disciples seem to have profited much by his liberality. One of them, his kinsman Ctesias, we are told, acquired considerable renown for his skill; and having been taken prisoner by Artaxerxes Mnemon, in a battle fought against his brother Cyrus, was successful in curing him of a severe wound, and thus obtained favour with his captor. Plato began to flourish about this time; but though he was connected with medicine, we cannot lay claim to him as eminent in surgery; and he was more famous for his philosophy than his physic. Perhaps the most distinguished in surgery, among the more immediate successors of Hippocrates, was Diocles Carystus. He devoted more attention to anatomy than any of his predecessors, was curious in bandaging wounds of the head, and invented the bellulon, an instrument for extracting darts. Carrying his surgery into the practice of medicine, he was not very happy in the result; from observing that external wounds, abscesses, and inflammations were attended with fever, he supposed that general fever was uniformly occasioned by one or more of these causes operating internally. He followed Hippocrates in practice, and, like him, cultivated his profession, "not for lucre or vain-glory, but from real love of the medical art, and a pure spirit of humanity." Praxagoras of Cos was the last of the Asclepiades who succeeded in leaving a name behind him. As a surgeon he is reported to have been bold in the extreme, incising the fauces freely, and excising portions of the soft palate, in bad cases of cynanche; and making incisions into the bowels to remove obstructions, when milder measures failed. Aristotle, the celebrated preceptor of Alexander the Great, although not strictly in the medical profession, was the promulgator of doctrines which for a long time had a powerful effect on medicine. While he followed out the general principles of the healing art, and was curious in anatomical research, he seems to have disdained to meddle with the practical details, and among the rest those of surgery.

Praxagoras.

Aristotle.

On the dismemberment of the vast empire of Macedonia after the death of Alexander the Great, learning took up its chief abode at Alexandria, under the protection of Ptolemy Soter. And here it was that popular prejudice first gave way, and permitted the examination of dead bodies, the greatest possible boon to the medical profession, inasmuch as it removed what had hitherto been the most serious obstacle to its advancement, ignorance of human anatomy. Herophilus and Erasistratus, the two great heads of the Egyptian medical school, were the first who had an opportunity of practising human dissection, the bodies of criminals having been given to them for that purpose; and they consequently not only corrected many errors, but made numerous and important discoveries, in anatomy; thus imparting a fresh stimulus, and affording a new and more solid basis to both medicine and surgery. By some they have been accused of carrying their enthusiasm in this inquiry to such an extent as to "open the bodies of living criminals for the furtherance of their physiological views;" but this is probably a mere exaggeration, originating in the horror with which human dissection was at first regarded; a horror which unfortunately is not even in our day altogether extinguished, notwithstanding the recent legislative enactments in favour of anatomical research. But we find even these privileged men falling into most palpable mistakes; for example, Herophilus plainly confounds the tendons and ligaments with the nerves. Yet the fact that the names which he gave to many parts still remain in use, will of itself remind posterity how much they are indebted to him for his anatomical labours. He was likewise one of the greatest surgeons of ancient times, and, as well as Erasistratus, acquired as much fame for brilliant cures as for anatomical knowledge. The surgical practice of the latter was characterized by peculiar boldness and decision, and strongly marked with the failing of his time and school, a love of multiplying and inventing murderous implements, and the relentless use of them. "In schirrosities and tumours of the liver, he did not scruple to make an ample division of the integuments, and try applications to that viscus itself. He followed the same practice in diseases of the spleen, which he regarded as of little consequence in the animal economy." And perhaps he was right in his supposition, though not in his practice. In cases of retention of urine, he made use of the particular catheter which long bore his name. Xenophon of Cos, said to have been a follower of Erasistratus, seems to have been among the first who arrested hæmorrhage from a member, by encircling it tightly with a ligature. Mantius, a pupil of Herophilus, wrote a treatise on surgical dressings, which he rendered complicated in the extreme. Another, Andreas of Carystus, wrote on the union of fractured bones, and invented several ponderous machines for reducing luxations of the femur. Indeed the surgeons of the Alexandrian school were all distinguished by the nicety and complexity of their dressings and bandagings, of which they invented a great variety. Among them, as in the time of Hippocrates, lithotomy was practised by particular individuals, who devoted themselves exclusively to that operation; and we are told that one of them, Ammonius, employed an instrument, by means of which he broke down stones in the bladder, plainly anticipating Civiale, and furnishing a marked example to the present age of the truth of Solomon's apophthegm, that "there is nothing new under the sun."[1] It is not improbable that some of their other practices might have afforded equally

[1] A curious illustration of this is given by Dr James Johnson, in the narrative of his visit to Pompeii. "The Dilator or Speculum, for which Mr Weiss of the Strand obtained so much repute a few years ago, has its exact prototype in the Bourbon Museum at Naples. The coincidence in such an ingenious contrivance would be absolutely miraculous; but unfortunately there is a key to the similitude, which de-

striking examples of this sometimes unpalatable truth; but unfortunately the greater part of the writings of the Alexandrian school perished in the conflagration of the famous national library in the time of Julius Cæsar; a calamity fraught with immense loss to the healing art, as well as to almost every other branch of knowledge.

Rome.

The arts and sciences followed the seat of empire in its transfer to Europe under Julius Cæsar, and Rome became the grand centre of intellectual illumination. Notwithstanding the shrewd sense displayed by the ancient Romans in most matters, it is strange, yet true, that for centuries all ranks of society, from the mere plebeian rabble to the censor, had entertained an abhorrence of all practitioners of medicine and surgery, and trusted for cures to spells and incantations. Indeed public edicts were issued, "discouraging all countenance to the professed exercise of physic, and recommending faith in traditionary prescriptions and religious rites." Cato the censor managed the sick of his own family according to the terms of this edict, and gravely wrote down the words of incantation for curing dislocation or fracture. For nearly the first 600 years of its existence, Rome, accordingly, had no regular practitioner of medicine. The first we read of was Archagathus, a Greek, from the Alexandrian school, who practised in Rome, chiefly as a surgeon, during the consulates of Lucius Æmilius and Marcus Livius. At first his surgical skill obtained for him no inconsiderable fame, but the ancient prejudice soon revived in full vigour. An enraged populace —perhaps not without some reason, for he seems to have been particularly fond of the knife and cautery—compelled him not only to suspend his practice, but, changing his original title of "healer of wounds" to that of "executioner," caused him to be banished from the Roman capital. Afterwards, however, a native of Bithynia, assuming the name of Asclepiades, established himself in tolerable repute by virtue of insinuating manners, shrewd common sense, and the performance of several fortunate cures "tuto, cito, et jucunde." But with him we have little concern, for his sagacity soon taught him that it was essential to his welfare to avoid the unpopular practice of surgical operations, and accordingly he confined himself entirely to the apparently less hurtful administration of medicine. The only important traces of his surgical practice are, that in ascites he practised and recommended discharge of the accumulated fluid by minute punctures of the abdominal parietes; and that for quinsy, which term probably comprehended many of the various acute diseases of the throat now known and distinguished, he not only employed bold blood-letting, local and general, by the lancet and by cupping, but also had recourse to scarification of the fauces, and even attempted laryngotomy. By novel and successful cures in his medical practice, and frequent indulgence in skilful quackery, he obtained great personal reputation, and so far overcame popular prejudice as to establish a tolerably fair field in Rome for future practitioners. He was the contemporary of Cæsar, and the personal friend of Cicero. The latter is eloquent in his praise, and through him seems to have formed a high estimate of the medical character. "Nothing," says he, "brings men nearer to the gods, than by giving health to their fellow-creatures." It would thus seem that, in his time at least, the ancient grudge against the doctors had abated in Rome. Among the disciples and immediate followers of Asclepiades was Cassius, described as Iatro-Sophista, who left behind him several works on anatomical and surgical subjects. In one of the latter he distinctly accounts for wounds on one side of the head producing paralysis on the other, from the decussation of the nerves; a tolerable proof that he was not only a good anatomist for the time, but also an observant practitioner.

Archagathus. Asclepiades, 96 B. C. Cassius.

Celsus.

Rome itself did not produce a single medical practitioner of any reputation before the age of Aulus Cornelius Celsus, although he himself chooses to be complimentary to some of his immediate predecessors, "Tryphon, Euelpistus, and Meges, the most learned of them all." Celsus, the contemporary of Horace, Virgil, and Ovid, likened to Hippocrates for the quantity of his sound practical information, and to Cicero for the elegance of his style, lived in the reigns of Tiberius, Caligula, Claudius, and Nero, in the beginning of the first century of Christianity, upwards of 150 years before Galen.[1] In his celebrated medical work, he places great reliance on Hippocrates and Asclepiades, more particularly the latter, and gives a complete and excellent digest of all the true medical and surgical knowledge of his times, although it is not certain that he himself either practised medicine or operated in surgery. "Of his surgical operations and remarks, many are yet far from being obsolete, and impress us with a high idea of his ingenuity and judgment. His mode of performing lithotomy (on the gripe) has been in recent times warmly defended by Heister, especially as applicable to children. He describes the operation for cataract by depression, and the method of forming an artificial pupil. The whole of his account of injuries of the head is admirable, and evinces wonderful tact and discrimination. His rules for distinguishing fracture, and for the application of the trepan, have been highly eulogized; nor is what he says about contrecoups less accurate. He is the first who has remarked that there may be rupture of a vessel within the cranium without fracture or depression." And he is the first who recommended the application of ligatures to a wounded artery, with the view of arresting its hæmorrhage, after pressure has failed. He improved amputation, an operation then not much in use; and recommended its adoption in cases of gangrene from external causes. He is minute in his details as to the treatment of fracture and dislocation; his description of carbuncle is good, and its treatment similar to that now pursued, namely, free application of the strongest escharotics to the gangrened part. He describes several species of hernia, and gives directions for their reduction. "It would be endless however to particularise. Whoever wishes to know the exact state of surgical knowledge in the world at the time of the Cæsars, may turn to the pages of Celsus, with the hopes of a gratification which will not be disappointed."[2]

Aretæus, born in Cappadocia, practised in Rome, proba-

stroys the charm of astonishment. A crafty Frenchman imitated from memory, and with some awkward deviations, the Pompeian Speculum, and passed it off as his own. Weiss improved upon the Frenchman, and hit upon the exact construction of the original! Many modern discoveries may probably have originated in the same way."

[1] A life of Celsus by Joannes Rhodius is subjoined to the second edition of a work of that learned Dane, entitled "De Acia Dissertatio, ad Cornelii Celsi mentem, qua simul universa Fibulæ ratio explicatur." Hafniæ, 1672, 4to. We must likewise refer our philological readers to "Jo. Baptistæ Morgagni in Aur. Corn. Celsum et Q. Ser. Samonicum Epistolæ, in quibus de utriusque Auctoris variis Editionibus, Libris quoque manuscriptis, et Commentatoribus disseritur." Hagæ-Com. 1724, 4to. The prænomen of Celsus appears to have been Aulus, and not Aurelius, which is a "nomen gentile." See Fabricii Bibliotheca Latina, tom. ii. p. 37. edit. Ernesti.

[2] He relates an interesting anecdote of Hippocrates, illustrative of his abuse of the trepan. "Knowing and skilful as he was, he once mistook a fracture of the skull for a natural suture; and was afterwards so ingenuous as to confess his mistake, and leave it on record." To this he adds, "This was acting like a truly great man: little geniuses, conscious to themselves that they have nothing to spare, cannot bear the least diminution of their prerogative, nor suffer themselves to depart from any opinion which they have embraced, how false and pernicious soever that opinion may be; while the man of real ability is always ready to make a frank acknowledgement of his errors, especially in a profession where it is of importance to posterity to read the truth:" a moral which cannot be too often forced upon the attention of the present generation.

Surgery. Aretæus, A.D. 50–80.

bly about the time of Domitian. He was the first who made use of blisters, using cantharides for that purpose. Dissection in his time was prohibited under the severest penalties: his anatomical knowledge was therefore neither profound nor exact; "nevertheless he had the sound penetration to regard anatomy as the only legitimate basis on which either medical or surgical science could rest." Heliodorus, the celebrated physician of the emperor Trajan, has left some excellent observations on injuries of the head; and Antyllus, almost a contemporary, was a zealous and successful surgeon. He boldly recommends bronchotomy in cases of threatened suffocation induced by disease of the throat; and, in inflammatory affections of emergency, advises arteriotomy in preference to venesection, showing that excessive loss of blood thereby need not be dreaded, it being readily prevented by dividing the artery completely across. He also alludes to the operation for cataract by extraction, which he however recommends very cautiously, and only when the cataract is small. He obtained the radical cure of hydrocele by free incision of the parts. Rufus the Ephesian, who seems also to have lived in the time of Trajan, was a zealous anatomist and surgeon, and has left a treatise on diseases of the kidneys and bladder. About the commencement of the second century, Archigenes the Syrian settled in Rome, and distinguished himself both in medicine and surgery. His writings, which were chiefly confined to the latter subject, are unfortunately lost. Between Celsus and Galen, however, we meet with no great Roman writer on medicine or surgery. These were among the last of the liberal arts that were encouraged by the Romans; and the proud patricians refusing to educate any of their family to such a profession, the medical practitioners of Rome were at first importations from Greece and Alexandria, and afterwards self-educated slaves and freedmen.[1]

Heliodorus. Antyllus. Rufus, A.D. 96–117. Archigenes.

Galen, A.D. 131.

Claudius Galenus was born at Pergamus, in Asia Minor, in the 131st year of the Christian era. After studying at Smyrna and Corinth, he completed his medical education at Alexandria, and ultimately settled in Rome, where he soon obtained a great reputation, both as a successful practitioner, and as a public lecturer on anatomy. Professional jealousy of his talents, however, drove him from Rome, to which he did not return until recalled by Marcus Aurelius. Shortly afterwards he was appointed physician to the young emperor Commodus, with whom, as well as with the public, he rose to great favour. A man of great erudition, brilliant genius, and indomitable industry, he produced works which exerted a most powerful and extensive influence over medical practice. He has the merit of rescuing medical inquiry from the chaos in which he found it, and restoring it to the paths of light and nature. His fame indeed was so great as to prove, in one sense, detrimental to the advancement of the medical profession, inasmuch as his opinions were received as oracular in the schools of all the civilized countries for no less a period than 1300 years, thus seriously retarding further investigation. His works were both numerous and elaborate; but unfortunately he seems to have been debarred from the study of the groundwork of his profession, human anatomy. His dissections appear to have been limited to the simiæ and other mammiferous animals, as most resembling the human structure, though on one occasion "he felicitates himself on the opportunities he had enjoyed of examining two skeletons preserved in Alexandria, and recommends all anxious to obtain a thorough knowledge of osteology to repair to that city." In his early years, he practised surgery at Pergamus with marked success; but in Rome he seems to have confined himself almost entirely to medicine, excepting the occasional performance of phlebotomy: probably the valorous Romans had not yet lost their hatred and dread of the terrible operations of surgery. Like others, however, he was still so much of a general practitioner, as to practise pharmacy as well as medicine, with a little of surgery; and he himself informs us, that he had a drug-shop in the Via Sacra. "He established two general principles as the basis of all surgery—synthesis, or the reunion of parts—diæresis, or their complete division, as by amputation or extirpation. In four cases he detected luxation of the femur backwards, a variety not mentioned by Hippocrates; and records two instances of spontaneous luxation of the same bone. He also treats of more than one species of hernia. But although in his writings we meet with a few bold chirurgical attempts, as in the application of the trepan to the sternum in a case of empyema, yet it must be confessed that by far the greatest part of his surgery seems to have been confined to fomentations, ointments, and plasters, for external affections, together with the art of bandaging, a love for which he necessarily acquired at the Alexandrian schools; and the employment of complicated machinery in fracture and dislocations." His researches were not limited to medical science, but comprehended literature and philosophy.[2]

The early Christians unfortunately appear to have injured medicine and surgery, by attributing to martyrs and their relics the power of healing wounds and curing diseases; "acknowledging the active interference of demons and blessed spirits in the affairs of men, and leaving true philosophy in total abandonment." A Cimmerian gloom was then fast overspreading the world, by which science and art were destined to be long obscured; and shortly after the time of Galen, we accordingly find the medical along with the other sciences encompassed by the dark clouds of ignorance and barbarism. One or two names however occur worthy of notice, but more from having preserved than advanced medical knowledge. Oribasius, a pupil of Zeno, lived in the time of the emperor Julian, whose friendship he enjoyed, and became a celebrated practitioner, as well as of great importance in the state. His works are principally compilations, though judicious and useful. His surgery is marked with timidity, discouraging operations, except in most extreme cases, and is chiefly confined to unguents and embrocations. He abstracted blood locally, by making deep and extensive scarifications, or rather incisions, with the knife; a proceeding somewhat resembling the important modern improvement in the treatment of erysipelas, but adopted under different circumstances, and with other objects in view.

Oribasius, A.D. 350.

During the fifth century the west was repeatedly invaded by the Huns, Goths, Alans, and Lombards. Science greatly suffered in consequence; and no name worthy of remembrance is to be found, until, nearly two centuries after Oribasius, appeared Aëtius, a native of Amida, and a pupil of the

Aëtius, A.D. 500–550.

[1] On this subject, a remarkable controversy took place in England during the earlier part of last century. It was occasioned by Dr Mead's "Oratio Anniversaria Harveiana, in Theatro R. Medicorum Londinensium Collegii habita, ad diem XVIII. Octobris, MDCCXXIII. Adjecta est Dissertatio de Nummis quibusdam a Smyrnæis in Medicorum honorem percussis." Lond. 1724, 4to. This was followed by a publication of Dr Middleton, "De Medicorum apud veteres Romanos degentium Conditione Dissertatio; qua, contra viros celeberrimos Jacobum Sponium et Richardum Meadium, servilem atque ignobilem eam fuisse ostenditur." Cantab. 1726, 4to. To this dissertation Dr Ward of Gresham College published an answer in 1727: Middleton published the first part of a defence in 1728, and Ward having rejoined in the course of the same year, his antagonist prepared a second part, of which Dr Heberden printed a few copies in 1761, eleven years after the author's death.

[2] Here we must refer our classical readers to a most important collection published under the title of "Medicorum Græcorum Opera quæ exstant. Editionem curavit D. Carolus Gottlob Kühn, Professor Physiologiæ et Pathologiæ in Literarum Universitate Lipsiensi Publicus Ordinarius." Lipsiæ, 1821–30, 26 tom. 8vo. Three of the volumes are each divided into two parts. This collection includes the works of Hippocrates, Aretæus, Dioscorides, and Galen. Dioscorides was edited by Sprengel, and the other writers by Kühn.

Alexandrian school. "His surgical writings are copious and valuable. His opinions were guided by experience, and his methods of management and cure are characterised by much caution and discrimination. We find a variety of surgical queries and suggestions which had escaped Celsus and Galen, as well as the description of several diseases which have been omitted by Paulus Ægineta. He recommended and practised scarification of the legs in anasarca, and made free use of both the actual and potential cauteries; he cut out hæmorrhoidal tumours; operated for aneurism; tried to dissolve urinary calculi by the administration of internal remedies; and has given a series of interesting chapters on inflammation of the intestines followed by abscess, on encysted tumours, on the varieties of hernia, on diseases of the testicle and castration, on the pricks of the nerves and tendons, and in fact on almost every important branch of surgical knowledge. If, mixed up with these, we find some things which the matured experience of ages has abolished, it is less to be marvelled at, than that surgery was already enriched with so many valuable facts and observations." He makes no reference to the reduction of fractures and dislocations, whence it has been plausibly inferred, "that in all likelihood quacks were at that time in complete possession of this branch of practice. Better were it for society that it was quite out of their hands now!" He seems to have been the first to open up a field of medical inquiry, which has since been so successfully cultivated,—the nature and composition of urinary calculi. He appears also to have turned much of his attention to diseases of the eye, and is the first who speaks of the dracunculus or Guinea-worm.

Alexander, A. D. 527–565.

Alexander of Trallis, a famous physician in the time of Justinian, about the middle of the sixth century, was an author of more originality than either Oribasius or Aëtius. He wrote on diseases of the eye, and on fractures; but both treatises have been lost, which is the more to be regretted, as, with this exception, he confined himself entirely to internal disease.

Paulus Ægineta, seventh century.

The celebrated Paulus Ægineta, also of the Alexandrian school, lived about the middle of the seventh century, and made both large and valuable contributions to surgery. He frequently performed the operations which he describes, and abandoned the labours of the mere theorist, for the more valuable results of practical observation and experience. "His sixth book has been considered by many, and not without reason, as the best body of surgical knowledge, previous to the revival of letters." He recommended bleeding from the immediate neighbourhood of the part affected, in preference to general blood-letting, because more effectual; and, for the like reason, opened the temporal artery in cases of very severe ophthalmia. He had recourse to copious venesection, with the view of accelerating painful descent of calculus in the ureter. He opened internal abscesses by caustics, and defined the points at which he thought it advisable to perform paracentesis in the different alleged species of ascites. In lithotomy, having first endeavoured to ascertain the situation of the calculus by the rectum, he made his incision, not in the centre of the perineum, as recommended by Celsus, but to one side of the raphe, as is now practised. Of the impropriety of extensive incision of the bladder he seems to have been well aware, directing that the external wound should be much freer than the internal, and that the latter should be in extent merely sufficient to admit of the passage of the stone. While Celsus limited the operation to patients between nine and fourteen years of age, he sanctions its performance after the age of puberty, but admits that the chances of success increase with the youth of the patient. He described more than one variety of aneurism, pointing out those cases in which he thought it advisable to attempt a cure by operation; and extended this to the aneurisms of the head and joints, excepting only those of the groin, arm-pit, and neck, instead of confining it to the tumours of the arm alone, as had been done by Aëtius. All aneurisms, excepting aneurism by anastomosis, which he clearly and accurately distinguished, he conceived to originate in rupture of the coats of the artery. He performed extirpation of the mamma by crucial incision, and practised both laryngotomy and tracheotomy. He is the first who seems to have performed the latter operation as a means of carrying on respiration during occlusion of the larynx, but naturally enough falls into the error of transverse instead of longitudinal incision. He describes different species of hernia, and did not hesitate to operate when the tumour became strangulated. He is also the first who treats of fracture of the patella. He was pre-eminent as an accoucheur, and was the originator of the obstetric operation of embryotomy.[1]

Actuarius.

From the time of Paulus, we find no Greek or Roman surgeon of note, until the appearance of Actuarius, a Greek, who practised with great distinction at Constantinople, probably about the beginning of the twelfth century, but at what exact period it is impossible to ascertain. Among his writings are found several surgical treatises, which however possess no greater merit than as compilations from previous authors.[2]

Arabia. A.D. 640.

Having thus traced surgery from its origin, through the Egyptian, Greek, and Roman dynasties, we come to notice the prolongation of its feeble existence in Arabia.[1] From Alexandria, captured by the Saracens under Amrou in 640, knowledge was gradually communicated to Arabia. Its people became acquainted with medicine through the medium of translations of the Greek authors; and the "seat of learning was transferred, for a time, from beneath the shadow of the cross to the empire of the crescent; from the classic shores of Italy and Greece, to the warlike followers of Mahomet, and the fiery descendants of Ishmael." Many valuable manuscripts, rescued from the savage destruction of the Alexandrian library, were carefully transcribed, or translated into the Syriac or Arabic languages, and dispersed in various directions. The first Arabic translation was made about the year 683, by Maserjawaihus, a native of Syria; but the most eminent in this labour was Honain, called, by way of eminence, "the translator," a Christian, born at Hira in 764. Towards the end of the eighth century, a college was founded at Bagdat by the Caliph Almanzor; and there medicine obtained a permanent footing, under the fostering care of the far-famed Caliph Haroun al Raschid. Public hospitals and laboratories were founded by him for the benefit of students, who are said to have amounted at one time to no fewer than six thousand, consisting chiefly of Christians banished on account of their religion; and the Caliph Almamon surpassed even his predecessors in munificent patronage, extended to every department of art and science, and in unwearied exertions to restore and propagate the various branches of learning. By supplication he prevailed upon the Grecian emperors to send him many works in philosophy; and, employing the best interpreters that he could find, ordered all these books to be translated, and encouraged the industrious study of them by his own personal example. The medical school at Jondisabour, the

[1] Mr Francis Adams, a very erudite surgeon practising in the vicinity of Aberdeen, has published the first volume of "The Medical Works of Paulus Ægineta, the Greek Physician, translated into English: with a copious commentary, containing a comprehensive view of the knowledge possessed by the Greeks, Romans, and Arabians, on all subjects connected with medicine and surgery." Lond. 1834, 8vo.

[2] Le Clerc, Histoire de la Médecine. Geneve, 1696, 8vo. Amst. 1723, 4to. Freind's History of Physick, from the time of Galen to the beginning of the sixteenth century. Lond. 1725–6, 2 vols. 8vo. Le Clerc only continues the history till the age of Galen. The literary history of the Greek physicians may be sought in the *Bibliotheca Græca* of Fabricius.

capital of Chorassan, established by Sapores the First as early as the end of the third century, had by this time risen to great celebrity; and from it Rhazes, Hally Abbas, and Avicenna derived their medical education. Mesue lived during the caliphate of Haroun al Raschid, in the end of the eighth century, and Serapion during that of Almamon, about a century later; both eminent medical men in their time, but both pure physicians. The first Arabian worthy in the surgical department was the celebrated Rhazes, who presided over an hospital at Bagdat in the end of the ninth and beginning of the tenth centuries. His works are not remarkable for anatomical knowledge, which is not surprising, since the study of anatomy was strictly forbidden by the Mahommedan religion, and consequently the Arabians had to rest contented with the writings of the Greeks on that subject. "One of their religious prejudices against dissection was, that the soul did not instantly forsake the body, but lingered in some particular portion of it for some time after apparent dissolution, so that the dismemberment of it might be a species of hideous martyrdom;" a very sufficient reason why a professor of such a belief should strenuously object to the anatomization of himself and his friends. Rhazes is the first who has described spina ventosa and spina bifida. Of the real nature of the latter, however, he does not seem to have had any clear idea. Regarding cancer, he advised that the knife should never be used except when the disease was limited, and the whole tumour could be completely removed; condemning the opposite procedure as cruel and unavailing; an opinion which after-experience has shown to be most just and true. In bites from rabid animals, he first cauterized the wounds, and then prescribed emetics to expel the "black bile;" an evacuation considered most essential to the cure. His account of hernia is better than any to be found in the Greek writers. His works on surgery, however, are little more than compilations from Hippocrates, Oribasius, Aëtius, and Paulus. His confidence in oculism does not seem to have been great; for, having in his old age become blind from cataract, he could not, though urged, be prevailed upon to undergo an operation for its removal. In his time lithotomy, and some other operations, seem to have been entirely in the hands of juggling impostors. Hally Abbas, surnamed the Magician, on account of the extent of his knowledge and acquirements, lived in the end of the tenth century. His great work, the Al-meleky, written about the year 980, is, in its anatomical and physiological department, a mere transcript from the Greeks; and his surgery possesses but few peculiarities. "From the idea that caustics were efficacious when a redundancy of the humours flowed to a particular part, he recommended their application for the cure of hydrocele. In the management of dropsical affections his attention was always directed to the remote causes; and he preferred puncturing in the linea alba, a little below the umbilicus, for the relief of ascites." Avicenna, who divides with Rhazes the honour of having first introduced chemistry into physic, flourished later than the two preceding Arabians. He was termed, in his day, the Prince of Physicians, and seems to have been regarded as almost miraculous for the extent and variety of his knowledge. He was born in 980, and died in 1036, without a rival, either in the medical profession, or in general science. In his great medical work, the Canon, the surgical department is not altogether forgotten, but holds a second place to physic; indeed, before the appearance of Albucasis, surgery seems to have been all but extinct amongst the Arabians. He has distinguished between closure of the pupil and cataract, and in operating for the latter recommends depression; extraction he considers a very dangerous experiment. It is probable that to him we owe the first use of the flexible catheter. His works are said to have remained the oracles of medical knowledge for nearly six hundred years.

Avicenna.

A.D. 980-1036.

Albucasis, who died in 1122, exerted himself more than his predecessors in behalf of surgery, which, by his own account, he found in a most deplorable condition; and he is chiefly distinguished as a surgical writer. Cauteries and caustics seem to have been his favourite remedies; and he becomes enraptured when speaking of the "divine and secret virtues" of fire surgically employed. The actual cautery he looked upon with veneration, and describes more than fifty affections in which his experience had found it beneficial. He is minute in his directions for its application, and forbids its use, "except by persons acquainted with the anatomy of the frame, and the position of the *nerves, tendons, veins, and arteries;*" from which latter circumstance some idea may be formed of the extent to which he himself was in the habit of roasting his unfortunate patients. He checked arterial hæmorrhage by his favourite method of cauterization, but also employed styptics, as well as complete division of the vessel, and ligature. He is supposed to have been the first to remark, that it is by the formation of a coagulum in the orifice of an artery that its calibre is closed and hæmorrhage arrested. He has described a particular instrument of his own for the cure of fistula lachrymalis, and the needle used by the surgeons of Irak for cataract. He speaks of operating for the relief of hydrocephalus, but the success of the practice does not seem to have been greater then than in its revival in our own time; for he confesses that he knew of but one successful case, and therefore does not recommend the operation. He seems to have been conversant with the mode of removing tumours by ligature when the knife is inexpedient; he advises amputation in gangrene of the extremities; and is the first who has described the mode of extracting calculus by incision in the female. His method of lithotomy resembled that practised by Paulus Ægineta; and, like him, he seems to have been bold in puncturing and excising the tonsils, removing the uvula when obstinately relaxed, and extracting polypous tumours from the fauces. He mentions bronchocele as occurring most frequently among women; but, fond of the knife and cautery as he was, he does not seem to have employed either for the removal of that tumour; indeed he tells us of "an ignorant operator who," in attempting extirpation of a bronchocele, "by wounding the arteries of the neck, killed the patient upon the spot." He invented the probang, for dislodging foreign bodies from the gullet; and in wounds of the intestines practised union of the divided parts by suture more than once with success. Though thus bold in his operations, and, like all the Arabians, too fond of the employment of instruments, he was not however without judgment and caution. For example, he condemns tracheotomy as worse than useless when the inflammatory affection of the windpipe is acute, and has extended to the bronchi; an opinion which is acknowledged as true, though unfortunately not always followed in the present day. And he exceeds even Rhazes in his dislike to operative interference with cancerous tumours, declaring that he never either cured, or saw cured, a single instance of that disease; a conclusion too nearly consistent with the history of that most implacable malady in all succeeding ages. His remarks on abscesses are most judicious; directing particular attention to their situation, and recommending their being early opened, whether "matured" or not, when in the neighbourhood of joints or other important parts, which would be injured by their continuance; a rule of practice which, if more faithfully followed, would materially diminish the number of diseased joints and bones. He also advised what has since been so much insisted on by Mr Abernethy, that when the abscess is very large, its contents should be evacuated by degrees. He is the only one among the ancient writers on surgery who has described the instruments used in each particular operation. Avenzoar, a Spanish Arab, practised physic with distinction, about the beginning

Avenzoar.

Surgery.

of the twelfth century, at Seville in Andalusia. He describes inflammation and abscess of the mediastinum, from which he had himself suffered; and mentions a case of abscess of the kidney, from which fourteen pints of matter were evacuated. He speaks of bronchotomy as expedient in dangerous cases of inflammation of the tonsils: and in stricture of the gullet proposes three modes of treatment; the occasional passage of a tin or silver tube; the use of a milk bath, that nutritious particles may be taken up by the pores on the skin; and the injection of nutritious fluids by the rectum. He also details cases of "rupture, fracture of the hip-bone, wounds of the arteries and veins, tumours, and other varieties of surgical disease, which he appears to have understood well, and treated with discretion." He does not complain, like Rhazes, that lithotomy was in the hands of mountebanks, but tells us that the Arabians then reckoned such operations "filthy and abominable, and unfit for any man of character to perform;" and held that "no religious man, according to the law, ought so much as to view the genitals." The brightest name in the history of Arabian philosophy is that of Averrhoes, the pupil of Avenzoar, born at Cordova about the middle of the twelfth century, and said to have died in the year 1206. But he cultivated the study of medicine only as a branch of general philosophy, and surgery he seems to have altogether neglected.

Averrhoes, A.D. 1206.

Such were the Arabians. Of these, Albucasis was the most famous in surgery, as Celsus had been among the Romans, and Paulus Ægineta among the Greeks. But even he could not escape the unfortunate failing of the Saracenic school; endless invention of manifold and complicated instruments, attaching far too much importance to the mechanical part of their profession, and mistaking the inspiration of terror and infliction of cruelty for energetic and judicious surgery. In order, for example, to arrest hæmorrhage from a wounded surface, if time pressed and assistants were scarce, it was not uncommon to dip the part into boiling pitch, a liquid which was then dignified with the appellation of a styptic. They however systematically divided physic, surgery, and pharmacy into three distinct professions; and so, by commencing the division of labour, may be considered as having done something not unimportant towards the ultimate advancement of medical knowledge. "The last traces of their intellectual illumination appeared among the Spanish Moors in the thirteenth century, when the Christian arms having become more and more powerful, they were compelled to substitute the field for the study—the sword for the pen—and, before an overwhelming opposition, were at length driven from a region whose fields they had tilled, and whose olives they had gathered, for a thousand years. With the decline of the Saracenic school, the daylight of science went down over the nations; and an intellectual darkness, which endured for three hundred years, enveloped the general face of society. All the fountains of science were dried up, and the world seemed retrograding into the unillumined chaos of ignorance."[1]

School of Salerno.

A knowledge of the Greek and Arabian systems of medicine was introduced into Italy, at Salerno, in the beginning of the eleventh century; and this school soon rose to celebrity as a seat of medical learning. In the time of the Crusades, Salerno was a place of great resort for warriors of all nations passing between Europe and Palestine; and by these wanderers, on their return, the light of medical science was thence slowly conveyed over Europe. It obtained the privileges of a university; but the medical school of Salerno did not long retain its high reputation. In modern times, it is chiefly remembered on account of the *Regimen Sanitatis Salernitanum*, a singular production, of which more than one hundred and sixty editions are known to have been published. Though written in the name of the *Schola Salernitana*, it has generally been ascribed to Joannes de Milano. The English king to whom it is addressed is supposed to have been Robert of Normandy, whose claims to the English crown were recognised by some of his contemporaries. The poem opens with these lines:

> Anglorum Regi scripsit Schola tota Salerni.
> Si vis incolumem, si vis te reddere sanum,
> Curas tolle graves, irasci crede profanum,
> Parce mero, cœnato parum, non sit tibi vanum
> Surgere post epulas, somnum fuge meridianum,
> Non mictum retine, nec comprime fortiter anum.[2]

In the twelfth century, the Jews practised medicine, not only among their own tribes, but also among the Moors and Christians; and though, like all others of this age, merely treading in the beaten track of the Greeks and Arabians, yet, from their superiority in such learning, they came to be reputed the most skilful practitioners. About the middle of that century, as has already been stated, surgery was completely separated from physic, by the edict of the Council of Tours prohibiting the clergy,[3] who then shared with the Jews the practice of the healing art in Christian Europe, from in any way causing the effusion of blood, at least as a means of curing bodily ailment. Surgery was in consequence abandoned to the uneducated laity, and sunk to a deplorable state of prostration; it became a mere matter of plasters and unguents; and if any thing happened to be written on the subject, it was but a bad compilation from the Arabians.[4] We shall however notice some of the more remarkable events in connection with it during its temporary abasement. In the year 1271, the foundation of the College of Surgeons at Paris was laid by Pitard, a surgeon of eminence in those days, and whose enthusiasm effected something towards raising his humbled profession. About the same time lived Gulielmus de Saliceto, a professor at Verona, said to have been "a powerful man" in both surgery and medicine. He seems to have earnestly dissuaded men from the copying and study of books in preference to practical experience, and he himself set a better example. In our own country Gilbertus Anglicanus is the first name connected with surgery; but he seems to have been little more than a compiler from the Arabians. He lived about the beginning of the fourteenth century; and shortly after him appeared John of Gaddesden, author of the *Rosa Anglica*, and said to have been an erudite and ingenious man, as well as a skilful practi-

Fourteenth century.

[1] Moir's Outlines of the Ancient History of Medicine. Edinb. 1831, 16to. Of this work we have not scrupled to make free use in the course of the preceding observations.

[2] *Regimen Sanitatis Salernitanum*; a Poem on the Preservation of Health, in rhyming Latin verse, addressed by the School of Salerno to Robert of Normandy, son of William the Conqueror, with an ancient translation; and an introduction and notes by Sir Alexander Croke, D.C.L. and F.A.S. Oxford, 1830, 12mo.

[3] The early clergy claimed the practice of medicine as their peculiar privilege, and, using it chiefly as a means of personal power and gain, disgraced it by ignorance, charlatanry, and imposture. It was to check this that the Roman council assembled by Pope Innocent II. in 1139, threatened with the severest penalties those monks and canons who applied to the practice of medicine, "neglecting the sacred objects of their own profession, and holding out the delusive hope of health in exchange for ungodly lucre." But even this, though followed by the more peremptory edict at Tours in 1163, where Alexander III. presided, did not make them altogether forego what they found so convenient and profitable. It was necessary to repeat the edict in 1179 and 1216; but notwithstanding, the monks continued still to practise physic, and it was chiefly by their evil influence that the school of Salerno was brought to decay.

[4] The writers of that age were aptly termed by Severinus, Arabistæ.

tioner. About the middle of the fourteenth century, Guy de Chauliac practised with renown at Avignon, and is "accounted one of the revivers of the languishing art." In his *Chirurgia*, a history of the state of surgery in his day,[1] we find the first mention of the Cæsarean operation. Contemporary with him was John of Ardern, an English surgeon. He wrote with simplicity and honesty, and may be regarded as a reviver of surgery in that country. In his practice he was peculiarly successful in the treatment of fistula in ano, and thereby acquired a great reputation. Valesco de Taranta, a Portuguese, practised at Montpellier, and wrote on surgery in the beginning of the fifteenth century. He was the first who proposed the cure of cancer by the application of arsenic. About the middle of the same century, lithotomy, the practice of which had hitherto been confined to itinerant and ill-informed operators, was restored to the regular profession by Germain Colot, a French surgeon, high in favour with Louis the Eleventh. He first contrived to witness the operation by the itinerants, then practised it on the dead body, and at last performed it successfully on a condemned criminal who happened to be afflicted with stone, and who consented to undergo the operation on condition of being pardoned if he survived. His success, in having thus doubly saved life, obtained for Colot much renown; and lithotomy ever after continued a regular part of surgical practice.[2] The fifteenth century contains other two events important to surgery;

1450. the discovery of the art of printing, about the year 1450, which gave a new impulse to science and literature, by rendering the accumulated stores of knowledge more accessible; and the importation of the venereal disease from America, by the first discoverers of that continent, giving the *small* pox as if in exchange, about the year 1492.[3] In this century also the Turks captured Constantinople, thus overthrowing the last remains of the eastern empire; and by the multitude of Christians who fled from that city many manuscripts of the Greek medical writers were brought to Italy, and their contents thence slowly disseminated over Europe.

Hitherto surgery can scarcely lay claim to an actual revival. Occasional attempts had been made to raise it from its low

Sixteenth century. position, but all proved abortive. At length, however, in the beginning of the sixteenth century, the practitioners of the healing art were happily convinced that the observation of nature was superior to compilation from the ancients, whether Arabian, Roman, or Greek; they consequently ceased to tread blindly and servilely in the footsteps of their predecessors, and a new era arose to the

1539. profession. About the same time Vesalius gave birth to anatomy, properly so called;[4] illuminated by which science, surgery became a worthy object of pursuit to men of talents and education, and under their cultivation it was gradually raised to an enlightened and liberal profession.

A. Paré.

The most conspicuous name in this new era of surgery is that of Ambrose Paré, a Frenchman. In this country surgery was then sadly depressed, having retrograded since the time of John of Ardern. Its list of practitioners comprised barbers, farriers, sow-gelders, cobblers, and tinkers; and it is not matter of surprise that from among these no name has been handed down as worthy of remembrance. The combination of the practice of surgery with the more harmless manipulations of the barber, was not confined however to this island, but existed also in France, and continued in both countries for upwards of 200 years. The great Paré does not reject the appellation of barber-surgeon, as applied to himself; nor does he seem to think that there is any thing derogatory in the title. He was surgeon successively to Henry the Second, Francis the Second, Charles the Ninth, and Henry the Third, of France; and followed the French armies in all their campaigns down to the battle of Moncontour in 1569. His consequent experience of gunshot and other wounds, on the field of battle, naturally directed his attention to the subject of hæmorrhage; and it is to him that we owe the revival and improvement of the method of arresting bleeding from arteries by ligature, and discontinuance of the canteries and styptics, which, to the disgrace of surgery, had hitherto been in exclusive use for this purpose. Yet so averse are mankind to abandon their ancient customs, that the improvement of Paré was not sanctioned till after much abuse and persecution, directed both against himself and his discovery; indeed so bitter and unrelenting were his jealous brethren, that he was compelled for his own safety to adduce garbled and incorrect extracts from Galen and other ancients, in proof that to them, and not to him, the invention was to be referred. So far he was less in error than he himself supposed, for we have already stated that he has merely the merit of reviving the use of the ligature.[5] Celsus distinctly advises its employment when pressure fails to stop arterial hæmorrhage; and Albucasis sometimes condescended to use it instead of his favourite cautery and cruel styptics. Paré, however, was amply repaid by future fame for the opposition which he had at first sustained. He rose to an unparalleled height of popularity with the army, by whom he was absolutely adored. On one occasion, his mere presence among the garrison of a beleagured city about to capitulate, re-animated the troops to such an extent, that their resistance became more energetic than before, and the besieging army perished beneath the walls. By his sovereigns he was also highly esteemed. From the general massacre on the fearful night of St Bartholomew he was rescued by the personal exertions of Charles the Ninth, his great merits being appreciated even by that weak and cruel monarch. But he was not content with the respect and praise of his contemporaries; his writings, the result of great experience and accurate observation, freed from the

[1] Some idea may be formed of the languishing state of surgery at this time, from his division of the surgeons into the following five sects. The first applied cataplasms indiscriminately to every description of ulcer and wound. The second in similar cases employed wine only. The third used emollient ointments and plasters. The fourth, chiefly military surgeons, promiscuously employed oils, wool, potions, and charms. The fifth, "consisting of ignorant practitioners and silly women, had recourse upon all occasions to the saints; praised each other's writings perpetually, and followed each other in one undeviating track, like cranes."

[2] In the beginning of the sixteenth century, cutting upon the staff was introduced by Johannes de Romanis and Marianus Sanctus, and very successfully followed by Laurence Colot, a descendant of Germain.

[3] The first author who clearly describes the venereal disease is Marcellus Cumanus, who wrote in 1495. It was not till 1530 that Fracastorius wrote his celebrated poem *De Morbo Gallico*, in reference to which it has been said that the chaste and classic elegance of its language was worthy of the best days of imperial Rome, and the mellifluence of its versification hardly surpassed by the bard of Mantua himself. By G. Torella, physician to Pope Alexander the Sixth, we are informed that the insane abuse of mercury as a means of cure was not quite a universal practice on the outbreak of the disease; for, in describing some particular forms of mercurial ointment, he himself states that "they destroyed an infinite number of people, who in this case did not die, but were downright killed; and these bold empirics must give an account, if not in this, in the next world, of their practice, and be drowned in the pit of repentance." It is but very lately that the "pit of repentance" ceased to be useful under very similar circumstances.

[4] A little later in the century, Fallopius taught anatomy at Pisa, and Eustachius at Rome, and to their efforts, as well as to those of Vesalius, the advancement of that science is much indebted. Fallopius died in 1563; Eustachius in 1574.

[5] As an example of how little the hint of Celsus was attended to, we may mention, that Procopius relates how Artabazes perished of a wound in the neck, "the artery of the neck having been cut through, so that the blood *could not be stopped.*" Their cauteries and styptics had no effect on the carotid, or its larger trunks.

yoke of authority, and digested by genius of a high order, have rendered him immortal. His works, first published in 1535, and afterwards more fully in 1582, exerted a most powerful and beneficial influence upon his profession. The influence was not however immediate; for at his death the light he had shed was for a time obscured, surgery reverting to the state of degradation in which he found it, in consequence of its baneful association with barberism. Pigrai was his successor, but an unworthy one: endeavouring to follow the footsteps of his master, he obscured and almost effaced them. The most interesting of Paré's surgical treatises is that on gunshot wounds, a class of injuries then of recent introduction, and little understood: the murderous cannon and firelock had not long been in use.

Seventeenth century. C. Magatus. Tagliacotius. Severinus. F. Aquapendente.

In the seventeenth century surgery again revived, resuming the impulse which the genius of Paré had imparted. Italy produced Cæsar Magatus, who simplified, and consequently must have improved, the treatment of wounds; the never-to-be-forgotten Tagliacotius, with his rude repairs of the human face; and Marcus Aurelius Severinus, a skilful and intrepid operator. At the end of the sixteenth and beginning of the seventeenth centuries, Padua was favoured with Fabricius ab Aquapendente, the preceptor of Harvey, a most distinguished physiologist, and the most eminent surgeon of his time. His *Opera Chirurgica* passed through no less than seventeen editions, and contain not only an excellent digest of surgery as it then was, but also many improvements of his own.

Wiseman.

About the middle of the seventeenth century arose the true father of British surgery, our own Wiseman, the Paré of England. One or two English names are to be found before him: William Clowes, a military surgeon of some eminence, attended the Earl of Leicester's army in the Low Countries, and wrote on gunshot wounds; and Lowe, a Scotchman, gave to the world a Discourse on the whole Art of Chirurgery, dated 1612: but Wiseman doubtless is the first Briton worthy of note in surgery. He was serjeant-surgeon to Charles II., and amidst the horrors of the civil wars had ample scope for the study of his profession. His surgical works, consisting of eight treatises, dated 1676, contain much information, at that time most valuable, and still amply rewarding an attentive perusal. In military practice he strongly advocated immediate amputation, "while the patient is free of fever," in the case of such injuries as rendered preservation of the member improbable, of course allowing the primary shock of the accident to be past; a point of practice which long discussion in after years served to confirm. It was not till his time that surgeons ceased to believe that gunshot wounds were necessarily envenomed by the powder and ball, and had to be treated accordingly with potent and cruel dressings.

Harvey. A. D. 1628.

The immortal Harvey, contemporary with Wiseman, cannot perhaps be classed among the eminent surgeons, having principally confined himself to anatomy and physiology, yet he is inseparably connected with that science by his discovery of the circulation of the blood; a discovery which has done so much for the advancement of all medical knowledge, but of surgery in particular.

Young.

James Young, a surgeon in Plymouth, may be said to have been also contemporary with Wiseman, having written in 1679. He is the first who proposed amputation by a flap, an improvement to which two French surgeons, Verduin and Sabaurin, lay claim; and he is also the first who recommends limited compression of the main artery in amputation.

F. Hildanus. Scultetus. Purmann. Heister.

Germany boasts of several eminent surgeons of this time; Fabricius Hildanus, a most successful practitioner, and author of a surgical treatise dated 1641; Scultetus, author of the work, celebrated for its horrid array of lethal weapons, called *Armamentarium Chirurgicum*, 1653; and Purmann, who displayed too great an attachment to the dangerous representations of Scultetus. Heister, a professor in the university of Helmstädt, wrote a system of surgery, which has been translated into most of the European languages, and is still in high repute.

Rau.

Holland likewise possessed successful practitioners of surgery, but tainted with an unworthy concealment of their methods of cure. Rau, a native of Germany, though a professor at Leyden, was perhaps the most successful lithotomist that ever lived, but he kept his method of operating a profound secret, and made it a mystery even to his own pupils; as appears from the circumstance that his two favourites, Heister and Albinus, of a more liberal spirit than their master, in attempting to divulge his secret for the benefit of the profession at large, have varied most materially in their statements. This illiberal spirit pervaded the other branches of medicine as well as the surgical. The famous anatomist Ruysch preserved inviolate the secret of his wonderfully minute injections, although really the discovery of his friend De Graaf; and Roonhuysen the accoucheur worked stealthily with his invented lever. The succeeding generation however removed this stigma from the Dutch; and their great Camper was equally celebrated for the number of his discoveries and the zeal with which he made them known.

Dionis. Eighteenth century. Petit.

From the time of Paré, France produced no surgeons of great eminence until the eighteenth century. In the seventeenth, we find the names of Dionis, Belloste, Saviard, and a few others of some renown, but not at all equal to their contemporaries in other nations. Some idea may be formed of the then feeble condition of surgery in France, from the fact, that Louis XIV. was not cured of a simple fistula in ano, until after his life had been in no small degree endangered by repeated abortive operations. That the French can boast of surgeons of the first class in the next century, however, is indisputably shown by the simple mention of Petit and Desault; names that must ever occupy a proud place in the annals of surgery. The former, adding to the most powerful talents great industry, and an innate love of his pursuits, rose rapidly to eminence, though not without much envious opposition, which seems to be the portion of nearly all those who occupy a pre-eminent place in the profession. On general surgery, he has left a work of much value; and his treatise on diseases of the bones, though produced at an early age, entitles him to be called the father of that branch of pathology. For many years it remained the best work on the subject. He was the inventor of the screw-tourniquet, and the first who operated for fistula lachrymalis by transfixion of the sac. He contributed largely to the Memoirs of the Royal Academy of Surgery; an institution which has done much for the advancement of surgery, not only in France, but throughout the world. Its Memoirs, containing the result of the labours of many eminent men, constitute a work of the greatest value.

Desault.

Desault, also of high reputation, both as an anatomist and as a surgeon, was the first who taught surgical anatomy, and gave clinical lectures on surgery. His improvements on the apparatus for fractures were most important; and a splint invented by him is still in use for fractures high in the femur. His modifications of cutting instruments were also good; among others, changing the amputating instrument to a straight knife, instead of the old curved weapon. He was the first who contemplated the cure of artificial anus, resulting from strangulated hernia; and he further improved Paré's revival of ligature of the arteries. The proposal of curing aneurism by ligature of the vessel on the distal side of the tumour originated with him; a proceeding, however, of which the merit is still dubious. His writings are both valuable and extensive. After the great names of Petit and Desault, not a few French surgeons of the same century, though less eminent, yet deserve mention; Le Dran, a copious and excellent author; Sabatier, famous in the department of operative surgery; &c.

Le Dran, &c.

Surgery.

Garengeot, Louis, La Motte, Frère St Cosme,[1] Portal, Pouteau, Lecat, Chopart, Morand, Moreau, &c.

America.

It is about the middle of the eighteenth century that our attention is first attracted to our transatlantic brethren. In 1763, lectures on anatomy and surgery were delivered in Philadelphia by Dr Shippen; and in 1791 the medical school of that city was completely established, under Benjamin Rush, the Hippocrates of Colombia; a school which has since lent invaluable aid to the progress of both medicine and surgery.

Pott.

Our own country was at this time by no means barren in surgery. Percival Pott and John Hunter are names which occur, the one in the middle, the other in the end, of the eighteenth century, and are fully equivalent to Petit and Desault; indeed Hunter may be justly ranked as the greatest man that ever graced the profession. Pott, the best author, operator, and practical surgeon of his time, greatly improved the practice of surgery in England, both by his writings and by personal example. Like Desault, his attention was particularly directed to the treatment of fractures, of which he had some painful experience in his own person, having sustained a severe compound fracture of the leg. He has left a justly celebrated treatise on the subject. On amputation his observations are most important, clearly discriminating between those cases, of injury more particularly, which demand the operation, and those which do not; at the same time marking the period most advantageous to its performance. Regarding injuries of the head, he wrote with more precision, and at the same time with more originality, than any previous author, and will ever remain a valued authority upon that subject. The same may be said of his description of vertebral disease, he having been the first who clearly distinguished between those curvatures of the spine depending on mere change of form in the bones, and those occasioned by caries or abscess: the latter formidable affection is still known as "Pott's disease" of the vertebræ. He greatly improved the treatment of fistula in ano, and abscesses in general; and by simplifying the whole art of surgery, discarding the cautery and escharotic unguents, or rather limiting them to their proper place and use, employing also the cutting instruments with caution and reserve, and placing more implicit trust in, and showing more respect for, the powers of nature than had hitherto been the custom, he achieved a most important and beneficial reform in surgery. Until his time, the maxim "Dolor medicina doloris" remained unrefuted. The actual cautery, for example, was in such general use, that "at the time when surgeons visited the hospital, it was regularly heated and prepared in the wards, and in the presence of the patients, as a part of the necessary apparatus. Mr Pott lived to see these remains of barbarism set aside, and a more humane and rational plan, of which he was the originator, universally adopted."

Hunter.

John Hunter, a native of Scotland, the pupil, first of Cheselden, and afterwards of Pott, though not remarkably distinguished as an operator, was the most gifted surgeon of which the medical profession can boast, and no less eminent as an anatomist, physiologist, and general philosopher. His researches comprehended a wider range than those of Pott, but arrived at the same end, the improvement of surgery. The knowledge obtained by his vast inquiries into physiology, pathology, and human and comparative anatomy, was, with all the power of his genius, brought to bear upon the practice of the profession, and with the happiest success. The doctrines of adhesion, granulation, ulceration, and inflammation with its various results, were, until detected and explained by him, comparatively obscure and uncertain; and no one is ignorant how much the successful treatment of disease, either by surgery or medicine, must ever depend on an accurate and familiar knowledge of these rudiments. To him we are indebted for the simplification of more than one operation, the discovery of the vitality of the blood, important advice as to the treatment of gunshot wounds, the enforcement of excision of bitten or poisoned parts, many new facts as to the physiology and pathology of teeth, and other valuable additions to practical surgery. But these assume an unimportant place among his deeds, when placed beside the two with which his name is indelibly associated—the cure of popliteal aneurism by ligature of the femoral artery, and the elucidation of the venereal disease; his work on the latter subject still remaining standard, and in many respects unsurpassed. His improvement of the operation for aneurism marks an era in the history of surgery, being one of the most important of its advances. Dissatisfied with the cruel, formidable, and unsatisfactory operation for popliteal aneurism, by incision of the tumour and ligature of the vessel at its diseased part, he made himself aware of the causes of failure by the old system, contemplated the plan of cure which bears his name, satisfied himself of its practicability by diligent study and experiment, successfully brought it to the test of actual practice; and then, extending the principle to all aneurisms, effected for surgery a great triumph over that formidable disease.[2] His first operation was performed in 1785, and was successful; proving that permanent removal of the force of the circulation in the aneurism is sufficient for its cure, by permitting consolidation and ultimate obliteration of the tumour. Since his time the method of applying the ligature has been considerably improved, and the certainty of success consequently increased. But "the more brilliant a discovery, and the more beneficial its results, the more certain is its author of becoming the butt of envy and the object of detraction." And accordingly we find that Hunter has not been permitted to remain in undisturbed possession of his discovery. Its merit has by some been claimed as due to Aëtius: others, with better hopes of success, support the pretensions of Guillemeau (a pupil of Ambrose Paré), Anel,[3] and Desault; but a candid inquiry into facts and dates will ever result in ascribing the honour to our illustrious countryman. Had he even been deprived of this, his name must still have been immortalized by othe and more palpable labour of his mind and hand—his books and museum.

A. D. 1785.

In the same century with Pott and Hunter, Britain also produced White, an excellent practical surgeon and lucid writer; Cheselden and Douglas, two eminent lithotomists, the former peculiarly successful; Sharp, famed for his Critical Inquiry into the State of Surgery; and Monro, a name indissolubly united with the birth and fame of the Edinburgh medical school.[4]

White. Cheselden. Sharp. Monro.

In Italy, where, during the times of Pott and Hunter, several eminent surgeons lived, Lancisi, Morgagni, Bertrandi, Troja, &c.,—the labours of Hunter in aneurism were ably followed up by Scarpa, who still further elucidated the doctrines regarding the new treatment of that disease, and established the success of the operation. He was also eminently successful in his researches as to the anatomy and patho-

Scarpa.

[1] Frère Jean de St Cosme, although a monk, had been educated as a surgeon. He was the inventor of the Lithotome Caché, and with it obtained wonderful success and celebrity as a lithotomist.

[2] "So discouraging were the results of the old operation, that many surgeons preferred performing amputation of the aneurismal limb."

[3] Guillemeau and Anel placed their incisions and ligatures in the immediate neighbourhood of the tumour.

[4] Dr Monro was appointed professor of anatomy to the company of surgeons in 1719, and during the ensuing year he was appointed to a similar chair in the university. Several other professors in the same faculty had previously been nominated; Sir Robert Sibbald, Dr Halket, and Dr Pitcairne, so early as the year 1685. But Dr Monro was the first who regularly delivered public courses of lectures, and he may in a great measure be regarded as the founder of the medical school of Edinburgh.

Surgery. Haller. logy of hernia, a subject which he has made peculiarly his own. The same century saw in Germany, Schmucker, Richter, and the great Haller, whose *Disputationes Chirurgicæ* bear, equally with his other works, the impress of both labour and genius of a high order.

Nineteenth century. Abernethy, &c. The nineteenth century will not yield to any former era in a numerous and bright array of names dear to surgery. It has seen the fall of Abernethy and Dupuytren, Cooper and Roux, Liston and Lisfranc, brilliant stars in the galaxy, and mourns others highly valued; but vast and powerful is the host who are still labouring, with distinguished success, in their noble calling. In all civilized countries, the dark days of the profession have, we trust, for ever passed away; and many are the illustrious names in which it now exults, more particularly in France and Germany. But we hesitate not to assert,—and we cannot think that national prejudice exerts any influence in leading us to the conclusion,—that no country can boast of a better crowd than that by which Britain, in the present century, has been and still is adorned.

Modern surgery. Having followed surgery thus far, from the earliest times, in its most notable points of history, we shall proceed to inquire briefly into the practice of the present day. And,

Operations. first, of the art of operating. It is a favourite phrase by which operations are stigmatized as the "opprobria of surgery." Nothing can be more unjust. So long as injury and disease are permitted to afflict mankind; so long as bones are crushed, and flesh bruised and torn; so long as tumours grow, and gangrenes spread—and we know nothing short of direct divine interposition that can wholly prevent such accidents—it is only by operation, dexterously executed and skilfully timed, that the human frame can be kept in repair, and life prolonged. To be able safely and expeditiously to remove parts which accident has rendered totally useless, and which would prove highly injurious if longer attached to the body; to take away diseased formations, or other noxious substances, and at the expense of but brief suffering, to dispel torture which had rendered existence a burden for previous weeks, months, and years; to accomplish such results, though it be by blood and pain, is alike creditable to the operator and beneficial to the sufferer. It is not a disgrace to the profession that certain injuries and diseases are of so grievous a nature as to be incurable but by operation, for such is the dispensation of Providence; it is the surgeon's boast to have recourse to the knife as seldom as possible; but it is also his pride to be able by it, as a last, and, to both parties, painful resource, to ward off suffering, deformity, and death. It is not, to operate, but to operate unseasonably, unnecessarily, unskilfully, that can ever bring disgrace; and to refrain from performing an operation when it is loudly and plainly called for, would carry not only opprobrium to surgery, but guilt and shame to the surgeon. We are speaking of surgery as it now is, not as it was. In former times operations were its disgrace. Knives, hot irons, screws, files, and saws, were employed with cruel and ignorant recklessness; but of late years, it has been the object of each truly good surgeon to simplify and diminish the number of instruments, and at the same time to use them as seldom as possible. He does not hesitate to employ them when his knowledge and experience tell him they have become indispensable. On the contrary, he will probably be urgent in their application, knowing that an early wound may save much after-suffering; but, in the first place, he will exert all his skill and all his powers, by milder measures to counteract injury and restrain disease, so as to supersede the necessity of operating. To effect this is doubtless the true triumph of his profession; and this triumph he often attains. But he must be Utopian indeed who can seriously hope that the period will ever arrive when operations shall have altogether ceased to be required. In the progress of surgery, many a murderous weapon, at one time in frequent use, has grown thick with rust, and become almost unknown; those retained are few, effective, and never employed without good cause. The growth of science and experience is bringing the ravages of disease more and more under control; operations are not only less frequent, but more simple and less dangerous in the performance; and it is the pride of the modern surgeon to witness and promote this great improvement of his profession. But there are, and ever must be, diseases which we cannot expect to cure, and injuries against which we cannot hope to strive successfully, so as to preserve life, by any measure short of operation. Modern surgery, accordingly, while anxious to limit the necessities for operation, is not the less aware of its importance as a means of cure; and has not only directed attention towards its improvement, but also extended its application, and with the happiest result, to diseases formerly unopposed. Many patients, for example, are now by the knife freed from morbid growths and natural deficiencies, who were formerly left an unprotected prey to deformity and disease.

The necessity for an operation having been clearly established, our object then is to perform it as safely and expeditiously as possible. We now no longer hear, as we did even so lately as fifteen or twenty years ago, of a poor patient being tortured for the space of an hour, by cruelties misnamed lithotomy: in a few minutes the bladder is cleared of extraneous matter; and almost the like number of seconds will suffice for amputation.[1] With this celerity, the safety of the patient is not only equally, but more secure; for rapidity is still held subservient to, though conjoined with, excellence of performance; and the mere absence of protracted pain confers a most important advantage on the reparative powers of the system.

But for the mitigation of pain, the surgeon is not now dependent solely on his quickness of hand. Anæsthesia, by vaporous inhalation, places the patient, temporarily, in a most blissful Lethe; not only abrogating all sense of suffering, but also contributing greatly to the system's power of enduring the operation. (Vide Chloroform.)

A prominent cause of improvement in the art of operating is an increased simplicity of the instruments, their arrangement, and use. On this subject, one who stood *facile princeps* among the operators of his day,[2] observes: Our armamentaria should contain simple and efficient instruments only; the springs, grooves, notches, and curves, seeming to be chiefly intended to compensate for want of tact and manual dexterity. The apparatus, though simple, ought to be in good order, and should always be placed within easy and convenient reach of the operator, so that he may be in a great measure independent of the lookers-on, who, owing to anxiety or curiosity, hurry and agitation, are apt to hand anything but what may at the instant be required. He will consider well what place he himself will most conveniently occupy during the operation; and having obtained proper assistants, he will make sure that they all understand what is expected of them. In short, before he ventures to begin, he will ascertain that everything is arranged, and in proper order; more particularly, that the cutting instruments have good points, that their edges are keen, and that the joints of forceps and scissors move freely and readily. The

---

[1] Nor are there many now, who, alluding to their operative powers, would be likely to express themselves as did the preceptor of the immortal Harvey, first surgeon of his time though he was: "If it be a movable tumour, I cut it away with a red-hot knife, that sears as it cuts; but if it be adherent to the chest, I cut it without bleeding, with a wooden or horn knife, soaked in aquafortis, with which, having cut the skin, I dig out the rest with my fingers!"

[2] Mr Liston.

principle on which the instrument is made to cut should be well considered. Every knife is to be looked upon as a fine saw; the teeth of some are set forwards, and these cut best from point to heel, as does a razor; but the greater number are set in the opposite direction,—for example, the common scalpel and bistoury,—and act efficiently only in being drawn from heel to point. The cutaneous tissues, and in many instances the subjacent parts, should be divided at once and completely, by a single incision made lightly and rapidly; for the pain experienced is in proportion to the pressure and tardiness of movement in the instrument applied. The pain of partial division of the skin, in tails left at each end of an incision, is very great; and, besides, such wounds are not so available, as they would otherwise be, for the intended purpose of evacuating fluid, for permitting the extraction of foreign bodies, or for the dissection of morbid growths. Also, the pausing of a surgeon in the midst of a dissection, and the resort to fresh and more extensive incisions of the surface, is not only always awkward, but attended with much additional and unnecessary pain to the patient. Every cutting instrument should be well balanced, and placed in a steady smooth handle; the point should either be in a line with the back, which ought then to be perfectly straight, or both edge and back should be so far convex, the point being in the middle of the blade. The form and size of the instrument ought always to be in proportion to the extent of the proposed incisions, both as regards their length and depth: nothing can be imagined more cruel and reprehensible, for example, than an attempt to remove the lower extremity of a full-grown person with a common scalpel or dissecting-knife. If an extensive incision is necessary, an instrument should be employed possessing length of edge sufficient to separate the parts smoothly and quickly. Should the operator be required to cut on important parts, to perform a delicate dissection of the living tissue, he will choose a short-bladed instrument, with a handle rather long and well rounded; and after the superficial incisions have been effected, he will hold it as he would a writing pen, lightly but firmly, so that he can turn the edge, and cut either towards or from himself, as occasion may require. A small well-made scalpel, with a good point, and less convexity than those usually employed, is the instrument best adapted for such a purpose. Grooved probes and directors should be used as little as possible. With a little practice, incisions may be made upon the most delicate parts, without risk, by the hand unsupported, one layer being cut after the other. If any instrument is wanted to make the proceeding more safe—if the closely investing fasciæ of a hernial tumour, for example, are to be cautiously raised—dissecting forceps will be found the most convenient instrument for elevation previous to incision. In dividing the skin, the knife, whether a scalpel or a bistoury, is to be held and entered with the point and blade at right angles to the surface. It is carried with a decisive movement down to the subcutaneous cellular tissue; the blade is then inclined towards the part to be divided, and by a rapid and slightly sawing motion—as little pressure being applied as possible—the division is effected to the desired extent. The incision is finished by withdrawing the knife in a position perpendicular to the surface, so as to divide the entire thickness of the skin at the extremity as well as origin of the wound. For dexterously effecting such manipulations, the "fingers must be educated;" and diligent practice in the dissecting-room will be found the best foundation for surgical dexterity, as it is for sound surgical knowledge: "it is only when we have acquired dexterity on the dead subject, that we can be justified in interfering with the living." By practice the pupil will be enabled to use either hand almost equally well, and none should neglect to attain this power, for an ambidexterous surgeon possesses a great advantage as an operator. An ordinary degree of expertness is within the reach of any one who will industriously seek for and improve the opportunities for its acquirement; but yet a certain combination of natural qualifications is undoubtedly necessary to the attainment of pre-eminence in operative surgery; for a great operator in one respect resembles a great poet,—"nascitur, non fit." The importance of these natural gifts did not escape Celsus. "He must be young, or at most but middle aged," says he, "and have a strong steady hand, never subject to tremble. He must be ambidexterous, and of a quick, clear sight. He must be bold, and so far void of pity that he may have in view only the cure of him whom he has taken in hand, and not, in compassion to cries, either make more haste than the case requires, or cut less than is necessary, but do all as if he were not moved by the shrieks of his patient." The coolness and courage thus inculcated are the most valuable natural gifts of the surgeon; and it would be well did every patient remember that they are equally important in himself, for on his steadiness and patience under suffering much of the celerity and success of an operation depends. Expert skill in operation contributes greatly towards perfect self-possession; for the dexterous surgeon, like an adroit master of the sword, "will not enter rashly into difficulties, but being engaged from necessity or conviction, will bring himself through with courage." He who has what is strangely termed "*common* sense," enjoys another of nature's choicest gifts; and to no possessor does it prove more valuable than to the surgeon, as by its judicious application the want of more than one of the prominent qualifications considered as essential to his success may be fully compensated.[1] But a combination of the natural essentials for an eminent operator, as may readily be imagined, falls to the lot of only a small number; and to that gifted few it were well, when circumstances will admit of it, to delegate the performance of the more dangerous and difficult operations. Every surgeon, however, should be ready to undertake the greater number of surgical proceedings without hesitation or delay; for though, as we have already stated, operations do not form the most important part of surgery, they still are, and ever must be, inseparable from its successful practice.

Hæmorrhage.

Hæmorrhage, the most prominent accompaniment of surgical operation, is now in much better command, both temporarily and permanently, than it used to be, and consequently is less dreaded by the surgeon. During the operation, complicated machines, encircling the whole limb —very painful from the great and general pressure, and increasing the loss of blood by swelling the venous torrents and retarding retraction of the minor vessels—are now superseded by the skilful application of the "educated" and steady hand of an assistant, compressing the trunk of the main artery, and it alone. This change is particularly advantageous to amputation, admitting of its performance with greater dispatch, and with less hæmorrhage. In more tedious proceedings—the cautious extirpation of tumours, for example—the surgeon commences his incisions where he knows the principal vessels enter the part about to be the scene of operation; they are consequently divided at once; an active and steady assistant secures their orifices

[1] The ancient Athenians had a law, that no slave or woman should study medicine; probably fearing want of education in the one class, and deficiency of common sense in the other. Perhaps it were well if a similar protection to the practice of the profession were in present force, as was proposed by the late Mr Alexander Wood of this city. In addition to the usual examination for the diploma of surgeon, he wished to establish a jury to determine on the common sense of the candidate, stating as his reason, "If they have not *that*, I would not give a —— for *the rest of* their medical knowledge."

by the pressure of one or more fingers, and the proceedings are completed with comparatively little loss of blood, and without the hindrance of applying ligatures to any arterial branches until all the knife-work has been completed. Sometimes, when the part is unusually vascular, and important vessels come from all sides, this rule cannot be followed, and ligature must be applied to each important branch as it is divided; but this necessity for delay does not often occur. The ligature,—a firm hempen thread, well waxed,—ought in all cases to be applied very carefully, and made to enclose the orifice of the artery alone, which for this purpose is pulled out by the spring-artery forceps, or, when the parts have been much consolidated by infiltration, by a sharp tenaculum. A double knot, carefully secured, having been made upon the isolated orifice, one end of the ligature is cut off close to the knot, the other being left protruding from the most dependent part of the wound, that the ultimate separation of the ligature and its enclosed slough may thus be watched and made certain. It was at one time recommended, and is still practised by some, to cut away both ends of the ligature close to the knot, in the belief that the union of the wound by the first intention would thus be favoured, and in the hope that the noose would become encysted in its original situation, and produce no further annoyance; that hope, however, has been disappointed. It was then thought, that by making the ligature of an animal substance, as catgut, it might be slowly removed by absorption, and thus be prevented from becoming a source of future irritation; but that plan also failed. No doubt, ligatures in such circumstances have long remained quiescent, but that has been seldom; sooner or later, perhaps after the cure has been thought complete, they occasion the formation of abscess after abscess, and produce much irritation, until they themselves are expelled; and thus recovery is in the end much protracted. The usual practice therefore now is, to leave one end of each ligature a little protruding from the lips of the wound, in order to secure their complete expulsion at the proper period. These remarks of course apply only to wounds which are approximated soon after infliction, with the hope of their adhesion. When the cut surface, on the contrary, is left open, in order to suppurate, both ends of each ligature should be removed close to the knot, the practice being then unexceptionable. Another innovation lately practised, was the substitution of torsion for ligature of the arterial orifice, thereby imitating the natural means of suppressing bleeding. The method has only been found to succeed well with vessels of the second and third class, such as those of the fore-arm and lip—being inapplicable to the smaller twigs, and not safe in the case of the larger arterial trunks. In every extensive wound, therefore, some ligatures must be applied; and that being the case, it has been found more convenient and satisfactory to apply ligatures to each orifice requiring artificial closure. Hæmorrhage from veins usually ceases spontaneously when the position of the part is attended to, and all pressure removed that might prove an obstacle to the venous return. If it should be found obstinate, pressure applied to the orifice will be sufficient. Under any circumstances, cauteries and caustics are now seldom if ever required for arresting hæmorrhage.

Wounds.

These remarks naturally lead to the consideration of incised wounds, and here we again find that simplicity and improvement in surgery are synonymous. "Hot dressings, filthy unguents, greasy poultices, stimulating plasters, and complicated bandages, have given place to light water-dressing, unirritating plaster sparingly applied, and careful position of the part."[1] To no one does a larger share of merit belong in this, than to him from whom we have made the above quotation; and we cannot do better than continue to glean from him a little more on this subject. "Formerly (and they are even still) wounds were put together without delay, and their edges squeezed into apposition, and retained by various means, such as sutures, plasters, compresses, and bandages. They were carefully covered up, and concealed from view for a certain number of days. Then the envelopes of cotton and flannel, the compress-cloths, the pledgets of healing ointment, and plasters, were taken away, loaded with putrid exhalations, and a profusion of bloody, ill-digested, fetid matter. A basin was forthwith held under the injured part, and the exposed and tender surface was deluged with water from a sponge, and then well squeezed and wiped. Then came a re-application of retentive bandage, of the plaster, of the grease mixed with drying powder, all surmounted by some absorbing stuff, as charpie or tow, to soak up the discharge. This was not unaccompanied by pain, often more complained of than that attendant on the original injury or operation. This process was repeated day after day, the patient was kept in a state of constant excitement, and often, worn out by suffering, discharge, and hectic fever, fell a victim to the practice. The wound was, as it were, put into a forcing bed, excited action beyond what was required was hurried on, and the consequence was, that immediate union seldom if ever could or did take place. A suppurating surface, on the contrary, with bad profuse discharge, and a very tedious cure, if any, were obtained." This was an uncomfortable state of matters, but there is now a change. Surfaces are not disposed to unite for some time after the division and separation have occurred. So long as there is oozing of blood, no good end is to be attained by their close apposition. Should this be attempted, the blood which continues to be discharged from the smaller vessels is necessarily prevented from escaping; and the consequences are, infiltration of the loose cellular tissue, distention of the cavity of the wound, and separation of the surfaces probably throughout their whole extent; unless, indeed, this be counteracted by well-adjusted pressure on every part. Then ensues a congested state of the surrounding vessels, with perhaps a troublesome hæmorrhage from branches that would otherwise have become sealed up; at all events, constitutional disturbance, a heated swollen state of the injured parts, profuse, bloody, and putrid discharges, must occur; and this will certainly be followed by suppuration from a foul cavity, which may be long in assuming a healthy state. It is when re-action has occurred, when gentle vascular excitement has taken place in and around the solution of continuity, and when plastic matter begins to be secreted and thrown out, that the process of adhesion can be expected to commence in earnest. The edges of a large wound, as that resulting from amputation of the extremities, may be approximated in part, either by position, or by a few points of interrupted suture (the metallic almost always preferred), as soon as bleeding from the principal vessels has been arrested. But the close apposition, and application of all the retentive means, had better be delayed for some time longer. In the interval, sensibility will be abated, the oozing moderated, and the chance of secondary hæmorrhage much diminished, by lightly covering the parts with lint dipped in cold water, and frequently renewed; or a piece of lint may be placed between the cut surfaces, and a constant irrigation kept up by threads passing from a vessel containing cold water. When all oozing has ceased, and the surface become glazed, the surrounding skin, previously shaved, is made thoroughly dry; coagula are removed, the edges are put carefully and neatly in contact, and retained by narrow slips of adhesive plaster placed at intervals. The plaster commonly in use does not retain

[1] Liston's *Practical Surgery*.

Surgery.

its hold sufficiently long, is loosened by discharge, heats the surface, and often gives rise to erythema. A better kind is made by spreading a strong solution of isinglass in spirit on the unglazed side of oiled silk, cut into slips of the necessary length and size; this plaster is quite unirritating, and often retains its hold until the very completion of the cure. Being transparent, it does not prevent any untoward process that may be going on underneath from being observed; and if any fluid collects under it, an opening can be made for its escape. If sutures have been previously employed for the partial approximation of the wound, they can be removed by cutting the thread, shortly after the fixing of the plasters, should these alone prove sufficiently retentive. No other dressing need be employed in the first instance; no compress, no pledget, no bandage; for in general they will not promote union of the wound, and may do harm. The slight discharge that oozes out is from time to time wiped from the surrounding skin, and from the glazed cloth on which the part is laid. In some cases of amputation, after a few days a roller may be applied, to encourage the subsidence of any slight œdema that may have arisen, and to bring the stump into a good form. By such simple treatment, a great deal of suffering is saved to the patient, and he enjoys much comfort and cleanliness; besides, the surgeon is relieved from a load of most unpleasant and harassing duty. In certain circumstances it may be expedient to deviate from this system of dressing, and to bring the wound at once into apposition. In such cases the use of lint-compresses are quite essential, arranged over the entire extent of the incision so as to keep the surfaces in apposition, and prevent inward accumulation of the blood that may continue to ooze.

Wounds produced accidentally are almost always attended with more or less bruising of the parts, and can unite only by the second intention. After bleeding has been suppressed by the method recommended for incised wounds, the cold applications are to be superseded by those of an agreeable warmth, such as poultice of bread and water, or, what is much to be preferred, from its simplicity, and lightness, lint of thick texture, and of sufficient size to cover the wound, soaked in tepid water, and overlaid by an ample piece of oiled silk to prevent evaporation. Heat and moisture, by which qualities a poultice produces its soothing and beneficial effects, by which the surface is relaxed, its capillary circulation encouraged, and discharge promoted, are thus amply afforded without any of the weight, putrefactive fermentation, stench, and filth not easily separable from common poulticings. The edges of the wound are approximated as much as possible by attention to position; and by the same means the return of blood is favoured, and engorgement of the vessels and inflammatory swelling prevented to a very great degree. If the wound run across the fibres of the skin and muscles underneath, these are to be relaxed by flexion or extension, as may be, of the neighbouring articulations. Rest of the injured parts is also essential, and to obtain this it is sometimes proper to apply splints. Contraction of the wound takes place naturally, and generally with sufficient rapidity; should the surface, however, from any cause become weak and flabby, the lint is to be wet with a gently stimulating solution, as of zinc, instead of tepid water. Support, by bandage or plaster, may for a like reason sometimes be required. But healing is often retarded by the plasters and bandages which are inconsiderately employed to hurry it on; the granulations are absorbed, the surface of the sore becomes foul, the discharge thin and offensive, perhaps inflammation of the surrounding skin takes place, with extension of the sore by ulceration. Sometimes adhesion and suppuration may be happily blended in the cure. Thus, when, in a suppurating wound, whether accidental or incised, the discharge begins to thicken, and diminish in quantity, when the granulations are florid, small, and accuminated, and when the surrounding parts are sufficiently lax to admit of easy approximation, the granulating surfaces may then be brought into close apposition, with every prospect of immediate union taking place.

When the wound is superficial throughout, and when the means used for effecting apposition are capable at the same time of preventing the interposition of blood, the dressing may be always completed at once; as, for instance, in penetrating wounds of the mouth; in division of the lip, as for harelip; and in repairing some deficiencies of the genital organs. In such cases, either the twisted or quilled suture is used, usually the former, and no other dressing should be applied. To put on strips of plaster, to cover the part with lint smeared with ointment, to interpose dossils of lint between the skin and end of the pins, to support the wound by a uniting bandage—all this is mischievous, and a remnant of the old meddlesome surgery. Any kind of application collects and retains the secretions, heats and excoriates the surface, promotes suppuration, and interferes with the process of union.

Such is an outline of the simple treatment of wounds now employed, with the happy effects of saving the patient from much pain, and the surgeon from much trouble; obtaining a more frequent occurrence of adhesion in incised wounds; shortening the process of suppuration, and depriving it of much of its inconvenience. It is almost needless to observe, that this, as well as every other treatment, will, however, prove of little avail, unless accompanied with a careful attention to the general health: in other words, the surgeon, not hesitating to encroach thus far upon the duties of the physician, must ever be employing his medical science.

Diseases of the joints.

In no class of diseases is the operating knife now more happily in abeyance, in comparison with former practice, than in affections of the joints. Many a limb is now saved, with its usefulness little if at all impaired, that would, in days not long passed, have been doomed at once, and with very little ceremony, to amputation.[1] This important saving of life and limb is mainly attributable to the advance of pathology. The cultivators of that science, among whom the name of Brodie deserves prominent notice, have shown with great perspicuity the various changes which morbid processes induce in the structure of articulations, and established a wonderfully accurate diagnosis of each affection. We can often tell in what tissue of the joint disease originated, of what nature the morbid change is, and can predicate almost with certainty the actual state of the parts, as to extent and manner of degeneration. According to the principle that "the knowledge of a disease is half its cure," great advantage is thus obtained in adopting and regulating the treatment suitable to the circumstances of each case. Besides, we can tell at once, and with tolerable accuracy, in what cases we shall probably succeed; and in those in which we are made aware that the disease is of such a nature, or has proceeded to such an extent, as to baffle all attempts to cure, we are enabled to save valuable time,

[1] John Hunter himself seems to have been in the habit of making very unwarrantable abbreviations of living limbs, as the following anecdote abundantly proves. "He once had a patient whose leg he considered it necessary to remove. He had got on his *dress*, and a profound silence reigned in the theatre. The surgery-man disappeared. In two minutes he returned alone, with a face as long as the leg. 'Why do you not bring in the patient?' demanded the expectant operator. 'Because, sir,' said the astonished surgery-man, 'because, sir, he has run away!'" It is to be hoped that the custom of amputating legs that are able to "run away" has fallen into complete desuetude.

and thereby to save life, by proceeding at once to the only cure available, by the knife. In whatever part of the joint disease may have originated—bone, cartilage, bursæ, or synovial apparatus—if not arrested, it soon extends to all, converting the whole joint into one mass of disorganization, It is of the utmost consequence, therefore, to be early in the employment of the appropriate means of cure. The first and most important object is to secure absolute want of motion in the diseased parts; and here it is that the greatest improvement has taken place in the treatment of joints. "If perfect repose and quiet of the affected parts be omitted, all other means are found nugatory, and were as well untried. Nothing but disrepute can accrue to the profession, if hot irons, moxas, and issues continue to be used inconsiderately, to the neglect of more powerful and less appalling means. Instant relief invariably follows the securing a state of perfect rest; other means, local and constitutional, are thus afforded a fair chance of doing good, and the natural efforts towards a cure are no longer thwarted and interrupted. But, above all, the effect on the general health is most remarkable and cheering. Even in very complicated and bad cases, in which sinuses communicate with the cavity of the joint, and the heads of the bones are ascertained to be in a state of ulceration, or partially necrosed, the good effects of perfect quietude of the joint will soon be manifested by cessation of pain, diminution of discharge, and speedy improvement of the general health. A cure of the local mischief may not be possible by this means alone, but much will often be gained, as regards the success of ulterior proceedings, by the rapid and certain amendment of the patient's condition." This salutary rest is the first part of the treatment of all diseased joints, and is continued, in general, throughout the whole period of cure; it is obtained by the application of splints, varied in form and construction according to the particular joint affected.

Disease of the soft parts of the joint usually commences in an inflammatory form, requiring depletion; when acute, the antiphlogistic treatment, local and general, must be very active, so as at once to arrest the morbid process; and hot fomentation and poultice will generally be found more soothing than cold applications. When the more violent symptoms have subsided, the disease giving way, a determination to the surface, with discharge, lends powerful aid towards its final extinction. For this purpose vesication may be produced, by cantharides or by nitrate of silver; or an eruption may be established by friction with a liniment of croton oil, or an ointment of tartrite of antimony, their strength proportioned to the nature of the part and age of the patient. In chronic swelling of a joint, whether the effect of inflammatory change, or slowly and gradually supervening after injury, the disease must not only be arrested, but absorption also procured of the deposit and effusion within the synovial capsule and bursæ. To obtain the former indication, local depletion and counter-irritation are employed, according as the circumstances of the case require; and to obtain the latter, uniform pressure of the whole swelling, and gentle irritation of the surface, are combined with the means of securing the all-important rest of the joint, according to the method first recommended by Mr Scott. The limb having been uniformly supported by a roller, from its extremity up to the diseased articulation, the surface of the swelling is covered by lint spread with some gently stimulating ointment—soap cerate with camphor, for example, or that with a greater or less proportion of the unguentum hydrargyri; and the whole articulation is then surrounded by long strips of adhesive plaster, drawn with moderate and uniform tightness, so as to support and gently compress the parts, without producing absolute pain or uneasiness. Above all, splints are applied to secure total immunity from motion; and they may be of leather or wood, or gutta-percha, as most suitable to the joint affected. When this dressing has become loose from subsidence of the swelling, it is re-applied as often as may be necessary. Should fresh inflammatory accession occur in the joint, from any accidental cause, during this treatment, the apparatus must be discontinued, until such accession has been subdued by the usual means already described; and when the pressure is resumed, it should at first be very moderate. During the treatment the limb must be kept or gradually brought into the most advantageous position for ultimate use, particularly if, from the duration, nature, and extent of the disease, there is reason to expect permanent impairment of the joint's motion. Thus, by steady extension with splints, the knee-joint may be brought into nearly a straight position, so that it shall be serviceable in progression; and the elbow may be bent, to form such an angle with the humerus, as shall be most convenient for prehension. But such alterations of stiffened limbs must be proceeded with very cautiously, otherwise they may rekindle the inflammatory process, with consequent renewal of disease in the joint.

The preceding treatment will be found applicable to almost all joints, the hip not excepted. In morbus coxarius, for example, it is useful for securing immobility of the articulation, an object of such paramount importance towards arresting the progress of that formidable disease; and in its advanced stage it is productive of at least relief. The joint is placed extended, that being the preferable position, in case of anchylosis, and surrounded by "soft lint soaked in a strong solution of gum acacia, which is laid on in strips over the side and pelvis, from the short ribs to the knee, and made to embrace the limb fully. A layer of dry lint is first applied, and then two or three others, soaked in the mucilage, follow; these are covered by a fold or two of coarse calico, and the whole is retained by a roller." Sometimes it is necessary to preserve the limb steady in position by a wooden splint, as in fracture, until the composition has dried, and the splint, so formed, adapted itself closely to the parts. "This gum-splint can be made of any form, so as to allow of its being taken off, trimmed, lined with wash leather, or protected with a layer of oiled silk, and re-applied with a clean bandage. It can also be fashioned so as to leave any part exposed: the discharge from issues and abscesses can thus be allowed to escape, and the parts can be dressed, and otherwise attended to, without disturbing the limb. In fact, the apparatus can be varied as circumstances demand, and is applicable in a great variety of cases, and to any articulation." A similarly useful splint is made "of leather dressed without oil, cut to a proper form, moistened in hot water, and applied with a roller. It soon becomes firm, and forms a case which fits the part accurately; it is then pared, fashioned neatly, and lined. In many chronic cases such splints answer admirably; but the gum-splints can be applied with less disturbance of the limb, which in many instances is a great recommendation."

"In the painful and dangerous affections of the articulations, when the cartilages are extensively absorbed, and when the cancellated texture of the bone is more or less diseased, good effects may yet follow judicious treatment. Besides following out the principle of preventing all motion, great relief will often be experienced from establishing a permanent discharge from the neighbourhood of the diseased tissues. This can be done simply and effectually, without causing alarm, or exciting much pain, by confining a small piece of caustic potash on the skin near the diseased joint. The sore thus formed is deepened, and made to discharge freely, when disposed to heal, by a few hours' application of the antimonial ointment. A seton may be preferred in some situations; certainly discharge can be thus kept up, and derivation obtained from the affected parts,

Surgery.

fully as well as by actual cauteries, moxas, pea-issues, or other farrier-like practices. Great care must be taken in the placing of issues; they should be near to, but not upon a joint. Serious results have sometimes followed their careless application; diseased action has been increased, they having reached, or even penetrated, the synovial capsule."

By the careful and judicious employment of such treatment, many affections of joints which resisted the less simple modes of cure formerly in use, are now successfully combated; and many limbs are saved which our forefathers would not even have attempted to cure. But still there are too many cases which baffle all efforts to arrest the progress of morbid change; and it becomes necessary, in order to relieve the labouring constitution, and preserve life, to remove either the diseased parts alone, or the remainder of the limb along with them by amputation. The former operation is termed resection, and is the preferable, because the less mutilating and severe, when the case is such as to promise a tolerable certainty of success. Should it fail, amputation then becomes necessary; but by the failure the chance of the patient's ultimate recovery is very much diminished. The cases for resection, therefore, should be carefully selected. The general health must not have been too much impaired; the disease must be almost entirely limited to the articulating surfaces; and the patient must be of that age and constitution most favourable to the reparation of injury. The articulating extremities of the bones are exposed by free incisions, planned according to the circumstances of the case, and the diseased portions are removed by suitable saws, or by cutting pliers. The soft parts are then replaced, and the cavity treated as a suppurating wound, the intention being that it should heal by healthy granulations from the bottom; and motion of the part is encouraged during the cure, with every prospect of the new articulation becoming both free and strong. The elbow-joint is the one to which the operation is most applicable, and to which these observations chiefly refer. The shoulder, too, is often operated on with perfect success. The hip, though not excluded from the benefits of such conservative surgery, is less favourably circumstanced; and it is only in few cases, specially affected as to either injury or disease, that here resection is advisable. The knee, of late years, has been subjected to the experience somewhat freely; and the general result seems on the whole favourable to well selected examples, except in the case of the young, the operation in them being apt to arrest growth in the limb, so that at the adult period of life the stunted member hangs loosely as a mere appendage, neither useful nor ornamental. Anchylosis is always sought. The wrist has been successfully operated on occasionally; and good practice in the region of the tarsus may be every day made on the principle of resection. This operation is founded on sound surgery, and ought in all practicable cases to take the place of mutilating dismemberments.

Resection of joints.

Amputation.

When, however, all milder means have failed, and resection is inapplicable, amputation must not be deferred until the disease has grown riotous in its progress, and the general health has been seriously impaired. When the surgeon is satisfied that amputation has become absolutely necessary,—that nothing else can save life,—the sooner it is performed the greater is the chance that this severe remedy will not fail in its issue; and it is consolatory to reflect that modern improvement has greatly mitigated its evils, and increased the probability of its success. It is performed more rapidly, more skilfully, and more successfully. The tedious dissection of a limb, called the "circular method," has now given place to the "flap-operation" by transfixion; the only valid objection that can be brought against which is, that perhaps a greater surface of wound is made; but this is much more than counterbalanced by the many benefits which it otherwise insures. The operation is more rapid; the cut surface is smooth and regular; adhesion, or union by the first intention, is more frequent; whether union be by the first or second intention, the cure is more speedily completed; the end of the bone is better covered, and the stump consequently more useful; and if the flaps have been skilfully formed, there will seldom be exfoliation of the end of the bone protruding through ulcerated integuments, or the formation of excruciating neuromata in the cut extremities of the nerves, rendering a renewal of operation necessary for final cure. The manipulations of the flap-operation are simple and well known, so need not be here detailed; but some rules necessary for its dexterous accomplishment are not always sufficiently attended to. The first regards transfixion; and it is, that after the first flap has been formed, the knife should not be again entered close to the top of the wound, but about an inch below, as thus cross-cutting of the integument is avoided. Another is, that in sawing the bone, the surgeon must not trust the distal portion of the limb entirely to an assistant, but, grasping it in his left hand, must himself regulate its support, and so avoid splintering the bone. Pressure to command the bleeding need not be severe, but must be true. As was formerly stated, the tourniquet is seldom if ever used when the fingers of an assistant can be obtained who is cool, steady, and well conversant with the course of the vessels. The pressure is not applied until the instant the incisions are commenced, and then only on one point; the limb consequently is not gorged with blood, as it would have been by the ordinary tourniquet; less blood therefore is lost, and besides, the flaps are much more easily retracted from the bone. When skilful assistants cannot be obtained, or when it is probable that many vessels will require ligature, and that consequently pressure must be long continued, a strong metallic spring may be used, each extremity terminating in a pad, one placed over the course of the vessel, the other resting on the opposite part of the limb; the assistant preserves its just application, and regulates its pressure, and the risk is avoided of his fingers giving way from cramp or fatigue. When the surgeon, from want of other means, is compelled to use the ordinary screw-tourniquet, its principal pressure should never be applied until the moment before incision; and as soon as the larger vessels have been secured, the whole apparatus should be removed, as thus the loss of much blood by regurgitation, and particularly from veins, will be avoided. The arterial orifices are secured by ligature, according to the method already mentioned; and should the venous trunks continue to pour out their contents, notwithstanding the removal of all constriction of the limb, pressure by the fingers of an assistant, though for only a short time, usually suffices to arrest the hæmorrhage. The wound is treated according to the principles formerly explained; and thus adhesion is not only favoured, to the saving of time and pain, but the occurrence of secondary bleeding is also made much more improbable; for no warm coagulum is bound up in the wound, to act as a sponge, and encourage escape of blood from all the untied vessels; and even when it does take place, the bleeding point is much more easily secured than when the stump is bound up tight and close from the first. Should the stump bleed seriously, six, eight, ten, twelve, or fifteen days after the operation, in consequence of sloughing or some other unhealthy state having supervened, the ununited wound is to be laid open, all coagula removed, and direct pressure applied. But should this fail, the surgeon ought instantly to secure the trunk of the vessel whose branches are at fault, at some distance above the stump—in amputation below the knee, tying the femoral, for example—at the same time supporting the stump by bandage.

Amputation is also less frequently resorted to in cases of severe injury than formerly. In fractures, skilful and careful management preserves many a limb useful and but

Surgery.

Surgery.

little out of shape, which before would have been considered too seriously injured to retain its vitality. Nor are compound luxations regarded with the same dread. In compound dislocation of the ankle-joint, for example, with protrusion of the bones, instead of at once amputating the limb, the dislocation is reduced, the protruding portions of bone having been removed in whole or in part, if so injured as to render that proceeding necessary; the limb is retained in a favourable position, and in a state of complete rest; the wound is treated by the simple soothing plan; inflammation is warded off or held in subjection by the usual means; if abscesses form they are early evacuated; the parts are uniformly and gently supported; the surgeon's *medical* acquirements are kept constantly on the alert; and thus, in very many cases, the limb is retained, with the injured joint, though stiff, exceedingly useful. The ordinary simple dislocations are now at once detected by the observant and well-educated surgeon, and as readily reduced if recent; so that branch of the profession promises to be soon rescued completely from the maltreatment of ignorant empirics. In both diagnosis and reduction, but especially in the latter, vast benefit is found from the use of anæsthesia. The patient lies without pain throughout the whole manipulations, and every muscle is as passive as in death.

Compound dislocation.

Fractures.

The whole treatment of fractures has been simplified and improved; the process of reparation in disunited bone is better understood, and the means which favour it are more skilfully and effectually adopted. In fractures, whether compound or simple, of the smaller bones, more particularly of the upper extremity, the gum-splint will be found very suitable. By the employment of these or other light splints—of wood, pasteboard, leather—well padded, so as not to fret the integument, and always of sufficient length to command the neighbouring joints, the bones are not only kept accurately in their proper place, but perfect quietude and freedom from all motion are likewise secured,—a point all important here, as in the treatment of diseased joints. Broken limbs are no longer laid out in state on pillows, altogether unrestrained. Absolute rest, following early reduction of the bones, and combined with strict attention to the workings of the general system, usually succeeds in preventing interruption of the cure by inflammatory mischief in the neighbourhood of the injury. Should this nevertheless occur, the retentive apparatus can be so arranged as to admit of the part in fault being attended to as freely and as often as is necessary, without disturbance of the rest of the limb; for example, blood may be abstracted locally, fomentation or poultice applied to a particular part, abscesses opened, and wounds dressed, without undoing all the retentive apparatus, and so jarring the fracture. In severe compound fractures this advantage is particularly important. The soft parts can be looked after as well as if no apparatus at all were applied; and the untoward results likely to follow such a serious accident can consequently be sometimes averted, and always moderated, while the hard parts are uniformly kept in the condition most favourable to their union. For many simple fractures an immovable retentive apparatus, by starch bandaging, is very suitable; always taking care, during the early period of its application, that no undue tension of the parts occur. In fractures of the lower extremity near the hip-joint, Desault's splint is still in use, somewhat modified; and with simple yet efficient means to maintain as much permanent extension as shall prevent shortening of the limb. When the break is lower in the limb, an improvement of Macintyre's double inclined plane is in many cases a most suitable apparatus, combining in an eminent degree the advantages of complete rest of the whole limb, with ready and convenient dressing of particular parts. The patient is also able, with safety, to be out of bed at an early period of the cure; a circumstance very favourable to the preservation of the general health.

Surgery.

Gangrene.

When, notwithstanding care and skill, gangrene occurs after severe fracture, either immediately or in consequence of greater inflammation having taken place than the hurt parts are able to bear, amputation must be had recourse to, and the period of its performance is now no longer a subject of dispute. Should the state of system permit, it is done immediately in sound parts, at a distance from the gangrene, without waiting for a line of separation, as in chronic gangrene, else the surgeon will expect the opportunity in vain, and meanwhile his patient sinks and dies.

Disunited fracture.

Sometimes, either by the carelessness of the surgeon and inefficiency of his treatment, or from the fault of his patient or defect of his constitution, union of the fracture fails to take place. In recent cases of such disunion, adjustment of the broken ends in accurate apposition, and undisturbed rest of the fracture and of the whole limb, as by starch bandaging, will occasionally effect a tardy union. But usually it becomes necessary to rouse the parts, and this may be done in various ways. One method is the introduction of a seton between the fractured extremities, gradually increasing the size of the tape, but taking care to remove it altogether as soon as it appears that excitement has been produced sufficient for establishing the regenerative process. A few days are usually enough; when permitted to remain for a long period, the mere presence of the foreign body, and more particularly the constant discharge which it maintains, tend to prevent the result in favour of which it was employed. After removal of the seton, the limb is placed in the proper position, and must be preserved in a state of most complete rest. Another and gentler mode of procedure is by subcutaneous puncture. A strong tenotomy knife is introduced and moved about freely, even roughly, so as to make raw both ends of the bone, and break up completely the intervening tissue; reducing the parts to a state somewhat resembling their condition at the time of the original injury. Then the retentive means are applied with great care, to be readjusted from time to time, with perhaps a repetition of the puncture, should the results of the former one seem to prove imperfect. This method of treatment, being milder than the seton, is to be preferred in the first instance; but in the event of it failing, then the seton may be used, or ivory pegs may be driven into the ends of the bones, with the view of producing callus, as advised by Dieffenbach. (Vide Miller's *Principles of Surgery*, p. 695.)

Fractures of the cranium.

In fractures and other injuries of the cranium, the trephine is now used with better judgment than formerly; more sparingly in most cases, more readily in others. It is not considered necessary to convert every fissure of the skull into a chasm, by following it out with the trephine; in depressed fracture with urgent compression of the brain, the application of the trephine is imperative, but no more bone is taken away than is necessary for the raising of the depressed portion, and the removal of what is so injured by the accident as to render its retention of vitality improbable; and to bore one or more holes in the cranium in search of extravasated blood, is generally regarded as a proceeding equally mischievous and unprofitable. But in punctured fracture the necessity for the trephine is absolute; it must be used freely and at once; and as this important point of practice is perhaps not yet sufficiently attended to, we shall be a little more explicit on the subject. The punctured or star-like fracture is occasioned by a sharp body striking the head with considerable force. The integuments are divided, and the surface of the bone presents an appearance of injury somewhat resembling what is often seen in ice when struck in a similar way. But this is a very slight extent of damage compared with what the inner table suffers, when the puncturing weapon has

Punctured fracture.

Surgery.

passed through the diploë, as is usually the case. The inner table, being by much the more vitreous, is shivered into numerous fragments, which being driven inwards by the force of the blow, perforate, or at all events grievously irritate, the coverings of the brain, producing inflammation, which, if not arrested, proves speedily fatal. After the infliction of such an accident, therefore, even should the patient be at the time so little affected as to walk to the surgeon to have his wound dressed, the trephine should be immediately applied to the punctured point, in order that a portion of the bone may be removed, sufficient to allow extraction of all the displaced portions of the internal plate. In no other way can we avert intense inflammation from the wounded dura mater, extending in all probability to the brain and its more immediate investments. Even should the practitioner be in some degree successful in moderating the more immediate mischief by antiphlogistics alone, the necessity for trephining will still remain, on account of abscess under the bone, occasioned and kept up by the fragments; the matter must be evacuated, and the cause of its formation must be removed. It is surely infinitely better, therefore, to operate in the first instance, and so avert all such calamities.

Abscess of the dura mater.

Abscess sometimes forms between the dura mater and the bone, as a consequence of mere contusion; its occurrence, and usually its site, are indicated by constitutional disturbance, peculiar œdema of of the scalp, unhealthy discharge from the wound, and a pale necrosed appearance of the bone. In such cases, also, perforation of the skull should not be delayed; for it alone can succeed in evacuating the matter and relieving the patient. But, on the whole, "trepanning of the skull, which with our forefathers appears to have been an every-day occupation, is an operation now very rarely resorted to." After its performance, from whatever cause, there is now no rasping of the bone, or cutting away of the integuments; the edges of the circular aperture are denuded of their periosteum as little as possible, and the soft parts, having been carefully replaced, are treated as a suppurating wound; the deficiency of the bone is filled up by a ligamentous expansion, which slowly ossifies as the patient lives on. When a large portion of the skull has been removed, it is well to afford support to the cranial contents by the application of a compress and bandage externally.

Erysipelas.

There is no more successful caterer to the amputating knife than erysipelas inertly treated; destruction of bones and joints has been too often its result. The improved treatment by incision, however, now in general use, saves many a limb entire and unscathed. So soon as tension of the surface indicates that the cellular substance is so infiltrated as to threaten destruction of the tissues—in that intense and peculiarly asthenic form of the disease which is called the phlegmonous—free incision must be immediately had recourse to; the knife is used not only to evacuate matter, but to anticipate its formation, and prevent its baneful consequences. In the milder cases, sufficient relief is obtained by making, with the point of a lancet, numerous punctures in rapid succession, effusion from which is encouraged by hot fomentations. In most cases, even when severe, division of the integument and subjacent cellular tissue suffices; but if the infiltration has extended to the inter-muscular tissue, the knife must follow: its free use may appear harsh, but is in reality a valuable kindness. The burrowing of matter is prevented, and consequently also sloughing of the soft parts, the opening up of bursæ and articulations, and the denuding of bones by destruction of their periosteum, ending in necrosis more or less complete. Museums were at one time copiously enriched with splendid specimens of necrosis of the long bones, throughout almost the whole extent of the limb, all the result of neglected erysipelas; but the bistoury has superseded the amputating knife, and such preparations fortunately are now become valuable by their rarity. The free internal administration of iron is of vast value in all cases of truly asthenic erysipelas, whether slight or severe, not only mitigating the symptoms at the time, but also preventing those secondary abscesses which otherwise are so apt to prove troublesome, especially in hospital practice.

Abscess.

In opening abscesses, "pointing" is not now waited for; before that takes place, irretrievable mischief may have been done. The *tactus eruditus* having acquainted the surgeon with the existence of purulent formation, it must be reached by his bistoury, at whatever depth, if it be in the neighbourhood of joints, bones, or vessels, and more particularly if close to important cavities or canals. The mere contact of purulent matter will not injure these, but its pressure will, and from it they must be relieved, lest their functions be interfered with or their structure destroyed. For example, purulent collections in the fauces are evacuated by the bistoury before the patient is threatened with suffocation; and abscesses in the perineum, and neighbourhood of the anus, are drained by an external opening before they have become troublesome fistulæ.[1] The knife must of course be used cautiously when the abscess is deep, lest the vessels and other important parts be wounded; but let not the fear of this deter the surgeon from relieving abscesses in their immediate neighbourhood; for "the vessels and nerves are displaced by the morbid accumulation, and the knife is passed safely, in their course, to such a depth as would greatly endanger them in the healthy state of the parts." The opening should in all cases be made sufficiently large to afford a free exit to the matter; it should be placed in the most dependent part of the cavity, with which view the prevailing position of the patient should be considered; and sometimes more than one opening should be made at once, to prevent the necessity for future counter-openings, or the formation of sinus,—as when the abscess extends over a considerable surface, and cannot be made to discharge through one aperture. After evacuation, in assisting which no pressure or squeezing should be employed, fomentations and the water-dressing are applied. Chronic abscess, when small, may be treated as the acute, by direct and free incision; but when large, there is risk by intense inflammation of the pyogenic membrane following; and it is better to empty the cavity by subcutaneous puncture from time to time, till the size has so far diminished as to admit of a direct wound being made with safety.

Improved seton.

In establishing an artificial abscess, or issue, the modern caoutchouc seton is a great improvement on the skein of silk or cotton formerly used, requiring no renewal on account of decay, and absorbing no discharge.

Ulcers.

Ulcers, like wounds, are now treated more simply and better; and better because more simply. The healthy suppurating sore is covered, like a suppurating wound, with the plain and light water-dressing; simple in the first instance, afterwards medicated by gentle stimulants or not, according as the progress of the sore may seem to require.

[1] Dr Radcliffe has probably few imitators at present in his clumsy though ingenious method of emptying abscess of the fauces. "He was once sent for into the country to visit a gentleman ill of the quinsy. Finding (supposing) that no external or internal application would be of service, he desired the lady of the house to order a hasty pudding to be made; when it was done, his own servants were to bring it up. While it was preparing, he gave them instructions how they were to act. When the pudding was set upon the table, the doctor said, 'Come, Jack and Dick, eat as quickly as possible; you have had no breakfast this morning.' Both began with their spoons; but, on Jack's dipping once for Dick's twice, a quarrel arose. Spoonsful of hot pudding were discharged on both sides; handsful were pelted at each other. *The patient was seized with a hearty fit of laughter, the quinsy burst, and the patient recovered.*" A moment's use of a straight sharp-pointed bistoury would have saved both time and the pudding.

When stimulants are used, their solution is at first weak, and is increased in strength very gradually, lest the discharge should be suddenly suppressed and the sore consequently inflamed; the object is simply to moderate discharge, and check weak exuberance of granulation. An inflamed ulcer is subdued by the hot-water dressing, combined with antiphlogistic regimen, rest, and elevation of the part. An irritable ulcer is soothed by the water-dressing, and occasional slight application of the nitrate of silver to the jagged angry edges of the sore; or the lint may be dipped in a bland anodyne solution. In all such dressings, the lint is kept constantly invested by a portion of oiled silk, larger than itself, to prevent evaporation of the fluid in which the lint has been soaked. When granulations prove exuberant, the surface may be compressed by dry lint and bandage, so as to produce recedence either by absorption or by ulceration, according to the degree and duration of the pressure applied. An indolent ulcer is stimulated to healthy action by pressure and support, combined, if necessary, with a direct stimulant application. This last description of sore is perhaps the most common, and is usually found afflicting the labouring classes, to whom the restoration of a limb is of more importance than to any other class of patients; a speedy cure is therefore of no little consequence. It is well effected by the method first recommended by Mr Baynton. When the patient applies for relief, there is usually considerable excitement around the sore, and this may, of itself, be the means of removing the indolent characters in the surface and edges, and restoring the ulcer to a healthy state, on subsidence of the inflammatory process from its destructive stage. But in the purely indolent condition, the foot and lower part of the leg, for it is the part commonly affected, having been uniformly supported by bandage, the sore is compressed by adhesive plaster, applied in strips encircling the whole girth of the limb, and with their extremities crossed over the sore; if this is large, and pouring out much discharge, it is well to cut a small hole in the plaster where it covers the ulcer. The application having been made to extend about an inch on each side of the sore, a little fine tow is placed above it, to absorb discharge, and the whole is retained by continuation of the bandage which supports the lower part of the limb. This dressing is removed at the end of forty-eight hours, or sooner if necessary. The sore itself is not to be washed or rubbed, for its own secretion is its natural and best protection; but the surrounding skin is wiped clean, and, if excoriated by the pressure, bathed with a spirituous lotion; the dressing is then re-applied as before. By such manipulation, repeated as often as is necessary, the indolent surface of the sore is stimulated to the formation of healthy granulations for raising its depressed surface, while at the same time the swelling of the surrounding skin and cellular tissue is diminished by absorption; and thus, the sore and its margins having been brought to one level, cicatrization proceeds. After the ulcer has in this way been converted into the simple suppurating sore, either the same dressing may be continued, exerting less pressure, or it may be superseded by the medicated lint and oiled silk. When nearly closed, all dressing may be discontinued; the natural secretion forming a crust, under which cicatrization is speedily completed. Of course healing will be materially assisted by rest and elevation of the limb; but the labouring man cannot always afford this; and the treatment by plaster, just described, possesses, in addition to its other virtues, this advantage, that with it the patient can continue in the erect posture with much greater impunity then when using any other application. For some considerable time after cicatrization, the limb should continue to be supported by a bandage or laced stocking. Another frequent ulcer is the scrofulous sore, with the areolar tissue infiltrated by tubercular matter, and crumbling down under a chronic disintegrating process, which yields a copious, thin, and mixed discharge. Such generally form in clusters, and can be brought to heal only after the unsound parts have been destroyed by the potassa fusa, so as to obtain a sound foundation on which the reparative granulation may arise. This description of sore, however, being combined with and dependent on the strumous diathesis, is healed only to break out afresh, unless constitutional means be diligently employed to rectify the state of the system.

Sores, however, are often changing their character and appearance, though perhaps but slightly; and consequently demand as frequent a change in the treatment. "A judicious practitioner, by varying his applications according to the appearance and disposition of the sore, will serve and benefit his patient much more efficiently than by trying empirically this or the other new specic, or blindly applying one remedy for every sore, because he has seen its good effects, or been informed of its answering miraculously in one or two instances." Be it likewise remembered, that in no class of diseases is attention to the general health in all cases more requisite.

Hospitals.

We may here allude to the general improvement in hospital arrangement and practice, in consequence of which the hospital sore, so long and so frequently a scourge in those valuable institutions, is now comparatively unknown. The ventilation, cleaning, and general arrangement of the wards, the diet, clothing, and classification of the patients, are all improved; but probably nothing has tended more to the disappearance of this formidable disease, than the substitution of tow for sponge in the dressing of sores; a change apparently simple and insignificant, but in reality most important. Formerly both nurses and dressers were in the habit of using one sponge for the sores and wounds of a whole ward, and if in one patient unhealthy action supervened, the vitiated discharge was soon afforded an opportunity of inoculating all. Now, sponges are not seen but in the operating theatre; washing of wounds and sores has been discontinued, because found to be prejudicial to cicatrization; and when the parts around require cleansing, this is effected by means of tow, which, when used, is immediately thereafter destroyed or thrown away.

In the management of hospital sore, and other affections of that class, the energetic application of nitric acid, or other suitable escharotic, to the edges of the sore, after they have been thoroughly dried, is found preferable to the expectant treatment by poulticing or other inert appliances.

Aneurism.

In aneurism, the discovery of Hunter has been most successfully extended. Further investigation in arterial pathology, especially as to the effects of ligature, has produced the most important results. The accumulated knowledge and experience, applied to practice by the talents and courage of Scarpa, Abernethy, Astley Cooper, Liston, Stevens, and Mott, have achieved most triumphant advancement in surgery; for thus the means of cure have been happily extended to cases of aneurism, formerly regarded as irremediable. There are many aneurisms, and not of unfrequent occurrence, on which the surgeons of the last century were content to look until the tumour burst, and their patient perished under their very gaze, which are now fearlessly encountered, and with the best hopes of success. In aneurism of the neck, Hunter and Scarpa led the surgeon to believe that a ligature placed on the carotid, between the tumour and the heart, might effect a cure, and Cooper proved that it did so. This arresting of the cephalic circulation is no longer looked upon with insurmountable dread, for experience has shown that even both carotids may be tied, with but a short interval between the operations, and without any untoward result. The surgeon's knife and ligature have, in the cure of aneurism, ventured even so near the heart as the arteria innominata,

Surgery.

but hitherto unfortunately without ultimate success; indeed it is doubtful whether the operation on this vessel can ever prove successful, there being so many inevitable obstacles to complete consolidation by ligature; as yet, ulceration has always supervened, occasioning fatal hæmorrhage. The subclavian has been deligated on account of axillary aneurism. Mr Liston had the honour to be the first who did so with success, and an equally happy result has not been unfrequent since. Ligature of the axillary and humeral arteries, though sometimes difficult, is regarded as scarcely unusual. The aneurisms of the groin and hip were left to run their course unmolested until Abernethy and Stevens showed that the Hunterian operation could be extended even to them. "The common, external, and internal iliacs are now tied without much difficulty, and very often with a successful issue. These operations are quite justifiable, provided always there has been no mistake in diagnosis, and that there is nothing in the state of the patient's health or in the condition of the arterial system to contra-indicate interference." The original operation on the femoral, on account of aneurism in the ham or in the lower third of the thigh, is now looked upon, when skilfully executed, as at once the simplest, most beautiful, and most successful interference with the larger arteries. Thus we see that all aneurisms of the extremities are within the reach of our art, and that a certain degree of success has attended the approaches towards the trunk, as far as the common iliac and arteria anonyma.[1] It is to be feared that "the force of (operative) surgery can no further go." It is indeed a triumph that it has gone so far; and we cannot reasonably expect that ligatures, placed nearer the great centre of circulation than either of the above-mentioned vessels, can ever be productive of a successful result. Surgical invention and enterprise have not, however, been easily baffled, and in those cases of aneurism too deep to admit of the Hunterian method of operation it has been proposed to reverse the procedure, and place a ligature on the distal side of the tumour. The operation has been put in practice, and in a few cases with some temporary advantage. Great difficulty, however, has sometimes been experienced in discovering the vessel destined for the ligature, in consequence of displacement by the tumour, or more or less obliteration of its calibre. In false aneurism from wound, as at the bend of the arm, if pressure methodically and firmly applied—the whole limb below the wounded point being duly supported—fail to arrest the formation of tumour, recourse is had to the ligature. If the tumour be recent, soft, and superficial, and the parts around not much infiltrated, the wounded point may be exposed at once by incision, and ligature placed above and below the aperture. But if the tumour be of considerable duration and size, ligature of the trunk, between the tumour and heart, may be the preferable and equally successful proceeding.

The more important steps in effecting deligation of the larger arteries, whether for true or false aneurism, may here be briefly mentioned. The incisions are made with a small, finely-edged scalpel, used lightly and cautiously; neither directors nor blunt knives should be employed, for they must bruise or tear to a certain extent, and the simpler and smoother the cut is, the greater is the probability that both wound and artery will assume a healthy action. The vessel having been exposed, its sheath is opened on the anterior aspect, to the extent of about an inch, and the point of a blunt aneurism-needle is gently passed beneath and around the artery, great care being taken to exclude nerve and vein from its circuit. A strong silk ligature having been thus passed, its loop is cut, and one half withdrawn along with the needle; the other is firmly secured on the artery, its effect on the tumour having, by previous pressure, been ascertained to be satisfactory. "All this must be done without disturbing the position of the vessel, without detaching it from the sheath, or breaking up its fine cellular connections laterally and behind, further than is barely sufficient for the passage of the needle. There must be no lifting of the vessel on the handle of the knife, or on the director, as if in triumph, for ulceration of the arterial coats, and secondary hæmorrhage on or about the separation of the ligature, are the almost inevitable consequences of such proceedings." If by accident the vessel has been disturbed from its connections, two ligatures are to be applied, one at each termination of the separated portion, but in general one single ligature is much preferable. Both its ends should never be cut away close to the knot, for, in addition to the ordinary disadvantages found to belong to this plan, there is no slight risk of abscess, caused by the deserted knot, inducing secondary bleeding by ulceration of the arterial coats. And indeed the surgeon will feel more comfortable in such anxious cases if he leave both ends pendant from the wound. For a like reason, separation of the ligature should be throughout its whole course spontaneous; rash pulling at its ends may be productive of the most serious results. The wound is brought together and otherwise treated according to the principles formerly detailed. Should secondary bleeding unfortunately occur, the vessel must be exposed and tied above the source of hæmorrhage. But if the original operation have been judiciously as well as dexterously performed, and the after-treatment carefully conducted, such an untoward result need scarcely be dreaded. Should pulsation return in the tumour to an undue extent, on the complete establishment of collateral circulation, pressure well applied will usually suffice to perfect the obliteration of the sac.

So much for the knife. But modern surgery has successfully revived the use of pressure, not seldom superseding the ligature, with success. The pressure is made not directly on the tumour, but at a distance from it; at the same point, in fact, where the Hunterian ligature would lie. It is not intense, so as to arrest the flow of blood completely, and it need not be constant in its application. Consequently, it is not intolerable to the majority of patients; and such moderate use of it has been found, in experience, to be sufficient in many a case for satisfactory cure of the aneurism. Being a minor procedure, it well may be employed in all suitable cases in the first instance, seeing that while the prospect of success is good, the risk of hazard scarcely exists at all under careful and judicious management, and, in the event of failure, the patient is still left in a favourable condition for the operation by ligature. Its great advantage over the latter is, that it avoids direct læsion of the arterial coats, which in all cases of idiopathic aneurism must be more or less diseased, and consequently prone to the casualty of secondary hemorrhage.

Veins.

In dilatation or varix of the veins, if methodical pressure and attention to the bowels fail to remove the disease, or at least its inconveniences, a radical cure is obtained by obstruction of the calibre of the main trunk, on the cardiac side of the dilatation, and this is effected either by the application of potass, or by including about an inch of the vein at that part, between two points of twisted suture, the needles being passed beneath the vessel, and removed as soon as sufficient change has been produced in the venous coats and contents. Either method is effectual in obtaining obliteration of the vein's calibre at the selected point; the latter is, perhaps, in most instances the preferable, but

[1] The aorta has been tied, but with a result which does not warrant repetition of the experiment; unless, indeed, circumstances be such as to render the protraction of life for but a few hours eminently desirable.

in both the procedure must be cautious, and the after-treatment watchful, in order to guard against hæmorrhage and extension of phlebitis.

Venesection.

The operation of phlebotomy has always been simple and of easy execution; in regard to it, the only modern improvement which we have to notice is the comparative rarity of its performance. It was too much the custom to bleed, so as to appear to be doing something active in treatment, not only when the proceeding has seemed to the ignorant practitioner likely to do no harm, but also when a wiser head could have told that it must do irremediable mischief. The good fortune of the first phlebotomist, Podalirius, seems to have produced in his successors an unfortunate attachment to the operation, which has been communicated from generation to generation, and from which our day is not yet wholly exempt. In some cases it is doubtless the only certain means of relief, and must be employed readily and boldly, but in fully as many it had better be done with a sparing hand or altogether omitted. What can be worse, for example, than to find a patient who has just sustained a severe accident—still labouring under the shock which the injury has produced, pulseless, and with the powers of the system all but extinguished—robbed by an ignorant or reckless man, unfortunately called to his aid, of those very powers of which he is at the time most in need, and without which the syncope must soon pass into death. Such a case is too frequent even now, but it is consolatory to know that the folly of such proceedings is becoming more and more extensively known, and that the thoughtless, mischievous practice of indiscriminate venesection is more and more abandoned.

Bruise.

A similarly absurd practice prevails in regard to the treatment of bruise. Leeches are instantly applied, in order that they may suck out the extravasated or "bruised blood," as it is called. These little animals drink only from the running stream, drawing for themselves from the blood-vessels, and therefore fail to perform what is expected of them by their employers. At the same time, their bites, admitting the external air to the extravasated blood, may induce suppuration of an unheathy kind in the cellular tissue. They are of use simply as a mode of local depletion, in order to moderate or avert an inordinate inflammatory process occurring as a secondary result of the accident.

The practice of blood-letting in inflammatory disease has undergone a great revolution within the last thirty years. Instead of being the ordinary treatment, it is now quite exceptional. And this change seems to depend on several circumstances: mainly these—a better acquaintance with the pathology of the disease, an alteration in the type of the disease itself, and a more skilful handling of the other and simpler antiphlogistics.

Hernia.

In the treatment of hernia, the advancement of anatomical knowledge has rendered operative procedure more simple, safe, and effective. And pathological experience having now fully established the great danger of delay after the taxis, fairly tried, has been found unavailing, the operation is had recourse to at once, with a much more certain prospect of success. In the greater number of cases the taxis will prove successful, when employed early and with skilful perseverance. But as soon as the surgeon is satisfied that his unarmed hands, assisted by his medical skill, are incapable of reducing the tumour, each moment of delay is culpable until he assumes the knife, and by it relieves the constricted parts, for by its keen edge the patient is infinitely less endangered than by even brief continuance of the incarceration—more especially if, as is often the case, the constricting cause can be removed by limiting the incisions to the outside of the sac, and so largely tending to prevent all risk of peritonitis. This principle, now generally acted on, saves many a patient who formerly would either have perished in excruciating torture, or lingered on with artificial anus, noisome to others, and a burden even to himself. But this is a subject too extensive to be here more fully considered.

Calculous disorders.

In the treatment of calculous disorders, modern improvement has effected much. Chemistry, happily combined with pathology, has taught the surgeon, in many cases, to anticipate cure by prevention, detecting the tendency to deposit in the secretions of the kidney, ascertaining the exact nature of that deposit, and then applying, according to its nature, the suitable corrective. When there is reason to believe that calculus has actually formed in the bladder, its presence is to be ascertained by careful sounding. Many affections—for example, diseased kidneys or fundament, worms or other causes of irritation in the bowels—occasion all the ordinary symptoms of stone; and it is only after the surgeon has distinctly heard the stroke of his sound on the foreign body, that he can be certain that a stone exists. The most convenient instrument for exploring all parts of the bladder is a sound, steel throughout, with a sharp and sudden curve. When, by its cautious and patient use, the presence of a calculus is no longer doubtful, and some estimate has also been made of its size and form, the question then arises between patient and surgeon as to the preferable mode of its summary extrusion; for removal by chemical solvents, though sanctioned by act of Parliament, is no longer trusted to in practice. It is only within these twenty years that a power of selection has existed; till then, the knife alone presented hopes of relief. Now, however, *cutting* is often superseded by *crushing*, and rightly. Indeed it is a *questio vexata* among many as to whether lithotomy or lithotrity be the better adapted for general use; and each has its zealous and uncompromising advocates. As is usual in such cases, we shall probably find that truth lies in the middle, and that both operations are to be practised, each finding cases to which it is peculiarly applicable. Lithotrity was at first a very imperfect art, difficult and complicated in performance, often failing in the attainment of its object, and not seldom followed by the most untoward results. Its practice was likewise in a great measure confined to a particular set of operators, not the best qualified for such undertakings, who, regarding it as a means of gain alone, were not long in bringing discredit on its reckless and indiscriminate use. Thus a great advantage was given to the old operation, over its imprudently managed rival. But the instruments and procedure of lithotrity have of late been greatly improved, and have become, as is usual in such improvements, more easy and simple, and at the same time more effective. They now receive the attention of every well-educated surgeon; the student applies to lithotomy and lithotrity with equal care and attention, and endeavours to perfect himself in the manipulations of both; and in consequence, the latter operation has been rescued from the empirical professor, and placed in the better qualified hands of the regular practitioner. There is not now, as in the time of "the invasion of professed stone-grinders," some years ago, an indiscriminate performance of one operation, in all cases, simply because the operator knows no other. The circumstances of the case had then very little influence in determining the nature of the operative procedure. If a surgeon was applied to, the knife was recommended; and "if the patient fell into the hands of the professed stone-grinder, he was certain, under all circumstances, of being subjected to the hammering and boring processes." Now, application being made to the regular practitioner, at least in the first instance, he, equally acquainted with either mode of operating, conscientiously advises the one which circumstances require, either operating himself, or employing one whom he may consider more dexterous and equally skilful. Lithotrity can only be safely performed by those "who understand well the healthy anatomy of the urethra and

bladder; who are acquainted with their sympathies, vital actions, and pathological changes, and who understand and practise the treatment of their deranged functions." And by such it is now performed, in the cases to which it is applicable. In patients above the age of puberty, when the symptoms have not been of very long duration, when the stone has been ascertained not to exceed a chestnut in size, when the urethra is free from contraction, when the bladder is capacious, tolerably healthy in its coats, and free from irritability of its lining membrane, and when the individual is of an easy, patient disposition; under a combination of such circumstances, lithotrity is the preferable operation. It is thus apparent, that possibly lithotrity may in time almost entirely supersede lithotomy in the adult; the chief thing necessary being, that the patient apply to a well-qualified surgeon at the very commencement of his ailments. But until wisdom shall pervade mankind to this extent, very many cases must occur in which the old operation, well performed, is much to be preferred; and this need not be greatly regretted, for the actual difference between the two operations as to suffering and danger is perhaps not so great as is generally supposed.

The simple instrument of two branches, as made by the Messrs Weiss, has superseded all the more complicated and less effective apparatus for lithotrity, as well as Cooper's forceps for removal of small stones by the urethra. The instrument having been introduced into the bladder, tolerably distended, is brought in contact with the stone; its blades are opened, and the stone brought between, great care being taken that the mucous membrane is uninjured; the blades are then approximated by the screw, and the interposed stone crushed more or less completely. When the stone is single, small, and friable, one such proceeding will suffice; if not, the fragments are seized and bruised in succession, either at the time, or at one or more subsequent sittings. The screw-power is preferred to that of the hammer, as equally efficient and more safe, not endangering the twisting or breaking of the instrument. Diluents are freely exhibited, to promote and facilitate passage of the detritus with the urine. Should the pain and irritation thus occasioned prove severe, opiates, hot bathing, &c., may be required. But, in general, if the case have been judiciously selected, and the operation skilfully performed, the subsequent irritation will be but slight; and, after a few days, examination of the bladder may be resumed, to ascertain whether or not all the fragments have been extruded. This exploration cannot be too minute and careful, for the greatest stumbling-block to the advancement of lithotrity in the confidence of the profession has been the uncertainty as to whether or not the bladder has by such proceedings been completely freed from every fragment, it being well known that but a very small portion of foreign matter remaining will become the nucleus of further deposit, and speedily re-establish the disease. The advantage of lithotomy is, that, for final exploration of the bladder, it has the finger, which, if at all experienced, can seldom be deceived. Lithotrity has but the sound for the same purpose, and must endeavour to make patience, dexterity, and care, compensate for the inferiority of the instrument.

But when the stone is large, and has been long resident in the bladder, this viscus has its cavity contracted, its coats fasciculated, and its surface irregular, affording receptacles for the fragments, from which the most careful manipulations may not dislodge them. Besides, such a bladder will not bear the annoyance of instruments often introduced; indeed the mere change of a tolerably smooth stone into angular fragments, may be sufficient to excite even fatal disturbance of the viscus and of the system. In all such cases, therefore, lithotomy is the preferable operation; it not only insures, with common care, complete removal of the source of irritation, but also by suspending the functions of the diseased viscus, gives it the advantage of rest, as well as the relief caused by loss of blood from the neighbouring vessels. Even when the bladder is tolerably sound, a large stone of ordinary consistence is unfavourable to lithotrity; for the fragments must also be large, until after much manipulation; and attempts to pass such fragments must be attended with much pain and some danger. The immediate result of lithotrity in such cases is, " like the partial delivery of a pregnant woman," very unsatisfactory. The fragments may become firmly impacted in the urethra, causing retention of urine, and all its direful consequences. When this happens, and the impacted portion will not yield to an attempt to push it again into the bladder, it must at once be reached and removed by incision in the mesial line; and then the surgeon may take the opportunity of extending the wound a little farther, and with his finger and a scoop effectually clear the bladder of all remaining detritus. Lithotrity is not very applicable to young subjects; the parts are not sufficiently capacious, and the concretion, usually of oxalate of lime, may be too hard to be easily pulverized. This is the less to be regretted, as in them well-performed lithotomy seldom proves unfortunate. Among them, therefore, and " those of mature age who are so foolish or so ill informed as to permit the stone to attain an inordinate bulk," lithotomy must still prevail. It is an operation certainly more alarming to the patient, and to the surgeon may be more difficult and perplexing; but when dexterously and skilfully executed, we doubt much if its average risk exceeds, or even equals, that of promiscuous lithotrity; its efficiency is indisputably greater. The mode of operation pursued by Mr Liston, the most dexterous, elegant, and successful lithotomist of recent times, is similar to the method of Cheselden. For its details, we beg to refer to Mr Liston's work on *Practical Surgery*, where the modern lithotriteur is also minutely described. He attributes much of his success to limited incision of the prostrate, so as to preserve the internal cellular tissue of the pelvis from infiltration of urine; and to the insertion of a gum elastic tube in the wound, so as to afford a free exit to the urine, and diminish the risk of its poisonous infiltration, while at the same time it facilitates the arresting of hæmorrhage, should this occur. " The operation of lithotomy," says he, " if performed in the easy and simple method recommended, is effected with much less pain than is supposed; it is completed, with perfect safety, in a short space of time, and offers very favourable results. It is, however, an operation which ought never to be undertaken without due consideration of all the circumstances that may arise; and the surgeon who does undertake it must have resources within himself to meet and overcome difficulties in all the various stages of the proceeding."

Stricture. In the treatment of stricture of the urethra, all armed bougies have been laid aside, in favour of the plain metallic catheter and bougie. The milder cases are easily overcome. A metallic bougie, selected of such a size as will with no great difficulty pass the constricted part, is gently insinuated along the urethra. After two, three, or four days, the introduction is repeated. Then at each farther re-introduction, at an interval of a few days, the size of the instrument is gradually increased, until it completely fills the orifice; a sign that sufficient distention of the canal has been achieved. After this, it is right to pass a full-sized instrument occasionally, at long intervals, to counteract any tendency towards return of the contraction. Soft pliable bougies may sometimes be useful for mere exploration of the canal, but are not of much use otherwise; it being difficult to guide their points, or ascertain the exact direction which they assume. During the cure, the state of the urine should be strictly attended to; for its acridity—one of the causes of stricture—may, by irritation of the urethra, materially retard progress. Should the bougie cause seri-

ous irritation of the urethra, as sometimes happens, the interval between its introductions must be increased, allowing the painful effects of each to subside before another is attempted, else much more harm than good will accrue from the use of the instrument.

It is important to remember that it is not necessary always to pass the bougie completely through the contracted part of the urethra in order to obtain its remedial and relaxing effect. To pass the instrument down and partially into the stricture is often enough; repeating this from time to time, till at length the instrument slips through into the bladder; and a medium-sized instrument, as No. 5 or 6, is often, in cases of tight stricture, safer, as well as more expeditious, thus employed in what has been called the "tunnelling method," than a small instrument, such as No. 1, thrust through, or attempted to be thrust through, at each introduction.

For the penetration of tight unyielding strictures, a firm silver catheter is the most appropriate instrument, its size being proportioned to the extent of contraction. For very obvious reasons, great caution must be observed in its use; steady, cautious, patient, and gentle pressure, in the right direction, must never be superseded by sudden and daring force, or irreparable mischief may ensue. "Lightness of hand, and gentleness of manipulation, will often enable a surgeon to overcome difficulties which to others may have proved insuperable. The operation of introducing a catheter through what has been called an impermeable stricture, is without doubt the most difficult in the whole range of surgical practice, and demands all the prudence, science, and skill of a master. The art can only be acquired, and that gradually, by frequent practice." When the stricture is very tight, and has afforded much opposition to the passage of the catheter, and more particularly when the operation has been undertaken on account of retention of urine, it is well to retain the instrument secured in the strictured part for twenty-four or eight-and-forty hours. The cure is thus much expedited, as well as recurrence of the retention prevented. The presence of the foreign body in the stricture calls up a natural effort for its extrusion, resulting in relaxation of the part, with profuse discharge; and so remarkable is the dilatation thus effected, that on withdrawing the instrument at the end of the time already specified, it is found "lying quite loose" in the passage, although at its introduction it had been grasped most tightly, and firmly fixed in the stricture. Immediately after its withdrawal, a much larger instrument can usually be introduced with ease, and the cure is then proceeded with as in ordinary cases. Sometimes the parts so strenuously resist the presence of the foreign body, that it is prudent to remove the instrument in less time than we have mentioned. Under no circumstances should it be retained beyond two days. It is apt to become coated with calculous deposit; and, besides, there is danger of its irritation proving excessive; ulceration may take place in the urethra, or abscess form along its course.

Thus many a bad stricture may be overcome, and the urethra restored to its healthy functions and dimensions. But, as already said, prudence and experience are inseparable from the safe use of the small catheter; with these, it is a most valuable instrument, and saves many a patient who might otherwise have become the victim of dangerous operation. It is seldom, indeed, that we now hear of puncture of the bladder, even by the rectum. And we as seldom hear of the catheter producing tears and wounds of the urethra, followed by abscess and fistula, or urinary infiltration, ending in the death of the patient, or at least in the destruction of a large portion of his genital integument and cellular tissue. When from any cause urine has escaped into the cellular tissue of the perineum, free and deep incision, so as to afford ready escape to the poisonous fluid, cannot be too early resorted to.

Should it happen that the surgeon, notwithstanding skill and perseverance, is foiled in passing the catheter, and relieving distention, then, instead of puncturing the bladder, he may proceed to "make a free opening in the perineum, directly upon the obstructed part; to cut upon the end of the catheter, carrying the knife forwards; to open the dilated portion of the urethra, and then to pass the catheter on to the bladder." Thus the viscus is relieved, and a sure commencement made of the cure of the stricture, while no permanent inconvenience ensues, as is apt to be the case after puncture of any part of the bladder.

In passing the catheter to relieve retention caused by prostatic disease, it should never be forgotten that the urethra is in such cases much elongated, and that in consequence the instrument ought to be three or four inches longer than those in ordinary use. The treatment of the enlargement of that gland is entirely palliative; proposals for its removal by excision cannot be ranked among the modern improvements.

There is a class of strictures, tight, irritable, relapsing, and sometimes associated with great tendency to untoward sympathy of the system, in which the ordinary modes of treatment prove unsatisfactory at the best, and sometimes altogether abortive. Fortunately, these are comparatively few. For their cure incision is advisable; dividing the whole of the constricted parts, and subsequently maintaining due dilatation by means of bougies. The incision may be from without, or from within; the former preferable, in most cases, as being exact in its operation, and avoiding risk by urinous infiltration of the tissues. The safest mode of performance is on the grooved staff, as recommended by Mr Syme.

Diseases and injuries of the windpipe.

Diseases and injuries of the windpipe are better understood, and more successfully treated, than formerly. In the latter, the surgeon is less meddlesome, and his patient is benefited accordingly. In wounds of the throat it was formerly the custom, after having secured the larger arterial branches, to proceed at once to closure of the wound, dragging it together by stitches and plasters, and covering all by lint and bandage, as if the principal object were to conceal the horrid gash from view. The consequence was, that the blood, which continued to ooze, finding no ready outlet externally, collected in the air-passages, and suffocated the patient, provided, as was most probable, he had not at the time sufficient energy for forcible expectoration; or if this danger was escaped, it was shortly succeeded by one equally imminent, closure of the windpipe at the injured part, from inflammatory swelling of the wound. Now the intelligent surgeon is less precipitate; he knows the danger of the old system, and avoids it by treating cut-throat on the same principles as he would an ordinary wound, making no approximation until all oozing has ceased, and then only drawing together the corners, trusting the centre to the more gentle apposition by bending the head forward, and by bandage retaining the chin approximated to the top of the sternum. Thus a free outlet is left to the discharges which must form; for the transverse nature of the wound, and the constant motion of its edges in respiration and deglutition, render union by the first intention impossible. Immediate risks are thus avoided; and if the patient's energy prove sufficient, the wound will gradually close by granulation. But too often, at least in attempted suicides, a low fever ensues, against which all efforts toward cure are unavailing. The patient should be kept in a comfortably warm and equable temperature, and the fore part of the neck should be protected by some loose covering, that the inspired air may be, as nearly as possible, of the same temperature as in natural respiration. Thus the occurrence of bronchitis is so far obviated; and so long as

air passes through the wound, no other dressing need be applied. When the pharynx is involved, nourishment is given from time to time through a tube introduced by the mouth; not through the wound, lest contraction of the tracheal opening should be interfered with, and its edges cicatrize separately, leaving the patient in a very miserable plight. Sometimes respiration becomes obstructed by swelling of the mucous membrane and accumulation of viscid mucus, so as to endanger suffocation, and render it necessary to open the windpipe longitudinally below the obstructed part. Tracheotomy has also been proposed as a preliminary part of the treatment, so as to permit immediate and accurate approximation of the wound, with a chance of primary union taking place. The tracheotomy, in this case, acts as a safety-valve, preventing untoward consequences.

In injuries of the interior of the throat, tracheotomy is sometimes necessary. When the glottis has been injured, for example, by the swallowing of acids, or hot water, or by the inhalation of steam, should the ordinary active treatment fail to arrest the urgent symptoms, tracheotomy must be had recourse to without delay, otherwise the patient will perish, either by immediate suffocation, or by effusion consequent on imperfect pulmonary circulation. A simple blow on the larynx may so completely paralyze the parts, as to render opening of the windpipe necessary for restoring the respiration. And the operation is also required when foreign bodies have lodged in the air-passages, and cannot be expelled by expectoration. If allowed to remain, they are productive of the greatest annoyance; perhaps suffocation is immediate; and if they do not speedily induce inflammatory accession of the most serious nature, they are certain ultimately to occasion phthisis, or other chronic disease of fatal tendency. If the foreign body is loose, it will be spontaneously ejected from the opening; if fixed, it must be dislodged by forceps.[1]

In diseases of the air-passages, tracheotomy often becomes necessary, on account of obstruction at the top of the windpipe preventing free entrance of air into the lungs. In acute inflammatory affections, croup, for example, its employment is open to difference of opinion. In the early stage, it has been said, on high authority, that "whilst active antiphlogistic remedies are indicated, and considered likely to afford relief, it could not with propriety be proposed; in the latter stages, after lymph has formed, when the lungs are gorged, and effusion has commenced at the base of the brain, no good purpose can be answered by an operation." Sometimes, in adults, a favourable opportunity for the operation may be selected between these stages; all the more as, in them, the morbid change of the lining membrane is more frequently confined to the larynx. And even in children, when the case is advanced, urgent, and apparently incapable of further benefit by simple remedial means, it comes to be a question whether the chance of relief by tracheotomy, doubtful though in many cases it must necessarily be, ought not to be afforded. To the chronic affections the operation is more applicable. Even in phthisis laryngea, the most intractable of these, advantage may be derived from it when performed at an early period; the diseased parts above the opening being set at rest, and an opportunity afforded of making direct application, through the wound, of the suitable remedies to the ulcerated surface. But it is in œdema of the glottis, whether as a primary affection, or supervening on previous disease, that its beneficial results are most frequent and most apparent; the patient is at once relieved from impending suffocation; the swollen parts are put to rest, and in time subside; and after a while they so far recover their healthy condition, as to admit of closure of the wound and re-establishment of the natural course of respiration. In all cases where opening of the windpipe is required, whether on account of accident or disease, tracheotomy is preferable to laryngotomy, and though a little more difficult, is equally safe in performance. An opening in the cricothyroid membrane will not always suffice for detection and removal of a foreign body; and being placed in the ordinary site of laryngeal disease, will usually fail to afford relief when undertaken on that account. The incisions in tracheotomy are made very carefully, so that stray vessels may be pushed aside in safety; the trachea is pierced during the act of deglutition, when the larynx is elevated and the windpipe elongated; a silver tube is immediately introduced, of calibre proportioned to the object in view, and of such a form as to prevent oozing from the wound by compression of the edges. After a short time all irritation from the presence of the tube ceases; but during the whole cure great attention must be paid that it be kept clear of the vitiated mucus. It should also be protected by some loose covering, in the same manner and for like reasons as in cases of cut-throat. In the treatment of all affections of the throat, the possibility of tracheotomy becoming requisite should always be kept in view; and the curative applications should consequently be confined as much as possible to the sides of the neck, leaving the fore part free, otherwise much difficulty may be thrown in the way of the operator.

Diseases of the rectum. The treatment of diseases of the rectum has become simplified and improved along with the rest of surgery. "Many attempts have been made to mystify the subject of diseases of this region, and to separate them in a great measure from general surgery. There is no such difficulty as has been supposed in understanding their nature; the principles which should guide their management are simple, and the means, operative and otherwise, easily enough applied." Of late a variance of opinion has arisen in regard to the treatment after operation on the rectum; one party maintaining that in all cases little or no dressing is required; the other, that in every case stuffing and compression of the wound are essential to the safety of the patient. As is usual when opinions are in extreme opposition, we find that truth occupies a middle place. In slight cases of operation, for fistula, hæmorrhoids, &c., no more dressing is required than what is sufficient to prevent immediate union of the divided parts, especially when the good general rule is followed out, of always tying every artery that springs, however small, in this quarter; while in others, a degree of compression must be made on the divided surface, proportioned to the extent of the incision and the probability of hæmorrhage by oozing. It would be very unnecessary to cram the wound in the first class of cases; in the second, it would be equally unwise to leave the parts wholly unsupported.

Tumours. As the pathology of tumours has become more and more understood, operative procedure has been withdrawn from some and extended to others. Diagnosis having become both more easy and more accurate, we can now more readily distinguish between those of a benign and those of a malignant disposition. In regard to the latter, experience has taught us usually to forbear from operative interference, unless at the very first accession of the disease; for though the more simple tumours, even when of large size and long duration, may be removed with every prospect of permanent cure, yet in those of a malignant nature, immunity from recurrence of the disease can be hoped for only when the removal is early; when the local affection is still limited and loosely attached; when there is a certainty of being

[1] A most interesting case of foreign body in the bronchus, successfully removed by operation, is detailed by Mr Liston in his *Practical Surgery*, p. 371.

able to remove, not only the morbid structure itself, but some portion of the unaltered tissues which invest it; before any affection of the neighbouring lymphatics can be detected; and before the general system seems to have been both largely and permanently involved. Among the more benign tumours, perhaps the most remarkable extension of active surgery is in regard to the solid tumours of the jaw. Thirty years ago these formidable formations were looked upon with horror and dread, as one and all of the most malignant tendency, and were consequently left to their own course. But now we have been taught that such is not, and ought not to be, the case; that many doubtless are most malignant, and must not be interfered with; but that others, and sometimes even those of the most formidable appearance, are sufficiently local and apathetic to warrant the adoption of active interference with the most sanguine hopes of success. Both the upper and lower jaws, involved in large and frightful tumours, have of late years been removed by operation; and when the case has been judiciously selected, good success has been invariable. In the soft medullary tumour of the upper jaw, commencing in the antrum, an opportunity warranting interference can seldom occur; for before the morbid formation has appeared externally in the mouth or nose, it has not only completely involved the bone in which it originated, but also included in the diseased mass the palate-bone, the ethmoidal cells, the orbit, and even the sphenoidal sinuses. It is only when such a disease, at an early period of its existence, is confined to the antrum, that removal of the superior maxillary bone can be of service; but unfortunately its true nature is seldom discovered until a portion of the tumour has become apparent by the giving way of the parietes; and when that has occurred the case is hopeless, for its extension backwards very far exceeds the outward protrusion. In its first stage the prominence of the cheek has the same smooth glistening appearance as in chronic abscess of the antrum; but the parietes of the tumour are hard and unyielding; they soon thin at one or more points, there communicating a pulpy feeling to the finger; and when they have completely given way, the ravages of the disease are as rapid as uncontrollable. The more benign tumour in this situation—originating in the bone, and usually the result of injury—is, on the contrary, slow in its progress and of very firm consistence; its surface is lobulated, and if ulcerated by accident, soon heals again; the internal structure, of a firm fibrous character, is limited by a dense cellular cyst; and the neighbouring bones are either simply displaced, or removed more or less by interstitial absorption; the progress of the tumour is in consequence almost entirely towards the surface. It is in such cases that the surgeon does not now hesitate to remove the superior maxillary bone; for with it he knows that he can take the whole diseased formation. It is doubtless a formidable operation, and not unattended with danger; but the risk is insignificant when compared with the ultimate benefit likely to accrue. It is, therefore, evidently of the highest importance to distinguish accurately these two classes of tumour, the treatment suitable to each being so widely different; in the one case operation is usually inadmissible, while in the other the sooner it is had recourse to the greater is the probability of a successful result. Care should also be taken not to confound either with the more simple affection of accumulated fluid in the enlarged antrum; for it has happened that a surgeon, after having made up his mind to attempt removal of the superior maxilla, has, "on trying to divide the connections of that bone, had his hands covered with purulent matter, and himself with shame and confusion." The same general description applies to tumours of the lower jaw as to those of the upper, with this difference, that the relative position of the former somewhat prolongs the favourable opportunity at which tumours even of malignant tendency may be removed. That very many tumours of the jaws are attributable to disease, or even faulty position, of the teeth, and to unskilful dental operations, is a fact as true as it is important, and should direct both surgeon and patient to greater and more frequent attention to those influential little portions of the osseous system. After the operation on either jaw, an unseemly void of course remains; but nature, assisted occasionally by the dentist, does wonders in repairing this, and the actual deformity is in many cases surprisingly slight.[1]

In operations for the removal of tumours in the soft parts, we have elsewhere stated that the incisions should be so planned as to divide the principal vessels at the outset, as thus both time and blood are saved. If the vessels implicated are large, temporary pressure on the trunk may be made by the assistant; but it can seldom if ever be necessary to practise a preliminary operation for the securing of that trunk by ligature. In most cases the dissection of the tumour should be made as rapidly as is consistent with the safety of important parts in the neighbourhood. But when the tumour is suspected of a malignant tendency, the duration of the proceeding must not be considered; the dissection must be methodical and deliberate. As it proceeds the parts must be examined carefully by both the finger and eye; and on its completion, the removed mass must be minutely surveyed, lest any shred of morbid formation be left in the wound. No successful result can be hoped for, unless the whole altered structure is completely and freely removed. Another point in regard to operations on tumours ought never to be forgotten, namely, that the most simple and best dispositioned formations may, in the course of time, degenerate into the malignant and intractable, and therefore should not be exposed to this contingency; they should be early removed, while yet simple, and auspicious of successful results.

Vascular tumours, of erectile tissue, are now safely and efficiently removed by ligature. Formerly they were usually left undisturbed. Sometimes attempts at excision were made, but the results were truly discouraging, the hæmorrhage proving most alarming, and not unfrequently fatal. In minor cases, obliteration of the vessels may be safely effected by vaccination, pressure, acupuncture, injection, seton, or the application of escharotics. But such treatment is inapplicable to the erectile tumours of large size. These are best managed by ligature, arresting their circulation, and so producing sphacelus of the adventitious structure. When the formation is of a broad base, several ligatures are required, passed beneath the tumour by needles; and when the integument is free, or but slightly involved, it should be reflected by preliminary incision, so that these ligatures may be the more effectually applied.

By similar procedure, even enlargement of the thyroid gland may be removed. Of course no one would think of attacking the whole tumour on account of the mere deformity; but it sometimes happens that enlargement of the isthmus occasions difficult respiration, congestion of the cerebral vessels, and other alarming symptoms; and in such cases the offending part has been successfully removed by a combination of incision with ligature, using the knife as deeply as the hæmorrhage will permit, and then completing the isolation of the lobe by strong ligatures applied by transfixion.

In the treatment of venereal affections, mercurial supre-

[1] For details of the operation we again refer to Liston's *Practical Surgery*, a work of great value, from the perusal of which both practitioner and student will derive much profit, and to which, we beg to acknowledge, we have been not a little indebted in the course of the present article.

Surinam || Surplice.

macy has gradually given way to the influence of common sense, and the disease has consequently become more mild and tractable, particularly in its secondary forms. When the exhibition of mercury seems advisable, little usually suffices; it is used, not abused as formerly.

Venereal disease. Hydrocele.

Hydrocele, which was at one time the apology for very severe surgical proceedings, by knife, setons, and escharotics, is now under very simple treatment; the palliative—is mere tapping of the cavity; the permanent—injection of it, after tapping, by some stimulating fluid, such as tincture of iodine, or port-wine; the former is usually preferred, injected in small quantity, and allowed to remain. But great care must be taken during injection that none of the fluid enter the cellular tissue of the scrotum, otherwise violent inflammation must ensue in the infiltrated parts.

Restorative surgery. The nose.

Restorative surgery, in former years scarcely attempted, is now making rapid progress. Noses are made and repaired most adroitly, not according to the old inconvenient system of the European father of rhinoplastics, but by a modification of the plan practised by the Koomas, a caste of Hindoos, and first introduced into this country by Mr Carpue. This decorative operation was at one time very successfully practised by Mr Liston, the author of an important change in the procedure—not bringing the columna from the forehead, but waiting till the new apex and alæ so obtained are consolidated, and then fashioning a column out of the upper lip. By this little operation a more vigorous and substantial support is obtained for the new parts; and, besides the lip, which formerly hung tumid and pendulous, is at the same time very much improved. Some of these nasal constructions are scarcely to be distinguished from the natural feature at a little distance, are quite sufficient for the ordinary uses of that organ, and sometimes have been brought to desiderate and enjoy the questionable accomplishment of snuff-taking.

By an operation conducted on similar principles as the rhinoplastic, the lower lip is renewed from beneath the chin; the ear, or rather portions of it, from the integument behind; and deficiencies in the urethra can be closed by adaptation of a portion of either the prepuce or loose neighbouring integument. Such proceedings some may affect to disregard as trivial; but they are not looked upon as such by the unfortunate individuals to whom they are applicable, and really constitute a most interesting and useful department of operative surgery.

Surrey.

Great improvement in both looks and usefulness may also be achieved for the lip, by means of incision alone, without any transplantation of parts; the knife being so directed as to loosen existing relations, and admit of new position and play.

Harelip.

Harelip, one of the most disagreeable of the congenital deficiencies, can be very perfectly remedied by paring the edges of the fissure, and securing them in close and accurate apposition by two or more points of twisted suture. According to the principles already detailed, no further dressing is applied; and if the patient be otherwise in good health, and the parts protected from external injury, adhesion will seldom or never fail to occur. The most important part of the operation, as regards restoration of the lip's natural appearance, is complete removal, by the paring of the rounded margins where the membrane that covers the edge of the fissure joins the true prolabium. If this be not attended to the operation is imperfect, for a most unseemly notch remains in the lip; in fact, the fissure is merely diminished, not obliterated. But when these rounded portions are completely removed, and the operation is in other respects well conducted, a mere line of cicatrization is all that remains of the deformity.

Clubfoot.

Club-foot, a most inconvenient as well as unseemly malformation, may sometimes be remedied in children by simple means, merely applying the necessary retentive apparatus, until the parts become fixed in the normal position in which that apparatus places them. But, in most cases, division of tendon is also required; which can be freely and safely effected by subcutaneous incision, so as to slacken the abnormal bonds completely, and admit of entire restoration to the normal state. To other deformities the principle of subcutaneous section has been happily applied with the best success; a field much too wide, however, for consideration in detail here.

We have thus briefly and imperfectly sketched some of the subjects which naturally occur to us as prominent examples of the modern advancement of surgery. It were easy to swell the list, in both number and illustration. But our assigned limits have already been attained, if not exceeded; and enough has probably been said, both to convey a general idea of the improvement recently effected, and to encourage a hope that such progress will still continue, year after year, bringing the practice of this useful, enlightened, and noble art closer to perfection. (J. M—R.)

SURINAM, a river of the colony of Dutch Guiana, which is sometimes called by its name, rises in a mountain-chain in the south of the colony, and flows northwards through its centre into the Atlantic, which it enters near Paramaribo, after a course of about 300 miles. Its chief tributaries are the Commewyne, Errewyne, and Para. Large vessels can ascend the river for 30 miles. The banks are in general well wooded; but below Paramaribo they are laid out in plantations. The mouth of the Surinam is defended by forts.

SURPLICE, the habit of the officiating clergy in the Church of England. By Can. 58, every minister saying the public prayers, or ministering the sacrament or other rites of the church, shall wear a decent and comely surplice with sleeves, to be provided at the charge of the parish. But by 1 Eliz. c. 2, and 13 and 14 Car. II., the garb prescribed by act of parliament, in the second year of King Edward VI. is enjoined; and this requires, that in the saying or singing of matins, and even songs, baptizing and burying, the minister in parish churches and chapels shall use a surplice. And in all cathedral churches and colleges, the archdeacon, dean, provosts, masters, prebendaries, and fellows, being graduates, may use in the choir, besides their surplices, such hoods as pertain to their several degrees; but in all other places every minister shall be at liberty to use a surplice or not. And hence, in marrying, churching of women, and other offices not specified in this rubric, and even in the administration of the holy communion, it seems that a surplice is not necessary. Indeed, for the holy communion, the rubric appoints a white alb plain, which differs from the surplice in being close-sleeved, with a vestment or cope.

Boundaries, extent, and description.

SURREY, one of the smallest of the English counties, has the Thames for its northern boundary, Berkshire and Hampshire on the west, Sussex on the south, and Kent on the east. Its form is nearly that of an oblong quadrangle; its utmost length, from east to west, about 39½ miles; its breadth, 25½ miles. According to Parliamentary returns its superficial area is 789 square miles, or 485,760 acres; though Stevenson estimates it at 519,040 acres. It lies between 51. 5. and 51. 31. N. Lat., and 3. E. and 51. W. Long.

That portion of it included in the valley of the Thames is exceedingly rich and fertile; and the scenery is there diversified by leafy dells, waving corn-fields, picturesque ascents, and prolific woodlands. The western and southern

Surrey.

districts exhibit, on the contrary, wide barren heaths and gorse-covered commons, so that Fuller's quaint description is not altogether exaggerated. "The county of Surrey," he says, "is not improperly compared to a cynnamon-tree, whose bark is far better than the body thereof; for the skirts and borders bounding this shire are rich and fruitful, whilst the ground in the inward parts thereof is very hungry and barren, though by reason of the clear air and clean wayes, full of many gentile habitations." Aubrey speaks of it in very similar language:—"It has been likened by some to a coarse cloth with a rich bordure or fringe, the inner part being less fruitful than the skirts." A range of chalk-hills, often attaining a considerable height, traverses the shire from east to west; the northern slopes clothed with verdure, and affording many noble prospects; the southern, barren, precipitous, and rugged, but noteworthy for their elevation and romantic character. Among the North Downs may be particularised Cooper's Hill, rendered famous by Denham's vigorous verse; St Anne's Hill, associated with the memory of Charles James Fox; the wooded heights of Norwood; Banstead Downs; Box Hill, and Sanderstead Hill. Of the South Downs, most worthy of notice are Leith Hill, so celebrated for the richness and extent of the prospects which it commands; the road from Albury, which affords a view of the whole extent of the Weald; Tilburstow Hill, near Godstone; and Anstie-bury Hill, overlooking a landscape of the utmost beauty.

The Surrey hills.

Its geological aspect.

The geological characteristics of the county have been identified by Dr Mantell with three principal groups, namely, the Wealden, which is the lowermost and most ancient; the Chalk, which overlays it; and the London Clay, filling up the depressions or basins of the chalk. Upon these last-named strata have accumulated, in many places, those drifts of sand, loam, and gravel known as post-tertiary detritus, or diluvium. In the neighbourhood of London, on Richmond, Tooting, and Wandsworth Commons, may be found the blue and tenacious London clay, yielding occasionally the bones and teeth of extinct mammalia; of birds, serpents, and crocodiles; fishes, crustacea, nautili, and other marine shells. Epsom and Bagshot Heath lie upon the Bagshot Sand. The North Downs are entirely of the chalk formation, affording ammonites, nautili, and belemnites; corals and other zoophytes; echini, crustacea, and the bones of saurians and turtles. The Shanklin, or lower green sand, occasionally rising to a considerable elevation, may be found at Reigate, Dorking, Godalming, and Tilburstow Hill. The Wealden occupies almost the whole of the southern portion of the country. The district between the Thames and a line running through Croydon, Sutton, Epsom, Leatherhead, and Guildford exhibits Bagshot Sand; between the boundary just indicated and the northern slopes of the Surrey Downs spreads the chalk formation. Shanklin Sand lies between the latter and the range of Tilburstow Hill, Bletchingley, and Leith Hill, a range which separates it from the Wealden.

Climate.

The face of the county being so varied, it is easy to understand that there will prevail extraordinary differences of temperature. The northern and southern districts are somewhat damp; in the former from their vicinity to the Thames, in the latter from the flatness of the surface and the luxuriance of the woodlands. The air on the chalk hills is, on the contrary, of a dry and bracing character. But, on the whole, Surrey may justly be regarded as a healthy county. Its climate is usually bland and genial, encouraging a quick vegetation and an early harvest. The popularity of its towns among fashionable places of resort is, in a great measure, due to their salubrity; and for different classes of invalids, the faculty constantly appreciate the advantages of Richmond, Dorking, Esher, and Reigate.

Surrey.

Products.

In the neighbourhood of London the cultivated land is principally devoted to the production of those esculents required for the metropolitan markets. Acres of market-gardens are there in continual cultivation. Chertsey and Godalming produce yearly a large supply of carrots, a vegetable first introduced by the Flemings when driven into England by the persecutions of Alva; but potatoes and cabbages are more generally and more extensively raised. Mitcham is famous for its flower-farms, devoted to the culture of medicinal herbs, such as lavender, mint, chamomile, penny-royal, rosemary, and hyssop. Farnham is celebrated for its hops, which flourish abundantly on its calcareous soil. Though now a principal staple of the district, the hop culture does not date farther back than 1597, when, according to Aubrey, it was introduced by Mr Bignell, a Suffolk gentleman. The varieties chiefly cultivated are the "white-bine grape hop," the "red-bined orchard hop," and the "never black." Red clover is extensively grown in the meadow-lands of Surrey, and sainfoin upon its extensive chalk-hills. Sir Richard Weston is said to have introduced the cultivation of the trefoil and turnip about the middle of the seventeenth century. Wheat and barley are largely produced, but not oats or rye.

Manufactures.

Surrey possesses no manufactures of an *indigenous* character; for the tanneries of Bermondsey, and the potteries and bone-factories of Lambeth belong rather to the metropolis than to the county. On the banks of the Wandle there are some important mills, especially those of copper, snuff, silk, and paper. Near Wandsworth are the extensive works of Price's Patent Candle Company, and Watney's Distillery: Beaufoy's Vinegar Distillery, the Breweries of Barclay and Perkins, and Goding; and Doulton's Potteries are seated on the southern banks of the Thames. Apsley Pellatt's well-known Glass-works occupy large premises in Holland Street, Blackfriars.

Live stock.

Surrey is not associated with any particular breed of domestic animals. The horses employed are chiefly of the large black kind, found at the great fairs of Croydon, Ewell, and Kingston. The breeds of sheep most esteemed are the South Downs, the Upland-Merino South Down, the large Wiltshire, the Dorsetshire, the Mendip, and the Romney. Near the metropolis the cows, chiefly kept to supply South London with milk, are of the short-horned or Holderness kind, though the Alderney, the Suffolk, the Galloways, and the Welsh are also encouraged. Dorking is noted for a peculiar breed of fowls.

Rivers, canals, and railroads.

To carry its products to the London market, and to maintain a communication between its principal towns, as well as to facilitate the frequent visits of tourists, there exists in the county a complete net-work of rivers, railroads, and canals. Of the Thames, which forms its northern boundary, we need not speak. "The chalky *Wey*, that rolls a milky wave," enters the shire near Frensham, flows through the vale of Farnham, passes Moor Park and Waverley Abbey, proceeds eastward through fertile meadows and agreeable valleys to Godalming and Guildford, and swollen by several streams, washes the town of Weybridge before emptying its waters into the Thames a mile distant, at a point called Ham Haw. It is rendered navigable for twenty miles from its mouth by means of locks and auxiliary canals. The *Mole*, characterised by different poets from the peculiarities of its career as the "nousling Mole," the "sullen Mole that hides his diving flood," and the "silent Mole," enters Surrey in several small rivulets which unite near Gatwick, and runs onwards to Betchworth. Near Box Hill it flows into the numerous apertures in its banks and bed called *Swallows*, which in summer reduce its waters to an almost imperceptible channel, and have given rise to the fiction that at this part of its course it runs underground. Through the vale of Mickleham it winds to Leatherhead, and thence, with numerous meander-

ings, past Stoke d'Abernon, Cobham, and Esher Place to East Moulsey, where it joins the Thames. The *Wandle* (or Vandle—Pope's "blue transparent Vandalis") rises at Croydon, and increased by several springs which well up from the meadows of Carshalton, runs northward by Mitcham and Beddington to Wandsworth, where, after a brief but useful course of ten miles, it flows into the Thames. A small but pellucid stream, the ***Hogg's Mill or Ewell River***, rises at Ewell, flows northward past Maldon, and runs into the Thames at Kingston.

Weybridge and Basingstoke are brought into communication by a canal, the Basingstoke, completed in 1793, which has a course of 37 miles, and is on an average 5 feet in depth. The Grand Surrey Canal, from its great basin near Adlington Square, Camberwell, to its junction with the Thames, opposite the Shadwell Docks, is 4 miles and 6 chains in length. It was commenced in 1801. The Wey and Arun Junction Canal connects the two rivers, whence it derives its name, at a point near Stone Bridge, 2 miles from Guildford, and New Bridge, on the Arun, in Sussex. Its course is about 18 miles. The act of Parliament authorising its construction was passed in 1813.

Few parts of Surrey are now without the advantages of railway communication. The London and Brighton line, from London Bridge, traverses the suburban districts to Croydon, and is thence continued to Reigate, Merstham, and Horley, with branches to Caterham, and through Cheam and Ewell to Epsom; while a short line of 6 miles in length unites Croydon with Wimbledon. The London and South-Western Railway, from Waterloo Bridge, crosses the western division of the county to Guildford and Godalming, with branches to Kew and Twickenham, and a short line between Guildford and Farnborough. The Crystal Palace and West End Railway runs from a point near to Chelsea New Bridge, through the populous districts of Wandsworth, Balham Hill, Streatham, and Norwood, to the Crystal Palace.

In 1801, the population of the county amounted to 269,043; in 1821, to 398,658; in 1831, to 485,700; in 1851, to 683,092 (325,051 males and 358,041 females). At the latter period the inhabited houses numbered 103,822; the uninhabited houses, 5770; houses building, 1540. The principal boroughs and towns of the county, with their populations in 1851, are—Lambeth, 251,345; Southwark, 172,863; Newington, 64,816; Bermondsey, 48,128; Camberwell, 54,667; Wandsworth, 50,764; Rotherhithe, 19,805; Clapham, 16,290; Croydon, 10,260; Richmond, 9065; Streatham, 6901; Kingston, 6279; Guildford, 6740; Putney and Roehampton, 5280; Reigate, 4927; Mitcham, 4641; Egham, 4482; Farnham, 3515; Dorking, 3490; Epsom, 3390; Chertsey, 2743; Godalming, 2218; Kew, 1009.

The eastern division of Surrey (population, 580,226; electors, 8020) returns 2 members to parliament. The western division (population, 102,856; electors, 3924) has the same number of representatives. Southwark, with 10,606 electors, and Lambeth with 21,737 electors, return 2 members each. Guildford, with 739 electors, has 2 members; and Reigate, with 548 electors, 1 member.

History. Before the Roman era, Surrey formed a portion of the dominions of a Celtic tribe, named by Ptolemy the Ῥηγνοι, or Regni, and after the Roman conquest, was merged into the province of Britannica Prima, though, for many years, it retained its native princes, or *sub-reguli*. Eventually it was swallowed up in the territory of the South Saxons, and reduced by Kenulf, king of Wessex, about 760, into that progressive kingdom which Alfred finally brought into constitutional harmony and national completeness. During the Saxon era Kingston was a town of considerable importance, and witnessed the coronation of Edward the Elder (A.D. 900), Athelstan (A.D. 925), Edmund I. (A.D. 940), Edwin (A.D. 955), Edward the Martyr (A.D. 975), and Ethelred II. (A.D. 978). At Merton, in 784, perished Kenulf, the prince of the West Saxons, slain in a domestic feud by Cynehard, brother of Sigibert, king of Kent.

From the period of the Norman conquest, Surrey can claim no separate annals. It was to Merton, however, that Hubert de Burgh retired for sanctuary, when the barons demanded his expulsion from the councils of the king. Runnimede, the meadow where, on the 15th day of June 1215, the sun shone upon an event ever-memorable in English history, the signature of the Great Charter, is within the limits of Egham, a Surrey parish. Wyat's brief and disastrous insurrection in 1554, involved in its calamities the town of Kingston. Queen Elizabeth in her progresses visited Beddington, Nonsuch, Croydon, and Loseley. At Kingston, in 1642, took place the first military movement of the great civil war; a body of royalists unsuccessfully attempting to seize upon its magazine of arms. And there, on the 7th of July 1648, Lord Francis Villiers, the brother of Charles the Second's Duke of Buckingham (Dryden's Zimri), met his death in the skirmish which closed the famous struggle.

Worthies of Surrey. Among the most celebrated of her sons Surrey counts George Abbot, born at a public-house in Guildford in 1592; dying in 1633, archbishop of Canterbury, at his palace in Croydon. A man, says Clarendon, of very morose manners and a very sour aspect; but, undoubtedly, a man of considerable natural powers and unquailing energy. His brother Robert became bishop of Salisbury, and a second brother, Sir Maurice, Lord Mayor of London; a singular prodigality of fortune, which almost justified Fuller's quaint description of the cloth-worker's sons as "a happy ternion of brothers." With Stoke, near Guildford, is associated the memory of a once popular novelist and pleasing poetess, Mrs Charlotte Smith, the author of the *Old Manor House*. At Merrow is the family vault of the Onslows, notable among whom is the Mr Speaker Onslow of history, who, for three-and-thirty years, filled the chair of the House of Commons with unequalled impartiality, dignity, and courtesy. At Beddington, Admiral Sir Benjamin Hallowell, the brother in arms of Nelson, and the eccentric donor of that hero's famous coffin, lived for some years, and died in 1834. Moor Park is connected with the famous names of Sir William Temple, and his amanuensis, "the eccentric, uncouth, disagreeable young Irishman," afterwards more widely known as "the great Dean Swift." At Waverley Abbey was born Poulett Thomson, a useful public servant, and Governor-General of Canada at a time of peculiar difficulty. The old house at Claremont was built by Sir John Vanbrugh; the present mansion was erected by Lord Clive, and in its neighbourhood was born William Huntingdon, the zealot, who loved to describe himself as S. S., or a "Sinner Saved." At the Rookery, near Dorking, was born Malthus, the political economist. Wotton was the birth-place of John Evelyn, and in Wotton Church lies his dust. Sturdy William Cobbett was born at an inn near Farnham, and died at Normandy Farm in the parish of Ash. A more philosophical grammarian, and an equally uncompromising politician, Horne Tooke, wrote his Επεα Πτεροεντα at Purley, and died at Wimbledon. Thomson the poet is buried at Richmond, where, too, for a period resided Collins, the lyrist of *The Passions*. At Bowling Green House, on Putney Hill, died William Pitt, January 23d, 1806. At Putney, Gibbon, the historian of the decline and fall of Rome was born; and Nicholas West, who, after a wild youth, became bishop of Ely, verifying, says Fuller, the adage, that naughty boys sometimes make good men. Cromwell, the minister of Henry VIII., was a native of Putney, and his father's forge is still shown to inquiring strangers.

Antiquities and memorable places. Our limits will but suffer us to glance at the more interesting antiquities of the county. Those which belong to the Roman period are not important. Some coins, an urn or two, and traces of their encampments have been discovered at Albury, Woodcote, Walton-on-the-Hill, and Pendhill. At Cowey Stakes, near Walton, Cæsar led his army across the river, though some antiquarians have thought fit to place the scene of his passage at Kingston. There are some brasses of a very early date and remains of Norman architecture at Stoke d'Abernon; at Great Bookham, Chipstead, and Peperharow, there are Norman doorways, arches, and columns. Specimens of early English are noticeable in the churches of Carshalton, Crowhurst, St Mary's, Guildford, West Horsley, and Merstham; Leatherhead, Reigate, and Shere, present some good examples of Decorated; while in the stately tower of Croydon, and at Bletchingley, Godalming, Leigh, and Putney, the student may study Perpendicular. Of Merton Abbey the ruins are barely perceptible,

and of very little interest; but Newark Priory and Waverley Abbey will well repay the attention of the ecclesiastical antiquarian. The historical student cannot fail to be as deeply interested as the archæologist, in Abbot's hospital at Guildford, Beddington Hall, the ancient archiepiscopal palace at Croydon, Nelson's residence at Merton, Loseley, the seat of the Mores, Farnham and Guildford Castles, and Crowhurst Place. To the man of letters, Wolsey's Tower at Esher, Thomson's grave at Richmond, and his house in Kew Lane, Cowley's house at Chertsey, Douglas Jerrold's cottage at Putney, Ham House, Kew, and the poet Denham's residence at Egham, must always be shrines worthy of a pilgrimage.

Honours. Surrey gives the title of earl to the head of the ducal house of Norfolk, Richmond has its dukedom, and Guildford bestows an earldom upon the family of North. The barony of Abinger and the earldom of Onslow are also derived from this county.

Principal seats. It is almost impossible to enumerate a tithe of the seats belonging to noblemen and gentlemen, which, in Surrey, are worthy of notice. We must not omit, however, Claremont, the residence of the exiled royal family of France; Beddington, until a recent date the seat of the Carews; Albury, the late Henry Drummond, Esq., M.P.; Norbury Park, T. Grissell, Esq.; Nonsuch, W. F. Farmer, Esq.; Gatton Park, Lord Monson; Addington and Lambeth Palaces, the residences of the Archbishops of Canterbury; Peperharow, Lord Middleton; Barn Elms, J. Short, Esq.; Wimbledon, the Duke of Somerset; Eastwick Park, David Barclay, Esq.; Clandon Place, Earl of Onslow; Woburn, Hon. Locke King; Ockham Park, Earl of Lovelace; Esher Place, J. W. Spicer, Esq.; Loseley, J. More Molyneux, Esq.; the Deepdene, H. T. Hope, Esq.; and Denbies, G. Cubitt, Esq.

Aubrey's *Perambulation of Surrey*, edited by Rawlinson; Manning and Bray's *Surrey*; Brayley's *Surrey*; Lysons' *Environs of London*; Lysons' *Magna Britannia*; Camden's *Britannia*; Leland's *Itinerary*; Fuller's *Worthies*; Salmon's *Antiquities of Surrey*; Ducarel's *History of Croydon*; Stevenson's *View of the Agriculture of Surrey*. SURVEYING. See Trigonometry.

SURVIVORSHIP. See Annuities and Mortality.

SUSA (Gr. τὰ Σοῦσα), called in the Bible Shushan (Heb. שׁוּשַׁן), an ancient city of the Persian empire, capital of the province of Susiana, and one of the residences of the court. There has been some difficulty in the exact identification of the site of this celebrated city, on account of the brief and sometimes obscure notices of ancient writers, and our imperfect knowledge of the geography of these regions. It stood, according to the testimony both of profane writers and of the prophet Daniel (ch. viii. 2–16), on the river Eulæus or Ulai (אוּלַי); but this river itself cannot be very certainly identified. The Choaspes, which flowed to the west of Susa, is generally believed to be the modern Kerkhah. The Coprates is identified with the river of Diz, and the Pasitigris with the Kuran, into which the former falls; but about the Eulæus modern investigators have differed considerably. Major Rawlinson supposes it to be the upper part of the Kuran, above its confluence with the river of Diz; and he thinks that the Hebrew Shushan was different from Susa, and identical with the modern Susan on the Kuran. Others hold that the Eulæus is the small river Shapur, an affluent of the river of Diz, and that the ruins of Shush, near the former stream, mark the site of Susa or Shusan. A third opinion is, that, while Shush represents the ancient Susa, the Eulæus does not correspond with any of the present rivers, but was a branch of the Choaspes flowing past Susa into the Coprates. (On this question see a number of papers in the *Royal Geographical Society's Journal*, vols. iii., ix., xii., xvi., and xxvii.) It is pretty certain that the ruins of Shush are those of the ancient Susa; for by recent excavations, there have been discovered there the remains of two palaces, one of which has a magnificent colonnade, similar in size and structure to that of Persepolis; and the columns have inscriptions in three languages, stating that the building was begun by Darius Hystaspes, who, according to Pliny, was the founder of Susa. The name of the city is said to have been derived from a Persian word signifying a lily, on account of the abundance of those in the neighbourhood. It was about 120 stadia, or about 15 miles in circumference, and was surrounded with a wall of brick. The climate of Susa was very salubrious, and the Persian monarchs used to make it their residence during the spring months. It was also the seat of the principal treasury of the empire, and vast sums of money were found here by Alexander, and some treasures were still left in subsequent times, even after they had been plundered by him. There is a monument in the neighbourhood, said to be the tomb of Daniel, but manifestly of modern origin.

Susa, a town of the kingdom of Sardinia, capital of a province, in the division and 37 miles W. of Turin, in a valley on the right bank of the Dora Ripaira. It consists of an old and a new town, both somewhat irregularly laid out, although the latter has some handsome streets and squares. Here are a cathedral, town-hall, college, several schools, hospitals, convents, &c. There are also some remains of antiquity, including a Roman triumphal arch, and the ruins of the castle La Brunetta, on a steep height, 11,000 feet above the sea. Pop. 3500.

Susa, a fortified seaport of Northern Africa, Tunis, 40 miles S. of Hammamet, on the S.W. shore of the gulf of that name. It is, next to Tunis, the chief trading place in the country, contains several mosques and bazaars, manufactories of woollen and linen cloth, shoes, &c., and a good harbour, which receives the largest vessels. Pop. 10,500.

SUSPENSION-BRIDGE. See Bridges and Statics.

SUSSEX, a maritime county of England, bounded on the N. by Kent and Surrey, E. by Kent, S. by the English Channel, and W. by Hampshire, is of an oblong form, 76 miles wide, and 27 miles in its extreme length. Its area is 1463 square miles, or 936,320 statute acres. Its divisions are six in number, and are locally called *rapes* or *ropes*, a term which Sir Francis Palgrave thus explains:—"The Normans were a hard people. Whenever they conquered, and did conquer outright, they went to work like plunderers, dividing the country by measurement—by the *rope*, as it was termed; measuring out the land amongst themselves, a process which singularly marks the original violence of their character, for in such allotments they neglected all the natural relations which might previously exist amongst the nations whom they conquered." In each of these rapes (*hreppai*, Icelandic) the Norman lord built, at a convenient point on the sea-coast, a castle or military station; in E. Sussex, in the rapes of Hastings, Lewes, and Pevensey; in W. Sussex, in the rapes of Bramber, Chichester, and Arundel, each, as it were, commanding a "high road to Normandy." These *rapes* are subdivided into 65 hundreds and 313 parishes, all—except the deaneries of Popham and South Malling, and All Saints, Chichester, which are peculiars of the see of Canterbury—in the diocese of Chichester. Boundaries, extent, and divisions.

The population of Sussex, in 1801, amounted to 159,311; in 1811, to 190,083; in 1821, to 233,019; in 1831, to 272,800; in 1851 to 336,844 (165,772 males, 171,072 females). At that period the distribution of the inhabitants was—

	Males.	Females.
Landed proprietors	408	342
Farmers and graziers	3,961	239
Farm bailiffs	454	
Outdoor labourers	25,684	86
Indoor labourers	1,570	704
Labourers employed in agriculture	37,880	1,877
Servants	2,725	12,726

The eastern division of Sussex (pop. 225,387, electors 6401,) returns two members to Parliament. The western division (pop. 111,457, electors 2853,) has the same number of representatives. Brighton, with 4609 electors, returns two members; Hastings, with 1235 electors, returns two; Chichester, with 627 electors, returns two; Lewes, with 697 electors, returns two; Arundel,

with 196 electors, returns one; Horsham, with 387 electors, returns one; Midhurst, with 429 electors, returns one; Rye, with 426 electors, returns one; and Shoreham, with 1843 electors, returns two representatives to Parliament. The election for East Sussex is held at Lewes; for West Sussex at Chichester.

The principal boroughs and towns of Sussex, with their populations in 1851, are—Brighton, 69,673; Hastings, 33,977; Shoreham, 30,553; Rye, 12,612; Lewes, 9533; Chichester, 8662; Horsham, 5947; East Grinstead, 3820; Cuckfield, 3196; Mayfield, 3055; Arundel, 2748; Bognor, 1913; Newhaven, 1358; Pevensey, 412.

A range of chalk-hills, known as the North Downs, in continuation of the chain which traverses Surrey and Kent, crosses to the north-eastern parts of the county from Tunbridge Wells to Hythe. The South Downs, a range of considerable elevation, 53 miles long, and 4 to 6 miles broad, runs through the entire county, in a line nearly parallel to that of the sea-coast, but broken into valleys by the rivers Arun, Adur, Ouse, and Cuckmere. Some of the heights are noticeable for their elevation. Ditchling Beacon is 858 feet above the sea-level; Firle Beacon, 820 feet; and Chanctonbury Ring, with its crown of firs, about 814 feet; Crowbury Beacon, 804 feet. The northern districts of the county were formerly covered with an almost impervious wood, the famous *Andredsleas* of the Celts; and there is still a general luxuriance of leafiness, which much commends the locality to the sketcher and tourist. How wide-spread was the forest growth, is evidenced by the names of hamlets still in existence, such as As-*hurst*, Lamber-*hurst*, Wad-*hurst*, Tice-*hurst*, and Crow-*hurst*. The Weald clay in the northern part is of a very tenacious character. It covers an area of about 425,000 acres. Between it and the chalk-range of the Southern Downs lie long narrow belts of gault and green sand, where the land is chiefly arable and pasture. The South Downs, and the broad stretches of luxuriant verdure which smile between them and the sea-marge, are eminently beautiful, and offer some of the most attractive "bits" of scenery in this portion of England. In the coombes and denes which break their rounded outline nestle clumps of ancient but still vigorous trees—ash, oak, and hazel, the white hawthorn and the bright green box; and on their slopes are clustered quiet villages, sleeping in the shadow of tall elms, with perhaps an old gabled manor-house and the gray tower of a venerable church peeping out of the leafy framework. On these Downs are constantly to be observed those circular belts of dark-green turf called "fairy-rings," popularly supposed to be the traces of fairy footsteps—of the *pharisees*, as the diminutive elves are named by the Sussex shepherds. The star-like gentian and the beautiful orchis are there abundant; the wheatear haunts the sweet thymy grass; and the hill-sides are everywhere dotted with the famous South Down breed of sheep. The south-eastern district, or Forest Ridge, is composed of Hastings sand, and is especially rich in romantic nooks and picturesque corners. Fairlight Down, 600 feet above the sea, commands a prospect of almost unequalled beauty; and the whole country around Hastings and Eastbourne has afforded endless materials to our Hardings, Stanfields, and Copley Fieldings.

Climate. In the northern districts of Sussex the climate is mild and genial, though their clayey soils and luxuriant woods incline it to humidity. On the coast it varies considerably. The air of Hastings is too relaxing for delicate persons, while that of Brighton is usually dry and bracing. At Worthing, the climate is so mild that figs are largely cultivated. Rottingdean rejoices in a fresh and strengthening air, free, however, from excessive keenness.

Rivers and railroads. The principal rivers of Sussex are the Cuckmere, the Ouse, the Adur, and the Arun. The Cuckmere rises in the south-eastern Downs—in several streams, which unite near Hellingly—and flows through a pleasant valley, or depression of the hills, into the English Channel at Cuckmere Harbour. The Ouse is a more important river, whose main channel has its source near Slaugham, on the southern boundary of St Leonard's Forest; passes Lindfield, and, increased by numerous tributaries, skirts Sheffield Park, running southward through a fertile country-side to Lewes; thence over an extensive flat, as Pennant says, which stretches many miles inland, and is "prettily bounded by extensive risings," proceeds to Newhaven, where its junction with the sea forms a convenient harbour. The Adur, rising in St Leonard's forest, in its brief course, passes ancient Bramber, and flows through a deep gully in the chalk-hills—the "Shoreham Gap"—into the sea at New Shoreham. The Arun is formed by other branches, one of which rises in Surrey; another in the neighbourhood of St Leonard's and Tilgate Forests; and a third, the Rother, rising in Hampshire, after washing the towns of Midhurst and Petworth, unites with the main stream at Pulborough, whence the augmented river flows, with many windings, through Arundel, and across a level country into the English Channel, below Littlehampton. The Arun is a navigable river, famous for its excellent mullets. The name is derived by Horsfield from *arundo*, a reed.

The railway communications are important. The London and South Coast line enters the county near the Three Bridges station (where a branch diverges to East Grinstead, and another to Horsham), proceeds southerly to Lewes, and thence to Newhaven. The main line runs on to Brighton. From Lewes the railway is continued to Pevensey and Hastings. There are short branches to Hurstmonceaux and Eastbourne. From Brighton a line proceeds to Portsmouth, in a direction nearly parallel to the sea-coast, touching the important towns of Shoreham, Worthing, Chichester, and Havant. The London and South-Eastern Railway crosses the eastern portions of Sussex to Battle and Hastings, whence it is continued through Winchelsea and Rye into the southern districts of Kent. There is a canal between Arundel and Chichester; and a more important one (see SURREY) connects the Arun navigation with the Wey.

Manufactures and products. There are now no manufactures in Sussex; but its iron-works in bygone days attained a great celebrity, employing a large number of the inhabitants of the Weald, where the strata embodying iron ore are principally found. These iron-works were of great antiquity; certainly known to the Romans, and probably to the Britons. Disused by the Saxons and the early Norman landowners, they rose into repute in the days of the Plantagenets; and in the 16th century the manufacture had assumed such considerable proportions as to excite the indignation of the poet Drayton. "These iron times," he cries, "breed none that mind posterity." Early in the 18th century, when coke took the place of charcoal in the iron manufacture, the trade in Sussex began to decline, and it has now for seventy years been hopelessly extinct.

Sussex, therefore, is a purely agricultural county. The Southdown breed of sheep is widely famous; they have no horns, and their faces and legs are dark-coloured. The wool is fine, and the flesh of excellent flavour. Sussex cows are scarcely less celebrated. They are of a deep-red colour, with small heads, and thin, transparent horns; are not kept for dairy purposes, but for the sake of the meat, always of a superior quality. In the eastern division, wheat and other grain are neglected, and hops are largely grown. The Sussex timber is even now in good repute; and in many parts of the county may yet be noticed elms, oaks, and other forest-trees, of surprising growth.

Watering places. Much of the prosperity of the county is due to the attractiveness of its sea-coast towns, whither, in the genial months of the year, repair by thousands the jaded London

Sussex.

citizens as well as the volatile leaders of the world of fashion. Hastings, Eastbourne, Rottingdean, Brighton, Worthing, and Bognor, owe their prosperity in no inconsiderable degree to the perfection of railway communication, which has

"To those in populous city pent
Glimpses of wild and beauteous nature lent,"

and created thriving towns in neighbourhoods hitherto unvisited and almost desolate. As many as 100,000 persons have been conveyed to Brighton by excursion-trains in one week.

History.

We have scarcely space even for a glance at the principal historical events associated with the "memorable places" of Sussex. "Hallowed ground," indeed, is trodden by the traveller at almost every step. The Regni held the county before the coming of the Romans, and even after the subjugation of England preserved a qualified independence, under their native king, Cogidubnus, whom Tacitus speaks of as always faithful to the Roman alliance. Regnum, the modern Chichester, was the capital, and thence to Augusta (or London) ran the great Stane Street, or Stone Street, a famous military highway. Another important road ran along the coast, and united Anderida (Pevensey), through Chichester, with Portus Magnus (Porchester). Ælla and his sons were the first Saxons who landed on the Sussex coast (A.D. 477). Their place of disembarkation is said to have been Wittering, near Chichester, which they assaulted and captured, spreading afterwards through the vast *Andredsleas* with fire and sword, and finally establishing the South-Sexe, or Sussex kingdom. Mr Kemble points out the probability of their settlements here having been very numerous, and among the earliest in England, from the frequent occurrence in this county of places whose names present the termination *ing*, which always indicates a "mark," or cluster of habitations. The religion of the Cross did not creep into Sussex, however, until long after Augustine had preached it to the men of Kent. It was introduced by Wilfrid, archbishop of York, who, about A.D. 680, was cast by a storm upon the coast—now bare and level, but then all richly wooded—of the peninsula of Selsey. A miracle attended its advent. Bede tells us that for three years no rain had fallen in "the Island of the Sea-Calf," and the drought had produced so great a famine, that very often bands of forty or fifty men would rush to the brink of a neighbouring precipice, and hand-in-hand cast themselves into destruction; but on the very day which witnessed the baptism of the proselytes there fell a soft and plenteous rain, restoring verdure to the earth, and hope to the heart of man.

The sea-board of Sussex suffered terribly from the ravages of the Danish jarls; but it does not appear that they effected any permanent settlements. The county afterwards formed a portion of the demesnes of the great Earl Godwin, and his greater son, King Harold. Within its limits—on a down covered with heath and furze, and surrounded by dangerous morasses—was fought (Oct. 14, 1066), the memorable battle which overthrew the Saxon dynasty, and eventually resulted in that union of Saxon solidity and Norman enterprise now recognised as distinctive of the English character.

Lewes, on the 13th of May 1264, was the scene of a contest scarcely less important in its results—the sanguinary battle of Lewes, between De Montfort earl of Leicester, and the barons' army, and the royal forces under Henry III. and Prince Edward. The slaughter was terrible, but De Montfort was victorious, and thus the final seal to Magna Charta was affixed in blood.

The French fleet, under D'Annebaut, made an attack on Brighton in 1545, and landed a body of troops, who were stoutly resisted by the natives, and compelled to retire. It was at Brighton Charles II. spent the night before his escape from the English shore (Oct. 15, 1651), in a small vessel fitted out by Capt. Nicholas Tattersall. In 1643, the Parliamentarian forces, under Sir William Waller, besieged Chichester for ten days, and, after its surrender, set to work lustily to purify it from "idolatrous images," and remove all "superstitious" decorations. The same leader, later in the year, beleaguered Arundel Castle for seventeen days, and reduced it to a heap of ruins. Off Beachy Head, on the 30th of June 1690, Lord Torrington's Anglo-Dutch fleet of 56 sail was attacked by a French force of 78 ships of war and 22 fire-ships, under Count de Tourville. The combat had no decisive results. And here we must pause, referring the reader for fuller historical details to the authorities indicated at the conclusion of this article.

Worthies.

At Field Place, near Horsham, on the 4th of August 1792, was born Percy Bysshe Shelley, and here that most psychological of poets wrote the greater part of *Queen Mab.* Chichester (Dec. 25, 1719) was the birth-place of William Collins, our great English lyrist; and in a house near Chichester Cathedral he died, in 1759. In the church of Horsted Keynes, sleeps the dust of one of the "wisest and virtuousest" of English prelates, Archbishop Leighton, who resided for ten years at Broadhurst, in its vicinity. Eartham is connected with the names of the poet Halley—to whom it descended from his father—and Huskisson, the statesman, who purchased it of him. John Fletcher, the greater of the dramatic fraternity of Beaumont and Fletcher, was born at Rye in 1579. Archdeacon Hare is interred in Hurstmonceaux churchyard. At Sheffield Place, Gibbon the historian spent his closing years, and in the adjacent church (Fletching) lie his remains. In a cottage named Lacies, near Salvington, was born the erudite Selden (A.D. 1584), and at the Chichester Free School he received his rudimentary education. Lewes is justly proud of Dr Mantell, the eminent geologist. Gilbert White, the naturalist, has associated his memory with the village of Ringmer and the Sussex downs.

Antiquities and objects of interest.

Sussex is rich in antiquities: we can but indicate the more important. Celtic earthworks may be traced at Cisbury, or Cissa's ties and Byrig, near Vindon; the Devil's Dyke, near Poynings; and Mount Caburn, near Lewes. Barrows, or *tumuli*, are scattered over the entire range of the South Downs. Roman relics are numerous, and of peculiar interest, especially the ancient walls of Anderida (Pevensey), and the fine villa at Bignor. To the historical student, there is a mine of wealth in Lewes Castle; in the stately towers of Pevensey; the picturesque keep of Arundel; and the ruins of Battle Abbey. There is a wide field, too, for ecclesiological speculation at Bayham Abbey, St Pancras Priory (Lewes), Michelham, and Wilmington. The most interesting churches are those of Shoreham, Steyning, Broadwater, Climping, Bosham, Winchelsea, and Etchingham. Chichester Cathedral must always be an attractive object to the archæologist as well as to "the man of taste." The lovers of English fiction will remember that Brambletye House suggested to Horace Smith his best romance, and that Ainsworth has transferred the features of Cuckfield Place to the "haunted house" in *Rookwood.* There is an interesting Elizabethan mansion at Parham, and a manor-house of an earlier date at Crowhurst. Brickwall House is curious in itself, and rejoices in some curious relics of Elizabethan days. Winchelsea and Rye are not without noteworthy traces of their past importance.

Honours.

The titles derived from this county are those of the Earls of Winchelsea, Ashburnham, Chichester, and Sheffield, and the Barons Arundel and Selsey.

Chief seats.

We can but name a few of the principal mansions and seats in Sussex:—Goodwood, the Duke of Richmond; Arundel Castle, Duke of Norfolk; Petworth, Colonel Wyndham (rich in art-treasures of the highest order); Sheffield Place, Earl of Sheffield; Eridge Park, Earl of Abergavenny; Maresfield Park, J. V. Shelley, Esq.; Buxted Park, Colonel Vernon Harcourt; Ashburnham Place, Earl of Ashburnham; Heathfield Park, G. E. Towery, Esq.; Buckhurst Park, Lord Delawarr; Stanmer Park, Earl of Chichester; Knepp Castle, Sir C. M. Burrell; Parham, Hon. R. Curzon; and Westdean House, Lord Selsey.

H. D. A.)

Sutherland.

Situation and boundaries.

SUTHERLAND, an extensive county in the north of Scotland, situated between 57. 53. and 58. 36. N. Lat., and between 3. 39. and 5. 15. W. Long.; having the sea on the S.E., W., and N., Caithness on the N.E., and Ross-shire on the S.; is separated from the latter for about 30 miles by the Dornoch Frith, and has communication with the south by Meikle Ferry and Bonar Bridge. The county forms an irregular square, extending from 45 to 50 miles both ways, and contains an area of 1754 square miles, or 1,112,560 imperial acres, divided into thirteen parishes, with a portion of the parish of Reay, forming part of the synod of Sutherland and Caithness. The other recognized divisions of the county are—Sutherland, being the south-eastern part; Assynt; the Reay country; and Strathnaver; and these names still serve to designate the different localities.

Surface.

The coast of Sutherland, in the N. and W. is rocky and precipitous, in the S.E. flat or sloping, except on the confines of Caithness, where the Ord projects into the sea with perpendicular abruptness; and presents a succession of inlets of the sea, and bold promontories, with several islets. The principal lochs or friths are—Lochs Assynt, Laxford, and Inchard, on the W.; Durness Bay, Loch Eriboll, the Kyle of Tongue, and the Bays of Torrisdale and Strathy, in

the N.; and Loch Fleet, branching out from the Dornoch Frith, on the S.E. Of the promontories, the more remarkable are—Rue Stoer, on the S. side of Loch Assynt; Cape Wrath in the N.W. extremity of the county; Far-out-Head, and Whiten Head on the N.E. coast. The interior consists of mountains, rising in Ben More, Assynt, to a height of 3230 feet, elevated plateaus covered with heath, vast fields of peat-bog, some pleasant straths watered by streams in which salmon and trout are found, and numerous lakes embosomed either in bleak, dismal regions of moorland, or begirt by a series of lumpy hills of conglomerate, whose naked and rugged sides have no covering even of heath. Wildness and sterility are the great features of the landscape, the dreary monotony being seldom relieved by tree or shrub; and this uniformity of desolation is only occasionally broken by some glen or strath presenting itself, as an oasis of verdure in the bleak desert. Of a different character, however, is the S.E. coast; for here the shore is flat or sloping for a distance varying from $\frac{4}{5}$ths of a mile to 2 miles, and a fringe or border of average fertility, well laid off into farms, highly cultivated, varied with plantations of considerable extent, and studded with handsome farm-houses, commodious steadings, and comfortable and tidy cottages. At about equal intervals are five fairly built and thriving villages, ornamented with proprietors' seats and a few handsome villas, sheltered from the north by a continous line of hills, or opening into the pleasant and fertile valleys of Strathfleet, Strath-Brora, and the Strath of Kildonan. This district has a fine southern exposure, and both in its appearance and productions can bear comparison with cultivated districts in the Lowlands.

Rivers.

The principal streams are Oikel, with its confluent the Shin, Fleet, Brora, and Helmsdale, all falling into the Dornoch Frith or German Ocean. The Oikel, of which the Dornoch Frith is an expansion, is by the tide navigable for ships of 50 tons as far as Bonar Bridge, a distance of 12 miles, and for boats about 8 miles further. On the N. coast the rivers are Dinart, the Naver, and the Halladale. All take their rise in the heights in the centre of the county, whence they disperse to different seas. Salmon is to be found in all the above-named rivers. Loch Shin, about 20 miles long and 1 mile broad, is the most considerable of the lakes; but, with the exception that its south-eastern extremity is lined by pretty little fields and neat cottages with a few trees at Lairg, it has not much of the picturesque in its appearance. Through this lake flows the river of the same name. It is said that there are about 200 lakes, many of them small, in the county, and that they occupy about 53 square miles, or nearly 34,000 acres. On the N. coast, the sea has formed some remarkable caves in the limestone rock; the most remarkable are that of Smoo, in Durness, 32 yards wide and 20 yards high; and that at Fraisgill, 50 feet high and 20 feet wide at the entrance, but gradually narrowing to its termination, at a distance of more than half a mile.

Minerals.

The oldest formation of rocks in Sutherland is gneiss, which extends over the whole county, and affords a great variety of aspect in the stratification. This formation is traversed by granite veins, which abound in various places in the south-east part of the county, as also in the upper parts of the parishes of Reay and Edderachylis. The gneiss is also traversed by veins of greenstone and porphyry. Those of the greenstone are found in great abundance in the south-east district of Assynt, and in the country around Scourie in Edderachylis. Porphyry veins are of rare occurrence. Mica-slate is developed to a considerable extent in two parts of the country: in that portion of the district of Moin which stretches southwards, and constitutes the whole of the mountains of Ben Hope, Ben Hee, and Meal Rynies; and that part of the county between Loch Fleet and Bonar Bridge. Granite fields prevail in the lower part of the parish of Reay, and in the parishes of Loth and Rogart. Syenite is to be met with in several places. It is most abundant in the mountain of Ben Laoghal, and that considerable tract of country which intervenes between the head of Loch Fleet and Lairg, at the head of Loch Shin. The quartz series of rocks occurs principally, in greater or lesser fields, in the western part of the county, from Loch Eriboll on the north to Loch Vattie on the south. This series is connected with sandstone and limestone. The latter is divided into four great fields connected with one another, and running in the same direction as the quartz. There is also a portion of nearly 6 miles in length at Durness, between Loch Eriboll and Cape Wrath. Redstone and conglomerate are extensively displayed on the east side, and at several points on the north coast, and in the interior. The oolite series of rocks, consisting of white sandstone, sandstone-flag, slate-clay, limestone, and coal, forms the coast between Golspie and the Ord of Caithness, and has a breadth at the River Brora of 3 miles. At Brora, coal occurs at several points, but although the seam is 3 feet 2 inches thick, the coal is so inferior in quality that it has been found to be not worth the working. Calcareous sinter and bog-iron ore are the only chemical alluvial deposits to be found in the county.

Valuation and rental.

This county, which is valued in the cess-books at L.26,193, 9s. 7d. Scots, is almost entirely the property of the Duke of Sutherland. In 1812 the gross rental of lands and houses, as returned under the Property-tax Act, was L.28,458, 8s. 4d., including about L.1700 as the rent of the salmon and other fisheries. In 1859 the rental of the same subjects, including shootings let, amounted to L.52,376, that of land alone being upwards of L.46,000.

Mansions.

The mansions of proprietors in the county are Dunrobin Castle, a palatial structure in the Old English baronial style, greatly enlarged and improved in the years 1845–51, at an expense of upwards of L.100,000; House of Tongue, Lochinvar House, Embo, and Skelbo Cottage,—all belonging to the Duke of Sutherland; Skibo Castle (Dempster's); Ospisdale (Gilchrist's); and Rosehall (Sir J. Matheson's). There are not more than two other proprietors in the county, and these have their mansions in Ross-shire. The farm-houses are, however, of a superior character, and several of them would form suitable mansions for moderate estates.

Means of communication.

Fifty years ago there were almost no roads, except bridle tracks, in the county; but for the last thirty years it has possessed a complete system of excellent roads intersecting the county in every direction, while no such thing as a toll-bar is to be seen upon them. There are also good inns, well kept, in every quarter in which the accommodation of travellers requires them. The roads are partly parliamentary; but by far the greatest extent of the several hundreds of miles of road connecting the different parts of the country was made and is maintained from the county rate. These roads, and other changes effected in the first quarter of the present century, have put this remote county on a level, in point of civilization, with districts more favourably situated for receiving an impulse from the great centres of intelligence and improvement.

Changes and improvements.

Previous to the year 1808, Sutherland was in a state of nature; and owing to the want of means of communication, the inhabitants continued in a state of primitive rudeness and ignorance. They were almost all engaged in tillage; but as their implements were of the rudest description, and as their skill and industry were unequal to the task of overcoming the unproductiveness of the soil and the rigours of climate, they only earned a miserable subsistence: their crops often blighted by mildew, they sometimes had recourse for sustenance to the expedient of bleeding their living cattle, and were frequently saved from absolute starvation by supplies of meal furnished by the landlord. The

Sutherland.

mountain region, the glens, and corries in which the inhabitants were located, presented insuperable obstacles to successful or profitable tillage; and as the very existence of a population so situated must always be precarious, the first Duke of Sutherland, a nobleman of enlightened views, resolute purpose, upright character, and withal possessing great wealth, had the foresight and the courage to effect in Sutherland a change which, whatever its hardships at first, has been attended with beneficial results. He removed the Sutherland man from his possessions in the heights of the county, and offered him an allotment on the coast-side at a nominal rent; or, if such was his choice, he was furnished with the means of emigrating to Canada. That any views of immediate gain influenced the proprietor in removing the tenants can hardly be maintained, when it is borne in mind, that although the Sutherland family have spent on this county many thousands drawn from their English estates, they have never, up to this date (1860), derived one penny of clear revenue from their extensive Highland property, forming nineteen-twentieths of the sixth largest county in Scotland. All has been spent in real or attempted improvements.

Agriculture.

For the last forty years tillage has been carried on in this county on the same plan, with the same appliances, and, taking soil and climate into account, with the same success as in the southern counties of Scotland. At Balnakiel, Keoldale, Eriboll, and Tongue, on the north coast, there are considerable corn farms; while on the south-east coast, in the parishes of Creich, Dornoch, Golspie, Clyne, and Loth, there are about thirty arable farms, paying each from L.150 to L.750 of annual rent, besides a small proportion of farms of from L.20 to L.100 rental; and, in addition to these, hundreds of lots of land, consisting of from one to ten acres. These lots are numerous in the inland parishes of Rogart and Lairg, and also along the west and north coast. As a body, the Sutherland farmers may, in intelligence, professional skill, and capital, stand a comparison with the agriculturists of any part of Scotland. The management of their farms, the adoption of every improvement in modes of tillage and implements of husbandry, the erection of handsome farm-houses with convenient steadings by the proprietor, and the raising of excellent crops of wheat, barley, oats, turnips, and hay—the grain sent south often fetching the highest price in the Edinburgh markets—furnish sufficient proof that the changes in the occupancy already referred to have been decided improvements so far as relates to corn farms. The regions in the interior, from which the aborigines were removed, are occupied with sheep farms, and the grazing of sheep or cattle appears to be the only purpose to which such districts of country can be applied. The sheep farms in the county are in number about thirty-five, carrying each from 1500 to 8000 sheep. The Cheviot is almost the only sheep on these farms, and it has not degenerated in the country of its adoption. From 2s. 6d. to 3s. 6d. per sheep is the general rental. A few years ago these farms were larger than they are now; but as leases fall in, their size is reduced and the number increased, portions of every large sheep farm being allotted to the corn farmers. The Dunrobin breed of cattle, originally from Argyleshire, was long celebrated; but on the larger farms these are giving way to other breeds, such as the short-horn and polled cattle, which come sooner to maturity. On the small holdings occupied by the cottars, now generally the descendants of those formerly dispossessed in making room for sheep farmers, there are substantial, comfortable cottages; and partly from the produce of their lands, which pay a very low or even nominal rent, and partly from earnings drawn from labour elsewhere, the occupants appear to live in more comfort than their forefathers did before the days of removals. But it can scarcely be maintained that their condition is as much in advance of that of the peasantry of the beginning of the century, as the condition of the farmer of 1860 is superior to that of the tacksman of 1800. Further, it may be stated, that to enable the people to live on these allotments, the landlord must forego one-half of the rent which the land would fetch. There are numerous fir plantations near the coast, which, however, take a long time to arrive at maturity. The sharp air of the German Ocean is unfavourable to the growth of timber, and close to the sea trees have a blasted and stunted appearance. Oaks, elms, and ash, in sheltered localities, attain considerable size. In the interior, any tree that is to be seen is dwarf birch. Horticultural productions are similar to those in more southern counties; and even at Tongue, on the north coast, there is a well-stored and productive garden.

Manufactures.

A cotton-mill had been for some time in operation at Spinningdale, but having been burnt down in 1806, the undertaking was abandoned. The only manufactory in the county is a woollen-mill on a small scale at Pittentrail in Rogart. Only one distillery, but no brewery, exists in the county.

Fisheries.

A few boats are engaged in the white fishing on the west and north coast. Lobsters and oysters are also found in considerable quantities. At Embo, Golspie, Port-Gower, Brora, and Helmsdale, about 30 boats altogether are employed in fishing all the year round; the two latter are herring-curing stations, and 200 boats are employed at Helmsdale, and 30 at Brora, during the herring season.

Commerce.

The exports are sheep, wool, cattle, ponies, grain, whisky, salmon, cod, haddock, and herring; meal and flour, however, are both imported, besides groceries, manufactured goods, and coals. The only way of accounting for the import of meal and the export of oats seems to be, that the farmers, who are all possessed of considerable capital, can keep up their grain in order to take advantage of high prices, and also that Caithness meal is generally preferred by the consumers.

Towns and villages.

Dornoch, the county town, is the only royal burgh in Sutherland, and has been stationary at a population of about 500 for the last sixty years. Though small, it is now pretty well built, and contains an excellent jail (often empty), court-room, and other public buildings, all erected within the last twenty years. The parish church is a cathedral on a small scale, which was renovated and restored in 1836. Golspie, with 900 inhabitants, is beautifully situated in the vicinity of Dunrobin Castle, has two banks, half-a-dozen good shops, and is ornamented by a handsome fountain, being a monument to the Duchess-Countess of Sutherland; while on Ben-Bhraggie, overlooking the village, 1000 feet above the sea, stands a monument 70 feet high, surmounted by a colossal statue, 30 feet in height, of the late duke; both it and the fountain having been erected by the tenantry in acknowledgment of their appreciation of the character of these noble persons. The other villages are Bonar, Brora, and Helmsdale, the last the largest place in the county. In Sutherland, as in the rest of the Highlands, the military spirit, that formerly sent forth a regiment from every county, appears to be extinct: the cause is to be found in the dissolution of feudal ties, and in the commercial character of the age, which draws off the surplus young men in quest of money and the comforts of life—things not to be found in camps or campaigns.

Churches and schools.

Before 1843, Sutherland contained no dissenting place of worship, and scarcely a single dissenter; but though at the disruption, the Duke of Sutherland was a firm supporter of the Established Church, at least nine-tenths of the people, headed by their more popular pastors, joined the Free Church, and continue steady adherents to that denomination. In 1851, there were 10 Established churches, with 3696 sittings; and 19 Free

Sutlej.

churches, having 7920 sittings. On 31st March 1851, the attendance at the Established churches was—forenoon, 255; afternoon, 200: at the Free churches—forenoon, 6723; afternoon, 4504. By the census returns of 1851, it appeared that a greater proportion of the population of this county than of any other in Great Britain attends school. This is owing to two circumstances—that there is little or no employment for youths under sixteen years of age, and that every inhabited district of the county has an excessive number of schools. In addition to the parish school, there are in every parish one or two General Assembly schools, as many Free Church schools, and in some a society school. In Dornoch parish, a radius of two miles would sweep over the parish school, three General Assembly schools, four Free Church schools, and a society school. In other parishes, an Assembly school has been planted within a mile of efficiently-taught but half-filled parish schools; while a Free Church school is always at hand to supplement deficiencies in both. Although there is no printing-press in the county, Sutherland matters are sufficiently discussed by neighbouring journalists. Gaelic is losing ground daily, and many young people on the coast cannot speak it.

Antiquities.

In various districts along the coast there are some remains of antiquity. The most interesting are two circular buildings, called Dun-Dornadil, or Dornadilla's Tower, and Castle Coll, both reared of large stones, nicely fitted, but without cement, and of which considerable portions are still entire, after the lapse of probably 1000 years. Castle Coll, which is situated on the east side of the county, on a stream that falls into the Brora, has an exterior circumference of 54 yards, with walls 4½ yards thick at the base, inclining inwards 9 inches in every 3 feet in height; and two small apartments on each side of the doorway, as if intended for guard-rooms. The highest part of the wall is now only 11 feet high, but old people remember it twice that height. Dun-Dornadil is in the parish of Darness, on the northern side of the county. It is a building of the same character with Castle Coll, but still more dilapidated, and is celebrated in the ancient Gaelic ballads as a place of renown at a very early period. At Backies, near Golspie, are the remains of a Pictish tower, with covered passages and chambers, all formed of stone without any cement, and apparently intended to be fire-proof. Others of a similar character, tumuli, and some small forts, may still be traced in various situations along the coast.

Representation.

The county sends one member to Parliament; and the town of Dornoch joins with Cromarty, Dingwall, Tain, Wick, and Kirkwall, in election of a burgh member.

The population, according to the census of 1801, was 23,117; in 1811, it amounted to 23,629; in 1821, to 23,840; in 1831, to 25,518; in 1841, to 24,782; in 1851, to 25.793; and in 1860 it is estimated at 26,500.

SUTLEJ, or SUTLUJ, the most easterly of the five rivers of the Punjab, in India, rises in the lakes of Manasarovara and Rawan Hrad, among the Himalayas, about N. Lat. 30. 8., E. Long. 81. 53. It flows north-west for 188 miles, through a country wild and sublime in the highest degree, as far as Khab, where it receives from the north-west the river of Spiti. The confluence of these rivers is one of the most grand and awful scenes in the world; the muddy stream of the Sutlej dashing tumultuously over its rocky bed, and mingling in a deep gulf with the deep, calm, and blue stream of the other. The rivers are, at the confluence, 8600 feet above the sea; and from this point the united stream flows south-west with a very rapid current and steep declivity. At Rampoor, which is a comparatively short distance off, the bed is only 3360 feet high, and the breadth of the stream is 211 feet. Near Bilaspoor it takes a sweep to the north-west, but soon returns to its former course. It joins the Beas a little above Hurekee; and the united river bears the name of Ghara until its junction with the Chenaub, when it takes that of Punjnud, which it bears till it joins the Indus. The Sutlej is believed to be the Zaradrus or Hesudrus of the ancients, and the Hypanis of Strabo.

Sutton Coldfield || Swaffham.

SUTTON COLDFIELD, a market-town of England, Warwickshire, on the slope of a hill, 7 miles N.N.E. of Birmingham. It is for the most part regularly laid out and well built; and it contains a handsome parish church, partly built by Bishop Vesey, in the sixteenth century, and containing some ancient monuments; a Roman Catholic chapel, a grammar-school, and several others; a public library, and a neat brick town-hall. South-west of the town lies the Coldfield, a bleak tract of 13,000 acres, stretching into Staffordshire; and to the north-west and west is Sutton park, a pasture-ground of about 3500 acres, given to the poor of Sutton by Bishop Vesey. There are no manufactories in the town; but many of the people are employed in the making of hardware in the vicinity, and within the limits of the parish there is a celebrated factory of music-wire. Pop. 4574.

SVEABORG, or SWEABORG, a fortified town of the Russian empire, Finland, on seven small islands in the Gulf of Finland, immediately S.E. of Helsingfors, the harbour of which it protects. It has docks and dockyards, and is a station of the Russian fleet, and the chief fortified place in Finland. Pop. 3500. For an account of the bombardment of Sveaborg by the British, June 9, 1855, see RUSSIA.

SWABIA (Germ. *Schwaben*), an ancient division of Germany, deriving its name from the Suevi. It is the same country that was originally called Allemannia, and occupied the right bank of the Rhine, where that river forms an acute angle at Basle; bounded on the N. by the Palatinate of the Rhine and Franconia, E. by Bavaria, S. by Switzerland, and W. by Alsace; including the mountains of the Black Forest, and the sources and upper courses of the Neckar and Danube. It thus corresponded with the modern Würtemberg, the southern part of Baden, and the province of Swabia and Neuburg, in Bavaria. It received the name of Swabia when the Allemanni were conquered by Chlodwig in 496, and brought into subjection to the Franks; and it was at first governed by dukes appointed by the Frankish kings. In 1080, Henry IV. made the dukedom hereditary in the family of Frederick of Hohenstaufen. The country was at this time in a very flourishing condition, and the reigning house soon became one of the most powerful in Germany: in the great civil war it stood at the head of the Ghibelline party, and included among its members several emperors,—Conrad III., Frederick I., Barbarossa, Henry VI., Frederick II., and Conrad IV. With the unfortunate Conradin, the son of the last of these monarchs, who was executed in 1268, the line of Hohenstaufen became extinct; and upon this the various princes, prelates, and cities of Swabia, that had been formerly vassals of the dukes, made themselves independent. Since then Swabia has not formed a separate state, but it was one of the ten circles of the German empire till 1806.

SWAFFHAM, a market-town of England, in the county of Norfolk, on the top of a hill, 27 miles W. by N. of Norwich, and 93 N.N.E. of London. It is generally well built, and has in the centre a large market-place, containing a handsome cross. The chief buildings are the parish church, a large cruciform structure of the fifteenth century, with a pinnacled tower, and some ancient monuments; a town-hall, jail, theatre, and assembly-rooms. There are also places of worship for Wesleyan Methodists, Baptists, and others; several schools, and a savings bank. Markets and fairs are held here, and there is some trade in butter. Pop. 3858.

Swammerdam || Swansea.

SWAMMERDAM, JOHN, a celebrated natural philosopher, was the son of John James Swammerdam, an apothecary and naturalist of Amsterdam, and was born in 1637. His father intended him for the church, and with this view had him instructed in Latin and Greek; but thinking himself unequal to so serious a vocation, he prevailed with his father to consent to his applying himself to physic. When grown up, he seriously attended to his anatomical and medical studies; yet spent part of the day and the night in discovering, catching, and examining the flying insects not only in the province of Holland, but in those of Guelderland and Utrecht. Thus initiated in natural history, he went to the university of Leyden in 1651; and in 1653 was admitted a candidate of physic in that university. His attention being now engaged by anatomy, he began to consider how the parts of the body, prepared by dissection, could be preserved, and kept in constant order for anatomical demonstration; and here he succeeded as he had done before in his contrivances for dissecting and preserving the minutest insects. He afterwards made a journey into France, where he spent some time at Saumur, and where he became acquainted with several learned men. In 1667 he returned to Leyden, and took the degree of M.D. The Grand Duke of Tuscany offered him 12,000 florins for his collection, on condition of his removing them himself into Tuscany, and coming to live at the court of Florence; but Swammerdam, who hated a court life, declined his highness's proposal. In 1663 he had published a *General History of Insects.* Respecting this work, his biographer, Boerhaave, subsequently wrote that "all the ages from the commencement of natural history have produced nothing to equal, nothing to compare with it." About this time his father began to take offence at his inconsiderately neglecting the practice of physic, which might have supported him in affluence, and would neither supply him with money nor clothes. This reduced him to some difficulties. In 1675 he published his *History of the Ephemeras;* and his father dying the same year, left him a fortune sufficient for his support; but he did not long survive him, for he died in 1682. Gaubius gave a translation of all his works from the original Dutch into Latin, from which they were translated into English, and published in folio, in 1758.

SWANAGE, or SWANWICK, a market-town of England, Dorsetshire, on a bay of the same name, N.E. of St Alban's Head, 22 miles E.S.E. of Dorchester. It consists of one main street, and has an old church, with a tower 80 feet high, Independent and Methodist chapels, a library, and baths. Many of the people are employed in the neighbouring quarries of Purbeck stone; others in plaiting straw and making buttons. Swanage is visited for the sake of sea-bathing; the climate is mild, and the bay is very beautiful. Pop. 2139.

SWANEVELT, HERMANN VAN, usually called "the Hermit of Italy," was a Dutch painter of distinction, and was born at Woerden about 1620. He is said to have been originally the pupil of Gerard Dow, and subsequently of Claude Lorraine, but there is no evidence of this beyond the most slender tradition. This artist went early to Italy, and spent his life in painting the delightful landscapes of that country. He was distinguished by the warmth and tenderness of his tints, and by the fine gradation of his aërial perspective. Many of his landscapes are exquisitely embellished with ruins, cattle, and figures, admirably grouped. His pictures are now exceedingly scarce. His death is said to have occurred in 1680, but many writers place it ten years later.

SWANSEA, a seaport on the south coast of Wales, is one of the chief towns of Glamorganshire, and ranks as the metropolis of the Principality. It is situated between high hills, at the entrance of a valley through which runs the River Tawy (whence the Welsh name of the town, "Abertawe," is derived), and at the head of a fine bay. Formerly Swansea was much frequented as a watering place, but its rapidly growing commercial and manufacturing interests have given a new character to the population, and even changed the face of the country. The natural features of the neighbourhood are attractive, but the smoke from the copper-works destroys vegetation, poisons cattle, and makes the hill-sides look barren and desolate. The smoke, however, does not find its way outside the town to the westward, and the town is fast increasing in that direction. Its proximity to the Welsh coal-field, combined with the facilities it affords as a seaport, have led Swansea to become the great seat of the copper-ore trade. Nine-tenths of the whole quantity of copper ore smelted in the United Kingdom is smelted at Swansea; the foreign ore being brought here from Cuba, South America, Australia, and elsewhere. The first copper-works were established in Swansea in 1719, and the first cargo of foreign copper ore was imported into the town in 1827. There are also silver, tin, and iron-works here, which are supplied with ore from abroad. The value of the silver and copper ore imported into Swansea is very large: a single cargo is often worth from L.60,000 to L.70,000, and a single smelting firm has imported ore to the value of a quarter of a million in three months. The principal exports are coal and patent fuel, the latter of which is largely manufactured in the town.

Swansea.

The progress of Swansea as a port is of recent date. In 1768 the total number of vessels visiting the place was 694, with a total amount of tonnage of 30,631. In 1800, nine years after the passing of an act for the improvement of the harbour, there were 2590 vessels, with a tonnage of 154,264. In 1850, two years before the opening of the first floating dock, the number of vessels was 3616; tonnage, 262,207. In 1859 the number of vessels was 4772; tonnage, 508,814. In the last-named year extensive new docks were opened, and supplied, together with the old docks, with elaborate hydraulic machinery by which the gates are moved, the bridges swung, and vessels are loaded and discharged. A branch line of railway to the new docks was opened at the same time.

Swansea became a corporate town upon the passing of the Municipal Reform Act, in 1835, and is now divided into two wards, and governed by a mayor, six aldermen, and eighteen common councillors. The town council also forms a Local Board of Health, under the Health of Towns Act. Swansea, in conjunction with the neighbouring towns of Neath, Loughor, Aberavon, and Kenfig, returns one member to Parliament.

The remains of Swansea Castle stand on an eminence near the centre of the town. This castle was built by Henry Beaumont, Earl of Warwick, in 1100. The Earl obtained a grant of the lands of Gower (a peninsula running out into the Bristol Channel to the west of Swansea), from William Rufus, and having dispossessed the Welsh prince Caradoc of those lands, built Swansea Castle and several other castles for the defence of his domain. Within the last century the castle has comprised at the same time a union, market-house, blacksmith's shop, Catholic chapel, and gaol. It was used as a debtors' prison by the Duke of Beaufort, the lord of the seigniory of Gower, up to 1859; when, through the intervention of Government, this and the only other two or three prisons of the same kind in the kingdom were abolished. A fine post-office, having the appearance of a church at a distance, was built adjacent to the old castle, and opened in 1857. There are three churches in the town—St Mary's (the parish church), Trinity, and St John's (a Welsh church); and numerous chapels used by the Welsh and English Dissenters of various denominations. The Wesleyan chapel is a handsome

Swartz || Sweden.

structure in the Italian style, and forms one of the chief ornaments of the town. Among the other public buildings worthy of note are the town-hall, the Royal Institution of South Wales (a literary and scientific institution containing a valuable library and museum), the endowed grammar-school, the harbour offices, and the Glamorganshire Bank. Two county newspapers are published at Swansea—the *Swansea and Glamorgan Herald*, and the *Cambrian*.

The terminus of the Swansea Valley Railway, opened in 1860, is at Swansea, and by means of the South Wales line the town is placed in direct communication with Gloucester on the one side, and Milford on the other. Constant steam communication by sea is kept up with Bristol and Liverpool. Swansea is 216 miles from London, and 84 from Bristol; and the borough has a population (in 1860) of about 50,000.

SWARTZ, Olof, a celebrated Swedish botanist, was born at Norrköping in East Gothland in 1760. He commenced his studies in Upsal, and began early to make excursions through various districts of Sweden in quest of botanical specimens. He made a voyage to America in 1783, and returned to England in 1788, on his way home. After staying about a year, diligently examining whatever was of note in regard to his favourite study in Britain, he returned to Sweden in 1789, and was made professor of natural history in the medical school of Stockholm. He published his first work on mosses at Erlangen in 1799. We can only signalize his works, which were as follows:—*Nova Genera et Species Plantarum*, 1788; *Observationes Botanicæ*, 1791; *Icones Plantarum Incognitarum*, 1794–1800; *Flora Indiæ Occidentalis*, 1806; *Synopsis Filicum*, 1806; *Summa Vegetabilium Scandinaviæ Systematicè co-ordinatorum*, 1814. Besides writing from the 5th to the 8th volume of the *Svensk Botanik*, a national work on Swedish botany, he also contributed numerous papers to the *Philosophical Transactions*, and to the *Transactions of the Linnæan Society* of London. He added some 50 genera and 850 species to the list of flowering plants, and a great number to the class of cryptogamia. He died in 1818.

Sweden.

SWEDEN.

The early history of Sweden, like that of most other countries, is involved in fable. Some historians pretend to give regular lists of the kings who reigned over this country from very early times, but these differ so much from each other, that no degree of credit is to be given to any of them. It is generally agreed that Christianity was first established here in the beginning of the eleventh century, by Olaf, surnamed Skotkonung; but different lists of kings are given down to the twelfth century. This may be partly accounted for from there being sometimes two kings reigning in the country at the same time, one over the Goths, the other over the Swedes, and sometimes either of these races would have two kings ruling over them.

On the death of Inge II. in 1129, the Swedes conferred the royal dignity on a private individual, named Swerker I.; and to conciliate the Goths, who supported the claims of Eric, descended from a female branch of the royal family, it was agreed that Eric should succeed Swerker, and that afterwards the representatives of each of the two families should reign alternately. Accordingly, on the death of Swerker in 1155, Eric ascended the throne, and signalised his reign by the subjection of the Fins and the establishment of Christianity among them, and by the compilation of a code of laws. The arrangement come to with respect to the succession led, as might have been expected, to endless disputes, but the order was observed with several succeeding sovereigns. About the year 1319, Magnus Smeck, then an infant, ascended the throne, and subsequently, in right of his mother, succeeded to the crown of Norway. In 1343 he was deposed by the diet, and his son Eric raised to the throne, but on the death of the latter, in 1359, he was restored. He established his son Haquin in Norway, and induced him to marry Margaret, daughter of Waldemar IV., king of Denmark; and having strengthened himself by his connection with these states he attempted to obtain absolute power in Sweden by abolishing the senate. The Swedes, however, immediately rose in defence of their liberties, expelled Magnus, and elected Albert, second son of the Duke of Mecklenburg, in his room. Albert soon after entered into a league, offensive and defensive, with the Earl of Holstein, the Jutland nobility, the Dukes of Sleswick, Mecklenburg, and the Hanse Towns, against the Kings of Denmark and Norway. At that time he proved very successful against Waldemar king of Denmark, driving him entirely out of his dominions; but he himself was defeated by the King of Norway, who laid siege to his capital. A new treaty was soon afterwards concluded, by which Albert was allowed to enjoy the crown of Sweden in peace. Having, however, formed a design of rendering himself absolute, he so displeased his subjects that Margaret of Norway was proclaimed queen of Sweden by the malcontents. A war immediately ensued, in which Albert was defeated and taken prisoner; but as the princes of Mecklenburg, the earls of Holstein, and the Hanse Towns, entered into a league in his favour, the war raged with more fury than ever. At length the contending parties were reconciled. Albert was set at liberty, on condition that he should in three years resign to Margaret all pretensions to the city of Stockholm; and the Hanse Towns engaged to pay the sum of 60,000 marks of silver if Albert should break that treaty. Eric, the son of Albert, died not long afterwards; and having no other child, he did not think it worth his while to contend for the kingdom of Sweden: he therefore acquiesced in the pretensions of Margaret, and passed the remainder of his days at Mecklenburg.

War with Denmark and Norway.

Is defeated and taken prisoner by Margaret of Norway.

Set at liberty, A.D. 1394.

Margaret died in 1415, and was succeeded by Eric of Pomerania. This prince's reign was cruel and oppressive. His misdeeds produced a revolt; and Charles Canutson, grand mareschal of Sweden and governor of Finland, having joined the malcontents, was declared commander-in-chief of their army. Eric was now formally deposed, and Canutson was chosen regent; but beginning to oppress the people, and aspiring openly to the crown, the Swedes and Danes revolted. This event was followed by a revolution; and Christopher duke of Bavaria, nephew to Eric, was chosen king of Denmark, Sweden, and Norway, in 1442.

Margaret is succeeded by Eric, a cruel tyrant, A.D. 1415.

On the accession of this prince, complaints against Canutson were presented from all quarters; but through the interest of his friends he escaped punishment; and in 1448, Christopher having died, after a tyrannical reign of about five years, he was raised to the throne to which he had so long aspired. The kingdoms of Denmark and Norway however refused allegiance to him, and a war immediately ensued. In 1454 peace was concluded, and Denmark for the present freed from the Swedish yoke. Nor did Canutson long enjoy the crown of Sweden. Having quarrelled with the magistrates and the Archbishop of Upsala, the latter formed so strong a party that the king could not resist him. Canutson died in 1470, after a long and turbulent reign.

Charles Canutson, A.D. 1448.

The affairs of Sweden continued to be involved in the utmost confusion till the year 1520, when a great revolution was effected by Gustavus Ericson, a nobleman of the first rank, who restored the kingdom to its liberty, and laid

A.D. 1520.

History.

Christiern king of Denmark invades Sweden, but is defeated and driven out.

the foundation of its future grandeur. In 1518, Christiern king of Denmark had invaded Sweden, with a design to subdue the whole country; but being defeated with great loss by young Steen Sture, at that time regent, he set sail for Denmark. Meeting with contrary winds, he made several descents on the Swedish coast, which he ravaged with all the fury of an incensed barbarian. The inhabitants bravely defended themselves, and Christiern was reduced to the utmost distress. He then thought of a stratagem which had almost proved fatal to the regent; for having invited him to a conference, at which he designed either to assassinate or take him prisoner, Sture was about to comply, when the senate, who suspected the plot, enterposed to prevent him. Christiern then offered to proceed in person to Stockholm in order to confer with Sture, on condition that six hostages should be sent to his place. They were accordingly sent; but the wind happening then to prove favourable, he set sail for Denmark with the hostages, of whom Gustavus Ericson was one. Next year he returned, and having drawn Sture into an ambush, the regent received a wound, of which he died some time after. The kingdom being thus left without a head, matters soon came to the most desperate crisis. The army disbanded itself; and the senate, instead of taking proper measures to oppose the enemy, spent their time in idle debates. Christiern in the mean time advanced into the heart of the kingdom, destroying every thing with fire and sword; but on his arrival at Stragnez, he granted a suspension of arms, on condition that they would elect him king. To this condition they submitted, and Christiern proved one of the most bloody tyrants that ever sat on the throne of any kingdom. Immediately after his coronation, he gave grand entertainments for three days; during which time he projected the diabolical design of extirpating at once all the Swedish nobility, and thus for ever preventing the people from revolting, by depriving them of their proper leaders. As the tyrant had signed articles by which he promised indemnity to all who had borne arms against him, it became necessary to invent some cause of offence against those whom he intended to destroy. To accomplish his purpose, Gustavus Trolle, formerly archbishop of Upsala, but who had been degraded from that dignity, in an oration before his majesty lamented the demolition of Stecka, his place of residence, and the losses sustained by the see of Upsala, amounting to a very large sum of money. He then proceeded in a bitter accusation against the widow and the son-in-law of Sture, the late regent, comprehending in the same accusation about fifteen of the principal nobility, the whole senate, and the burghers of Stockholm. In consequence of this, about eighty of the principal nobility and people of the first rank in Sweden, among whom was the father of Gustavus Vasa, were hanged as traitors. Innumerable other cruelties were committed, part of which are owned by the Danish historians, and the whole are minutely related by those of Sweden. At last he departed for Denmark, ordering gibbets to be erected, and causing the peasants to be hanged on them for the slightest offences.

He treacherously carries off six hostages, of whom Gustavus Ericson is one, A.D. 1519.

Is chosen king, and proves a most bloody tyrant.

Massacres the nobility.

Adventures of Gustavus Vasa or Ericson.

This monstrous cruelty, instead of securing him on the throne, exasperated the whole nation against him. It has already been mentioned, that Gustavus Ericson, or, as he is commonly called, *Gustavus Vasa*, was among the number of the hostages whom Christiern had perfidiously carried to Denmark in 1519. At length he escaped from confinement and fled to Lübeck, which he in vain endeavoured to gain over to his aid, and afterwards he took refuge in the mountains of Dalecarlia. A price being set upon his head, and death threatened to every one who afforded him the least assistance, he was frequently reduced to the deepest distress. He wrought for some time as a labourer in the mines of Fahlun; and on more than one occasion he narrowly escaped detection. At length he seized a favourable opportunity to reveal himself at an annual feast of the peasantry, who were soon excited to enthusiasm in his cause, and instantly resolved to throw off the Danish yoke. Gustavus did not allow their ardour to cool, but instantly led them against the governor's castle, which he took by assault, and put the garrison to the sword. This inconsiderable enterprise was attended with the most happy consequences. Great numbers of the peasants flocked to his standard; some of the gentry openly espoused his cause, and others supplied him with money. Christiern was soon informed of what had passed; but despising such an inconsiderable enemy, he sent only a slender detachment to assist his adherents in Dalecarlia. Gustavus advanced with 5000 men, and defeated a body of Danes; but he was strenuously opposed by the Archbishop of Upsala, who raised numerous forces for Christiern. The fortune of Gustavus, however, still prevailed, but the archbishop was defeated with great loss. Gustavus then laid siege to Stockholm; but his force being unequal to such an undertaking, he was forced to abandon it with loss.

The Danes defeated.

This check did not prove in any considerable degree detrimental to the affairs of Gustavus; the peasants from all parts of the kingdom flocked to his camp, and he was joined by a reinforcement from Lübeck. Christiern, unable to suppress the revolt, wreaked his vengeance on the mother and sisters of Gustavus, whom he put to death. His barbarities served only to make his enemies more resolute. Gustavus having assembled the states at Wadstena, he was unanimously chosen regent, the Diet taking an oath of fidelity to him, and promising to assist him to the utmost. Having thus obtained the sanction of legal authority, he pursued his advantages against the Danes. A body of troops appointed to throw succours into Stockholm was cut in pieces; and the regent sending some forces into Finland, struck the Danes there with such terror, that the Archbishop of Upsala, together with the Danish governors, fled to Denmark. Christiern then sent express orders to all his governors and officers in Finland and Sweden, to massacre the Swedish gentry without distinction. The Swedes made reprisals by massacring all the Danes that they could find, so that the country was filled with slaughter.

Horrid cruelty of King Christiern.

Success of Gustavus.

In the mean time Gustavus had laid siege to the towns of Calmar, Abo, and Stockholm; but Norby found means to oblige him to retire with loss. Gustavus, in revenge, laid siege to the capital a third time, and applied to the regency of Lübeck for a squadron of ships and other succours for carrying on the siege. This request was granted on condition that Gustavus should oblige himself, in the name of the states, to pay 60,000 marks of silver as the expense of the armament; that, until the kingdom should be in a condition to pay that sum, the Lübeck merchants trading to Sweden should be exempted from all duties on imports or exports; that all other nations should be prohibited from trading with Sweden, and that such traffic should be deemed illicit; that Gustavus should neither conclude a peace, nor even agree to a truce, with Denmark, without the concurrence of the regency of Lübeck; and that if the republic should be attacked by Christiern, he should enter Denmark at the head of 20,000 men. On these hard terms Gustavus obtained assistance from the regency of Lübeck; nor did his dear-bought allies prove very faithful. They did not indeed transfer their services to his enemy; but in a sea-fight, where the Danes were entirely in their power, they suffered them to escape, when their whole force might have been entirely destroyed. This treachery had nearly ruined the affairs of Gustavus; for Norby was now making preparations effectually to relieve Stockholm, and would probably have succeeded in the attempt, if at this critical period news had not arrived that the Danes had revolted, and driven Christiern from the throne; and that the king had retired into Germany, in hopes of being restored by the arms of

History.

his brother-in-law the emperor. On hearing this intelligence, Norby retired with his whole fleet to the island of Gothland, leaving but a slender garrison in Calmar. Gustavus did not fail to improve this opportunity to his own advantage, and quickly made himself master of the town. In the mean time Stockholm continued closely invested, but he thought proper to protract the siege till he should be elected king. Having for this purpose called a general diet, he first filled up the vacancy in the senate occasioned by the massacres of Christiern. He had the address to procure the nomination of such as were in his interest. The assembly was no sooner met, than one of his partisans made a speech, containing the highest encomiums on Gustavus, setting forth in the strongest terms the many eminent services which he had rendered to his country, and concluding that the states would show themselves equally ungrateful and blind to their own interest if they did not immediately elect him king. This proposal was acceded to by such tumultuous acclamations that it was impossible to collect the votes; so that Gustavus himself acknowledged, that their affection exceeded his merit, and was more agreeable to him than the effects of their gratitude. He was urged to have the ceremony of his coronation immediately performed; but this he delayed, in consequence of some designs which he had formed to reduce the exorbitant power of the clergy. He had himself embraced the doctrines of the reformed religion, and did all in his power to establish the reformation in his new kingdom. His design could not fail to raise against him the enmity of the clergy, and of all the more superstitious part of his subjects. The first years of his reign were accordingly embittered by internal disturbances and revolts, which were aided and fomented by the deposed Christiern, who was at one time very near regaining possession of the Swedish dominions.

He is chosen king of Sweden. A. D. 1523.

Unsuccessful attempt of Christiern.

Christiern having established a powerful interest in Norway, once more made an attempt to recover his kingdoms, and was joined by the Dalecarlians; but being defeated by the Swedish forces, he was compelled to return to Norway, where, being obliged to capitulate with the Danish generals, he was detained in captivity during the remainder of his life.

Unsuccessful negociation for a marriage with Queen Elizabeth. A. D. 1542.

In 1542, Gustavus having happily extricated himself out of all his troubles, prevailed on the states to make the crown hereditary in his family; after which he applied himself to the encouragement of learning and commerce. A treaty was set on foot for a marriage between his eldest son Eric and the princess Elizabeth of England; but this negociation failed of success.

Gustavus dies, and is succeeded by Eric. A. D. 1560.

Gustavus Vasa died in 1560, and was succeeded by his son Eric XIV. The new king was possessed of all the exterior ornaments which gave an air of dignity to the person, but he had neither the prudence nor the penetration, of his father. He created the first nobility that were ever known in Sweden; but this he had no sooner done than he quarrelled with them, by passing some act which they thought derogatory to their honour and dignity. The whole course of his reign was disturbed by wars with Denmark and disputes with his own subjects. In the former he was unfortunate, and towards the latter he behaved with the greatest cruelty. At last, he is said to have become mad. He afterwards recovered his senses, but was soon dethroned by his brothers; one of whom, named John, succeeded him in the kingdom.

Eric deposed, and succeeded by his brother John.

This revolution took place in the year 1568, but with no great advantage to Sweden. Disputes about religion between the king and his brothers, and wars with Russia, threw matters into the utmost confusion. Prince Sigismund, the king's son, was chosen king of Poland, which proved the source of much trouble to the kingdom. In 1590 King John died, and as Sigismund was at a distance, public affairs fell into the utmost confusion; the treasury was plundered, and the royal wardrobe spoiled, even before Duke Charles could come to Stockholm to undertake the administration till King Sigismund should return. This however was far from being the greatest disaster which befell the nation at this time. It was known that the king had embraced the popish religion, and it was with good reason suspected that he would attempt to restore it upon his arrival in Sweden. Sigismund was also obliged, on leaving Poland, to promise that he would remain no longer in Sweden than was necessary to regulate his affairs. These circumstances served to alienate the minds of the Swedes from their sovereign, even before they saw him; and the universal dissatisfaction was increased by seeing him attended on his arrival in Sweden in 1593 by the pope's nuncio, to whom he made a present of 30,000 ducats to defray the expenses of his journey to Sweden.

Prince Sigismund chosen king of Poland. A. D. 1568.

Succeeds to the crown of Sweden. A. D. 1590.

A party formed against him.

What the people had foreseen was too well verified. The king refused to confirm the protestants in their religious privileges, and showed such partiality on all occasions to the papists, that a party was formed against him, at the head of which was Duke Charles, his uncle. Remonstrances, accompanied with threats, took place on both sides. Sigismund was apparently reconciled to his uncle, and promised to comply with the inclinations of the people, though without any inclination to perform what he had promised. The agreement indeed was scarcely made, before Sigismund conceived the horrid design of murdering his uncle at the Italian comedy acted the night after his coronation. The duke, however, having notice of the plot found means to defeat it. This enraged the king so much, that he had resolved to accomplish his designs by force; and he therefore commanded a Polish army to march towards the frontiers of Sweden, where they committed all the ravages that could be expected from an enraged and cruel enemy. Complaints were made by the protestant clergy to the senate; but no other answer was returned than that, till the king's departure, they should abstain from those bitter invectives and reproaches, which had provoked the Catholics, and that during his absence they would be at more liberty.

Forms a design of murdering his uncle.

In 1595 Sigismund set sail for Dantzig, leaving the administration in the hands of Duke Charles. The consequence of this was, that the dissensions which had already taken place being continually increased by the obstinacy of the king, Charles assumed the sovereign power; and in 1604 Sigismund was formally deposed, and his uncle Charles IX. raised to the throne. He proved a wise and brave prince, restoring the tranquillity of the kingdom, and carrying on a war with vigour against Poland and Denmark. He died in 1611, leaving the kingdom to his son, the celebrated Gustavus Adolphus.

Sigismund deposed, and is succeeded by Charles IX. A. D. 1604.

State of Sweden on the accession of Gustavus Adolphus. A. D. 1611.

Though Charles IX. by his wise and vigorous conduct had in some measure retrieved the affairs of Sweden, they were still in a very bad condition. The finances of the kingdom were entirely drained by a series of wars and revolutions; powerful armies were preparing in Denmark, Poland, and Russia, while not only the Swedish troops were inferior in number to their enemies, but the government was destitute of resources for their payment. Though the Swedish laws required that the prince should have attained his eighteenth year before he was of age, yet such striking marks of the great qualities of Gustavus appeared, that he was allowed by the states to assume the administration before this early period. His first act was to resume all the crown-grants, in order that he might be enabled to carry on the wars in which he was engaged, and to fill all places, both civil and military, with persons of merit. At the head of domestic and foreign affairs was placed the chancellor Oxenstiern, a person every way equal to the important trust, and the choosing of whom impressed Europe with the highest opinion of the young monarch's penetration.

History.

Soon after his accession, Gustavus received an embassy from James I. of Britain, exhorting him to make peace with his neighbours. This was seconded by another from Holland. But as the king perceived that the Danish monarch intended to take every opportunity of crushing him, he resolved to act with such vigour as might convince him that he was not easily to be overcome. Accordingly, he invaded Denmark with three different armies at once; and though the enemy's superiority at sea gave them great advantages, and the number of the king's enemies distracted his attention, he carried on the war with such spirit, that, in 1613, a peace was concluded on terms favourable to himself. This war being finished, Gustavus applied himself to civil polity, and made some reformation in the laws of Sweden. In 1615, hostilities were commenced against Russia, on account of the refusal of that court to repay some money which had been formerly lent. The king entered Ingria, took Kexholm by storm, and was laying siege to Plescov, when, by the mediation of James I., peace was concluded, on condition of the Russians repaying the money, and yielding to Sweden some part of their territory. In this and the former war, notwithstanding the shortness of their duration, Gustavus learned the rudiments of the military art, for which he soon became so famous. He is said to have taken every opportunity of improvement with a quickness of understanding seemingly more than human. In one campaign, he not only learned, but improved, all the military maxims of La Gardie, a celebrated general; brought the Swedish army to a more steady and regular discipline; and formed an invincible body of Finlanders, who had afterwards a very considerable share in the victories of Sweden.

He invades Denmark, and obliges the king to conclude a peace.

Russia invaded with success.

Extraordinary military genius of the king.

Peace was no sooner concluded with Russia, than Gustavus was crowned with great solemnity at Upsala. Soon afterwards he ordered his general La Gardie to acquaint the Polish commander Codekowitz, that as the truce between the two kingdoms, which had been concluded for two years, was now expired, he desired to be certainly informed whether he was to expect peace or war from his master. In the mean time, having borrowed money of the Dutch for the redemption of a town from Denmark, he had an interview on the frontiers with Christiern, the king of that country. At this interview, the two monarchs conceived the utmost esteem and friendship for each other; and Gustavus obtained a promise, that Christiern would not assist Sigismund in any design he might form against Sweden. In the mean time, receiving no satisfactory answer from Poland, Gustavus began to prepare for war. Sigismund entered into a negociation, and made some pretended concessions, with a view to seize Gustavus by treachery; but the latter having some intimation of his design, the whole negociation was changed into reproaches and threats on the part of Gustavus.

Prepares for war with Poland.

Immediately after this, Gustavus made a tour in disguise through Germany, and married Eleonora the daughter of the elector of Brandenburg. He then resolved to enter heartily into a war with Poland; and with this view set sail for Riga with a great fleet, which carried 20,000 men. The place was well fortified, and defended by a body of veterans, enthusiastically attached to Sigismund; but after a vigorous siege, the garrison, being reduced to extremity, were obliged to capitulate, and were treated with great clemency.

Marries a daughter of the elector of Brandenburg.

Riga besieged and taken.

After the reduction of Riga, the Swedish monarch entered Courland, where he reduced Mittau; but ceded it again on the conclusion of a truce for one year. Sigismund, however, no sooner had time to recover himself, than he began to form new enterprises against the Swedes in Prussia; but Gustavus setting sail with his whole fleet for Dantzig, where the king of Poland then resided, so defeated his measures, that he was obliged to prolong the truce for another year. Sigismund was not yet apprised of his danger, and refused to listen to any terms of accommodation: Gustavus entering Livonia, defeated the Polish general, and took Dorpat, Hockenhausen, and several other places of less importance; after which, entering Lithuania, he took the city of Birsen. Notwithstanding this success, Gustavus proposed peace on the same equitable terms as before; but Sigismund was still infatuated with the hopes that, by means of the emperor of Germany, he should be able to conquer Sweden. Gustavus finding him inflexible, resolved to push his good fortune. His generals, Horn and Thurn, defeated the Poles in Semigallia. Gustavus himself, with 150 ships, set sail for Prussia, where he landed at Pillau. This place was immediately surrendered to him, as were several other towns. Sigismund, alarmed at the great progress of Gustavus, sent a body of forces to oppose him, and to prevent Dantzig from falling into his hands. But this measure did not produce any powerful effect; and in May 1627, Gustavus arrived with fresh forces before Dantzig, which he would probably have carried, had he not been severely wounded by a cannon-shot. The states of Holland sent ambassadors to mediate a peace between the two crowns; but Sigismund, depending on the assistance of the emperor of Germany and king of Spain, determined to hearken to no terms, and resolved to make a winter campaign. The king of Sweden was however so well intrenched, and all his forts were so strongly garrisoned, that the utmost efforts of the Poles were to no purpose. The city of Dantzig, in the mean time, made such a desperate resistance as greatly irritated him. In a sea engagement the Swedish fleet defeated that of the enemy; after which Gustavus, having blocked up the harbour with his fleet, pushed his advances on the land side with incredible vigour. He made a surprising march over a morass fifteen miles broad, assisted by bridges of a peculiar construction, over which he carried a species of light cannon invented by himself. By this unexpected manœuvre he obtained the command of the city in such a manner, that the garrison were on the point of surrendering, when, by a sudden swell of the Vistula, the Swedish works were destroyed, and the king was obliged to raise the siege. In other respects, however, the affairs of Gustavus proceeded with their usual good fortune. His general Wrangel defeated the Poles before Brodnitz. At Stum the king gained another and more considerable victory in person. The emperor had sent 5000 foot and 2000 horse under Arnheim, who joined the main army commanded by the Polish general Coniecspolski, in order to attack the Swedish army encamped at Quidzin. The enemy were so much superior in number, that the friends of Gustavus warmly dissuaded him from attacking them. But the resolution of the king was not to be shaken, and the engagement commenced. The Swedish cavalry charged with such impetuosity, contrary to their sovereign's express order, that they were almost surrounded by the enemy; but, coming up to their assistance, he pushed the enemy's infantry with so much vigour, that they gave way, and retreated to a bridge that had been thrown over the Werder. But here they were disappointed, for the Swedes had already taken possession of the bridge. A new action ensued, more bloody than the former, in which the king was exposed to great danger, and thrice narrowly escaped being taken prisoner; but at last the Poles were totally defeated, and with immense loss. The slaughter of the German auxiliaries was so great, that Arnheim scarcely carried off one half of the troops which he brought into the field. This defeat did not hinder the Polish general from attempting the siege of Stum; but here he was as unsuccessful as in his previous enterprises. Arnheim was recalled, and was succeeded by Henry of Saxe-Lauenburg and Philip Count Mansfeldt. The change of general officers, however, produced no good consequences to the Poles; a famine and plague raged in their camp, so that they were at last obliged to consent to a truce for six years, to expire in the month of June 1635.

History.

The Poles defeated.

The Poles defeated a third time. A. D. 1627.

The Poles defeated by sea, and Dantzig invested.

The king obliged by an inundation of the Vistula to raise the siege.

The Poles and Germans defeated with great slaughter in two engagements.

They are again defeated, and obliged to consent to a truce of six years.

History.

Gustavus kept the port and citadel of Memel, the harbour of Pillau, the towns of Elbing, Brunsberg, and all that he had conquered in Livonia.

Gustavus resolves on a war with the emperor.

Gustavus having thus brought the war with Poland to an honourable conclusion, began to think of resenting the conduct of the emperor in assisting his enemies and oppressing the protestant states. Before embarking in such an important undertaking, it was necessary that he should consult the diet. Here the propriety of engaging in a war with Germany was warmly debated; but, after much altercation, the king, in a very noble speech, determined the matter, having declared in such strong terms the virtuous motives by which he was actuated, that the whole assembly wept, and every thing was granted which he could require.

It was not difficult for him to begin his expedition. His troops amounted to 60,000 men, hardened by a succession of severe campaigns in Russia, Finland, Livonia, and Prussia. His fleet exceeded seventy sail, carrying from twenty to forty guns, and manned with 6000 seamen. Embarking his troops, he landed at Usedom on the 24th of June 1630, the Imperialists having evacuated all the fortresses which they there possessed; and the isle of Rugen had been before reduced by General Lesley, in order to secure a retreat if fortune should prove unfavourable. Passing the strait, Gustavus stormed Wolgast, and another strong fortress in the neighbourhood, leaving a garrison for the defence of these conquests. He then proceeded to Stettin, which consented to receive a Swedish garrison, and the king persuaded the duke of Pomerania to enter into an alliance with him. In consequence of this the Swedish troops were received into several towns of Pomerania; and the most bitter enmity took place between the Imperialists and Pomeranians.

Reduces Wolgast, Stettin, &c. A. D. 1630.

These successes of Gustavus struck the empire with consternation; for, being already overwhelmed with civil dissensions, they were in no condition to resist so impetuous an enemy. At last Count Tilly was invested with the dignity of field-marshal. In the mean time, the king, being reinforced by a considerable body of troops in Finland and Livonia under the conduct of Gustavus Horn, defeated the Imperialists before Griffenhagen, and soon afterwards took the place by assault. By this and some other conquests, he opened a passage into Lusatia and Silesia; but in the mean time Tilly cut off 2000 Swedes at New Brandenburg. This advantage, however, was soon overbalanced by the conquest of Frankfurt on the Oder, which Gustavus took by assault, making the whole garrison prisoners. Thus he commanded the rivers Elbe and Oder on both sides, and had a fair passage, not only to the countries already mentioned, but also to Saxony and the hereditary dominions of the house of Austria. He soon afterwards laid siege to Landsberg, which he took by assault.

Count Tilly the emperor's general.

Cuts off 2000 Swedes.

Frankfurt and Landsberg taken by Gustavus.

About this time the protestant princes held a diet at Leipzig, to which Gustavus sent deputies, and conducted his negociations with such address as tended greatly to promote his interests. Immediately after this he reduced Greifswald, and with it all Pomerania. Having then marched to Gustrow, he restored the dukes of Mecklenburg to their dominions.

He reduces Pomerania, and restores the dukes of Mecklenburg.

All this time Tilly was employed in the siege of Magdeburg; but being alarmed at the repeated successes of the Swedes, he now left Pappenheim with part of the army before that city, while he marched with the rest into Thuringia, to attack the landgrave of Hesse-Cassel and the elector of Saxony. After a most obstinate defence, Magdeburg fell into the hands of Pappenheim, who committed all imaginable cruelties. The king formed a plan of recovering the city; but was obliged to abandon it, by Pappenheim's throwing himself into the place with his whole army, and by the progress which Tilly was making in Thuringia. Relinquishing this enterprise, he ordered an attack on Havelsburg; which was conducted with such resolution, that the place was forced in a few hours, and all the garrison made prisoners. Werben was next obliged to submit after an obstinate conflict, in which many fell on both sides. These successes obliged Tilly to attempt in person to check the progress of the Swedes. He detached the vanguard of his army, composed of the flower of the Imperial cavalry, within a few miles of the Swedish camp. An action ensued, in which Bernstein the Imperial general was defeated and killed, with 1500 of his men. Gustavus, after this advantage, placed himself in a situation so much superior to that of his enemies, that Tilly was fired with indignation, and marched up to the Swedish lines to give him battle. The king kept within his works, and Tilly attacked his camp, though almost impregnably fortified, and maintained a most terrible fire from a battery of thirty-two pieces of cannon; which, however, produced no other effect than obliging the Swedish monarch to draw up his army behind the walls of Werben. Tilly had placed his chief hopes in being able to spike the enemy's cannon, or set fire to their camp; after which he proposed making his grand attack. With this view he bribed some prisoners; but they betrayed him, and communicated his design to Gustavus. The king ordered fires to be lighted in different parts of his camp, and his soldiers to imitate the noise of a tumultuous disorderly rabble. This had the desired effect. The count led his army to the breach made by the cannon, where he was received with such a volley of grape-shot as cut off the first line, and put the whole body in disorder, so that they could never be brought back to the charge. In this confusion the Imperial army was attacked, and after an obstinate conflict obliged to quit the field.

Magdeburg taken by the Imperialists, and the inhabitants cruelly used.

History.

Havelsburg and Werben reduced, and the cavalry of the Imperialists defeated by the Swedes.

Count Tilly defeated by Gustavus.

Soon after this action the queen arrived at the camp with a reinforcement of 8000 men; at the same time a treaty was concluded with Charles I. of England, by which that monarch allowed the marquis of Hamilton to raise 6000 men for the service of Gustavus. These auxiliaries were to be conducted to the main army by a body of 4000 Swedes; and were in every thing to obey the king while he was personally present, but in his absence were to be subject to the orders of the marquis. With these troops the king had resolved to make a diversion in Bremen; but the marquis finding it impossible to effect a junction with the Swedish army, resolved, without debarking his troops, to steer his course for the Oder, and land at Usedom. Gustavus was very much displeased at finding his project thus disconcerted; but making the best of the present circumstances, he commanded the British troops to act on the Oder instead of the Weser. The number of this little army was magnified exceedingly by report, insomuch that Tilly had some thoughts of marching against them with his whole force; but on the departure of the marquis for Silesia, he reinforced the army in that country with a large detachment, which was thought to contribute not a little to the defeat which he soon after received.

A body of British soldiers comes to the assistance of the Swedes.

Since the late action Gustavus had kept within his intrenchments, where his army was well supplied with provisions and stores. Tilly made several attempts to surprise or draw him to an engagement; but finding all his endeavours fruitless, he marched into Saxony, and laid siege to Leipzig. This precipitate measure proved highly advantageous to the Swedish monarch. A treaty offensive and defensive was immediately concluded with Gustavus; and the elector willingly promised every thing that was required of him. Tilly, in the mean time, carried fire and sword into the electorate. At the head of an army of 44,000 veterans, he summoned the city of Leipzig to surrender; denouncing, in case of a refusal, the same vengeance against it as had been executed on Magdeburg. The governor was so much intimidated, that he instantly submitted; and he also surrendered the castle of Passenberg, which was in a

Saxony ravaged by Count Tilly, who takes Leipzig.

History.

condition to have resisted till the arrival of the Swedish army. The elector, enraged at the loss of these valuable places, ordered his army to join the Swedes with all expedition, and pressed the king so warmly to engage, that at last he yielded to his desire. On the 7th of September 1631, Gustavus led out his army in the finest order, the Swedes forming one column on the right, and the Saxons another on the left; each amounting to 15,000 men. Tilly drew up his men in one vast column, probably with a view of surrounding the flanks of the king's army. The king led his troops against that wing of the Imperialists commanded by Pappenheim, whom he drove back to a considerable distance. General Bannier in the mean time cut in pieces the troops of Holstein, and mortally wounded the duke, who commanded them. Pappenheim conducted his troops seven times to the charge, but was as often repulsed by the Swedes. Tilly all this while was engaged with the Saxons; but having at last driven them off the field, the whole strength of the Imperial army was turned against the Swedish left wing. The Swedes sustained the attack with the greatest firmness, until the king detached the centre to assist them. The Imperialists then were no longer able to maintain their ground; but gave way everywhere except in the centre, which was composed of eighteen regiments of veterans accustomed to victory, and deemed invincible. They made incredible efforts to maintain their reputation; and, though swept off in great numbers by the Swedish artillery, never shrunk or fell into confusion. Four regiments, after their officers had been killed, formed themselves, and withdrew to the skirt of a wood. Tilly retired at the head of 600 men, and escaped by the coming on of the night. Seven thousand Imperialists lay dead on the field of battle; 4000 were taken prisoners; a fine train of artillery was lost, with upwards of 100 standards, ensigns, and other military trophies.

Battle of Leipzig. A. D. 1631.

The Imperialists defeated with great slaughter.

Gustavus now determined to penetrate into Franconia, where he reduced several places, especially the fortress of Würzburg. Tilly having collected his scattered troops, which formed an army still superior in number to that of Gustavus, marched to the relief of this place, but came too late. He then directed his march towards Rottenberg, where four regiments were cut in pieces by a Swedish detachment. After this, the king reduced Hanau, Frankfurt on the Maine, and Mentz, having destroyed a body of Spaniards who had attempted to obstruct his passage.

The Swedes take a number of towns, and cut off four regiments of the enemy.

The court of Vienna was now thrown into the utmost confusion, and sent everywhere begging assistance, and soliciting the Catholic princes to arm in defence of their religion. The emperor was most embarrassed in finding a general capable of opposing Gustavus in the field; for the late misfortunes of Count Tilly had entirely sunk his reputation. Wallenstein, an old experienced officer, was selected; but as he had formerly been disgraced, it was apprehended that he would not accept of the command of which he had once been deprived. This objection however was surmounted; and Wallenstein not only accepted of the command, but, at his own expense, augmented the army to 40,000 men.

Wallenstein chosen general by the emperor.

During the whole winter the Swedish army kept the field, and before the approach of summer had reduced a great number of places, while the landgrave William made great progress in Westphalia. Gustavus Horn was repulsed before Bamberg, but soon had his revenge, by entirely destroying two regiments of Imperialists. To prevent the troops from being affected by the loss before Bamberg, the king resolved to give battle to Tilly, who was marching into Bavaria to prevent the Swedes from gaining a footing in that electorate. He pursued the Imperial general through a vast tract of country, defeated his rearguard, and having reduced a variety of towns and fortresses on the Danube, penetrated as far as Ulm. Advancing to the river Leck, the count posted himself in a wood on the opposite side, to dispute his passage. Gustavus endeavoured to dislodge him by a regular fire from seventy pieces of cannon. The slaughter was dreadful; and Tilly himself, being wounded by a cannon-ball in the knee, died a few days before he was to have been superseded by Wallenstein. The following night the Imperial army evacuated the post. Gustavus immediately crossed the river, and seized the towns of Rain and Neuburg, which the enemy had abandoned, and Augsburg next submitted. From Augsburg the Swedes advanced towards Ratisbon, but were disappointed in their design of obtaining possession of that city, as the Bavarians had thrown a numerous garrison into the place. In the mean time, ambassadors arrived from Denmark, offering the mediation of that crown for obtaining a lasting peace between the contending parties. This negociation however failed of success, as the ambassadors had not been instructed to offer terms favourable to the protestants. Gustavus, now resolving to retort on themselves the cruelties which the Bavarians had inflicted on the protestants, laid the towns of Morzburg, Friesengen, and Landshut, in ashes. The inhabitants of Munich saved themselves by submission. Gustavus also defeated the forces of the elector, who had been joined by a considerable body of militia.

A great number of towns taken by the Swedes.

Count Tilly defeated and killed.

Three towns laid in ashes by the Swedes.

While the king was thus employed, Wallenstein had assembled a very numerous army. He was strongly solicited by the elector of Bavaria to come to his assistance; but, in revenge of the elector's having formerly obtained the command for Tilly in preference to himself, he drew off towards Bohemia to encounter the Saxons. Arnheim, who commanded the Saxon forces in that place, was an enemy to Gustavus, who had formerly rallied him for his cowardice. He therefore permitted Wallenstein to gain an easy victory, in hopes that his master, the elector of Saxony, a prince entirely devoted to his pleasures, might be induced to relinquish the friendship of such a restless and warlike ally as Gustavus; and indeed he used all the eloquence of which he was master to detach him from the Swedish cause. Several advantages were in the mean time gained by the Imperialists. Pappenheim defeated the archbishop of Bremen's cavalry at Werden; and three Swedish regiments were cut off near Kadingen. Pappenheim was however forced to retire, and to withdraw his forces from Stade, of which the Swedes took possession. Wallenstein and the elector of Bavaria, who had now joined their forces, threatened Gustavus with greatly superior numbers. The king, being reinforced with 15,000 men, no longer declined the engagement; but Wallenstein was too wise to trust the fate of the empire to a single battle against such an enemy as the king of Sweden. Gustavus attacked his camp, but was repulsed with the loss of 2000 men. Several other misfortunes happened to the Swedes; and at last, after various manœuvres, Wallenstein directed his course towards Misnia, in order to oblige the elector of Saxony to declare against the Swedes, and to draw them out of Bavaria. Gustavus, notwithstanding the inconstancy of Augustus, immediately set out to assist him. With incredible diligence he marched to Misnia, where the Imperialists were assembling their whole strength. Hearing that the enemy were encamped at Weissenfels, and that Pappenheim had been detached with a strong corps, Gustavus resolved to engage them before they could effect a junction. With this view he marched to Lützen, where he attacked Wallenstein with incredible fury. The Swedish infantry broke the Imperialists in spite of their utmost efforts, and took all their artillery. The cavalry not being able to pass the river so expeditiously as the king thought necessary, he led the way, attended only by a single regiment and the duke of Saxe-Lauenburg. Here, after charging impetuously, he was killed. The news of his death was in an instant spread

Gustavus killed.

over both armies. The courage of the Imperialists revived, and they now made themselves sure of victory. But the Swedes, eager to revenge the death of their beloved monarch, charged with such fury that nothing could resist them. The Imperialists were defeated a second time, just as Pappenheim, with his fresh corps, came up to their assistance. On this the battle was renewed, but the Swedes were still irresistible. Pappenheim was mortally wounded, and his army finally routed, with the loss of 9000 killed in the field and in the pursuit.

The Imperialists totally defeated.

Christina, an infant, proclaimed queen of Sweden.

This victory proved more unfortunate to Sweden than the greatest defeat. The crown devolved on Christina, the daughter of Gustavus, an infant of six years old; the nation was engaged in an expensive foreign war, without any person equal to the arduous task of commanding the armies, or regulating domestic affairs, as Gustavus had done. Christina was immediately proclaimed queen. The regency devolved on the grand bailiff, the marshal, the high admiral, the chancellor, and the treasurer of the crown. Oxenstiern was invested with the chief management of affairs, and conducted himself with the greatest prudence. The reign and character of Christina have been detailed under the article Christina, to which we may refer our readers.

Charles Gustavus appointed heir to the crown of Sweden.

From the treaty of Westphalia, Sweden enjoyed some years of repose. Charles Gustavus, Count Palatine, having gained the favour of Christina, was appointed generalissimo of the forces, and heir-apparent to the crown. A marriage was proposed between them; but the queen would never listen to this or any other proposal of the kind. In 1650, the ceremony of the queen's coronation was performed; but in four years after, she resigned the crown in favour of Charles.

A. D. 1654.

State of Sweden on the accession of Charles X.

The new king found himself involved in considerable difficulties on his accession to the throne. The treasury was quite exhausted; great part of the revenue was appointed for the support of Christina's household; the people were oppressed with taxes; and the nation having been disarmed for several years, began to lose its reputation among foreigners. To remedy these evils, Charles proposed to resume all the crown-lands which had been alienated by grants to favourites during the late reign; to repeal a duty which had been imposed on salt; to put the kingdom in a posture of defence; and to enter on a war with some neighbouring state. Under a pretence that Casimir king of Poland had questioned his title to the throne, he prepared to invade that kingdom. Several embassies were sent from Poland to Stockholm; but some point of ceremony always disappointed them of an audience of the king, so that they were obliged to return without executing their commission. As soon as matters were in readiness, General Wittemberg made an irruption into Poland from the side of Pomerania. The Poles opposed him with an army of 15,000 men; but instead of fighting, they began to negociate, and in a short time entirely dispersed. Charles himself soon followed with a powerful army, and pursued his march without obstruction, all the cities throwing open their gates to him as he approached. As he advanced to Cracow, Casimir resolved to make one effort to save his capital. His army amounted only to 10,000 men; and these were unfortunately such as had never stood fire. After a feeble resistance, they fled with precipitation, having lost 1000 men killed and taken prisoners. A few days after this Charles defeated the Poles a second time, about eight leagues from Cracow; on which Casimir fled with his family to Oppeln in Silesia. The capital was then invested, and, though defended with the utmost valour, was in a short time obliged to capitulate. Thus in less than three months Charles apparently became master of Poland; but it was soon evident that the Poles had no intention of abandoning their former sovereign.

War with Poland resolved on.

The Poles defeated, and the kingdom reduced.

In 1656, a war took place with the elector of Brandenburg. While Charles was employed in the conquest of Poland, that prince had invaded Royal and Ducal Prussia, and reduced the most considerable towns with little opposition. The king of Sweden took umbrage at his progress; and having marched against him, defeated his forces in several slight encounters, and obliged him to acknowledge himself a vassal of Sweden. These rapid conquests alarmed all Europe; and the different powers sought for means of driving the Swedes out of Poland, which they had so unexpectedly and unjustly seized. The Poles were no sooner assured that they should obtain assistance, than they everywhere revolted and massacred the Swedes. Casimir returned from Silesia; and those very troops and generals who had before submitted to Charles without opposition, now ranged themselves under the banners of his antagonist. Charles immediately marched from Prussia to chastise the insolence of the Poles, and totally defeated a body of 12,000 men. This event did not hinder all the Poles incorporated with his troops to desert. Their defection considerably reduced his army; and the campaign being performed in the depth of winter, he was at last obliged to retreat to Prussia. In his march he was harassed by the Poles; and a body of 4000 Swedes was surprised and defeated by them at Warka. This loss however was soon after recompensed by a complete victory gained by Adolphus the king's brother, and General Wrangel. In the mean time the king was taking measures for laying siege to Dantzig; but was prevented by the Dutch, who threatened to oppose him, unless a proper regard was paid to their interest. Charles accordingly granted them advantageous terms; and afterwards gained over the elector of Brandenburg, by ceding to him the sovereignty of Prussia, that he might be at liberty to turn his whole strength against Poland.

War with the elector of Brandenburg.

A. D. 1656.

The Poles revolt.

Charles gains a victory, but is obliged to retire.

Concludes a treaty with the Dutch and the elector of Brandenburg.

By the treaty just concluded with the elector, the latter was to assist Charles in his war with Poland; but the elector was so tardy in his measures, that the Poles, having obtained assistance from the Tartars, had reduced the city of Warsaw. The two princes now marched in concert against their enemies, who were encamped in a strong situation in the neighbourhood of the city above mentioned, their camp being fronted by the Vistula. The Poles were driven from their intrenchments with prodigious slaughter. The Poles and Tartars then laboured to break the alliance; and with which view, having entered Ducal Prussia, they defeated the electoral army, and took many prisoners. The Swedes soon obtained their revenge. General Steinboek attacked the same Polish army at Philippowa, and overthrew it with such slaughter as obliged the Poles for that season to quit the field. A more formidable enemy than the Poles now began to make their appearance. The Russians invaded the provinces of Carelia, Ingermania, and Livonia; while the elector of Brandenburg began to waver in his fidelity. To preserve this only ally at such a critical juncture, Charles was obliged to grant him more advantageous terms than those already mentioned; and the Russians were repulsed in the provinces of Carelia and Ingermania. But in Livonia they had better success. For seven months, however, they battered the walls of Riga, without venturing to pass the ditch or storm the practicable breaches.

The Poles and Tartars defeated with great slaughter.

The Russians invade the Swedish dominions.

Charles, notwithstanding the number of his enemies, was now become so formidable by the valour and discipline of his troops, that entire armies often fled on his approach. At last, in 1657, the Poles, finding they could not resist him in the field, contented themselves with harassing the Swedes on their march, and cutting off the foragers and convoys. This proved much more destructive to the Swedes than their former method; so that Charles was obliged to enter into an alliance with Ragotski, prince of Transylvania, by assigning him certain provinces in his neighbourhood, in order to furnish himself with irregular troops, who might fight the Poles in their own way. He did not thus obtain any real advantage; for the confederates, after wasting a whole

A. D. 1657.

Charles enters into an alliance with Ragotski, prince of Transylvania.

History.

campaign in Lithuania, were obliged to retire without accomplishing more than the reduction of a single fortress. Charles then returned with the Swedish army to Prussia.

Leopold king of Hungary declares against Sweden.

Leopold, the young king of Hungary, having long beheld the Swedes with a jealous eye, now resolved to declare for Poland. The more effectually to curb the ambition of the Swedish monarch, he solicited the king of Denmark to come to a rupture with him. This application was attended with immediate success, and the Danes invaded Bremen.

Ragotski's army destroyed by the Poles and Tartars.

Charles hastened to oppose this new enemy, and he thus gave great offence to Ragotski, who, by neglecting to take the proper measures for his own defence in the absence of the Swedes, suffered his army to be destroyed by the Poles and Tartars. At the same time the Turks invaded Transylvania, under pretence that Ragotski, being a vassal of the grand signior, had no right to invade Poland without his permission. Ragotski, opposing them in the field, was defeated and killed, leaving Charles destitute of the only ally on whom he could depend.

He is defeated and killed by the Turks.

The king, however, not dismayed by this misfortune, traversed Pomerania and the duchy of Mecklenburg; after which he attacked Holstein, while General Wrangel with another corps entered the duchy of Bremen. The general executed his measures with the utmost vigour. In fifteen days he retook all the towns which the enemy had reduced; defeated and drove the Danish army out of the country, killing 3000 of their best soldiers. In Holstein the king reduced several fortresses, laid Itzehoe in ashes, defeated a body of Danes, and laid siege to Frederic Udda, into which the Danes had thrown a strong garrison. Leaving to Wrangel the conduct of this siege, he himself retired to Wismar in order to observe the situation of affairs in Poland; and no sooner was he departed than Wrangel attacked the place with such fury, that he became master of it in two hours. In the province of Halland the Swedes were defeated, but the enemy derived no advantage from their victory. At sea the fleets met, and maintained an engagement for two days, without any considerable advantage on either side. In Poland affairs were not better conducted. The house of Austria had now declared for Casimir; and a German army having entered Poland, reduced Cracow, though not without sustaining great loss.

Bravery and success of General Wrangel.

The house of Austria declares against Sweden.

The king of Sweden was now surrounded by enemies. The elector of Brandenburg had declared against him; and he had besides to engage the armies of Austria, Poland, Russia, and Denmark. In this dangerous situation he resolved to attack Denmark, so as to oblige that state to come to a speedy accommodation. His designs were forwarded by a very early frost, which enabled him to transport his troops without shipping. Having marched over the ice to the island of Funen, he cut in pieces a body of 4000 Danish soldiers and 500 peasants. The whole island was reduced in a few days; after which he passed to Langland, then to Laaland, after that to Falster, and lastly to Zealand. The Danes were terrified at this unexpected invasion, and were resigning themselves to despair, when Charles offered to conclude a peace on equitable terms. The king of Denmark gladly consented, intending to renew the war as soon as he thought it could be done with safety.

Charles invades Denmark with great success.

Peace concluded. A. D. 1658.

Charles was no sooner retired, than the king of Denmark began to act secretly against him; on which, resolving to anticipate him in his designs, he appeared unexpectedly with a fleet before Copenhagen. The Swedish monarch laid siege to the capital, but with so little prudence that he made no progress, and was at length compelled to turn the siege into a blockade, which continued to the end of the war. Charles X. died of an epidemic fever, and was succeeded by his son Charles XI.

The war renewed, and Copenhagen besieged.

Charles XI. A. D. 1660.

The new king, Charles XI. was a minor at the time of his father's death; and as the kingdom was involved in a dangerous war with so many enemies, the regency determined to conclude a peace, if it could be obtained on reasonable terms. A treaty was accordingly concluded at Olivia, by which Casimir renounced his pretensions to the crown of Poland, and that state gave up all pretensions to Livonia. Bornholm and Drontheim were ceded to Denmark, and an equivalent in Schonen remained with Sweden. During the minority of the king, nothing remarkable occurs in the history of Sweden. In 1672 he entered into alliance with Louis XIV. which two years after involved him in a war with the elector of Brandenburg. At first the Swedes carried all before them. Almost all the towns in Brandenburg were reduced, when the elector arrived with an army to the relief of his distressed subjects. He retook several towns, defeated the Swedes in a general engagement, and soon after forced them to abandon all their conquests. In conjunction with the Danes, he then invaded the Swedish dominions: many places of importance were reduced; and, in 1676, Sweden received a most destructive blow by the defeat of her fleet in an engagement with the combined fleets of Denmark and Holland. The king soon afterwards took the government into his own hands, and in some degree restored the fortune of Sweden; but although he was more successful where he commanded in person, the same losses and disgrace attended the Swedish arms in every other quarter. In 1678, the Swedish fleet was defeated in two engagements. At Landscrona a most obstinate battle was fought, from ten in the morning till six at night, when both parties were obliged, by fatigue, to retire to their respective camps. At Oldeval, in Norway, the Swedes were defeated; and the Danes laid desolate the islands of Oeland, Smaaland, Unno, and Kuno; while the electoral troops and Imperialists reduced Count Königsmark to the utmost distress in the neighbourhood of Stralsund. In this deplorable situation of affairs Königsmark found an opportunity of attacking his enemies to such advantage, that he obtained a complete victory; after which he ravaged the duchy of Mecklenburg. Notwithstanding this success, he could not prevent the elector from reducing Stralsund. He was afterwards obliged to evacuate Pomerania; and, to complete his distress, the fleet which transported the Swedish army from Pomerania was wrecked on the coast of Bornholm.

History.

Treaty of Olivia.

War with Brandenburg.

The Swedes defeated by land and sea.

A. D. 1676.

At this unprosperous crisis a peace was concluded at St Germains between France and her enemies, by which the Swedes and Danes were left to decide their quarrel between themselves. Denmark was by no means a match for Sweden, even in the distressed situation to which she was reduced; and a treaty was therefore concluded, on terms much more favourable to Sweden than could have been expected. The peace was confirmed by a marriage between Charles, and Ulrica Eleonora, daughter to the king of Denmark. From this time the Swedish monarch applied himself to the reformation of the state; and by artfully managing the disputes between the nobility and the peasants, he obtained a decree empowering him to alter the constitution as he pleased. The proceedings of the king after this decree were such as to exasperate the nobility, and produce violent commotions.

Peace concluded.

Charles becomes absolute.

On the 15th of April 1697, died Charles XI. leaving his crown to his son, the celebrated Charles XII. at that time a minor. On his accession, he found himself under the tuition of his grandmother Eleonora, who had governed the kingdom during the minority of the late king. Though Charles was at that time only fifteen years of age, he showed a desire of taking the government into his own hands. His counsellors, Count Piper and Axel Sparre, signified his desire to the queen-regent. By her they were referred to the states, and there all were unanimous; so that the queen, finding that opposition would be vain, resigned her power with a good grace; and Charles was invested with absolute authority in three days after he had expressed his desire of

Charles XI. dies, and is succeeded by his son Charles XII.

reigning alone. He was scarcely seated on the throne when a powerful combination was formed against him.

A powerful combination formed against him.

Augustus king of Poland formed designs on Livonia; the king of Denmark revived his disputes with the duke of Holstein, as a prelude to a war with Sweden; and Peter the Great of Russia began to form designs on Ingria, formerly a province of Russia.

Holstein ravaged by the Danes. A. D. 1699.

In 1699 the king of Denmark marched an army into Holstein. Charles sent a considerable body of troops to the duke's assistance; but before their arrival the Danes had ravaged the country, taken the castle of Gottorp, and laid close siege to Tonningen. Here the king of Denmark commanded in person, and was assisted by the troops of Saxony, Brandenburg, Wolfenbuttel, and Hesse-Cassel. Britain and Holland, as guarantees of the last treaty with Denmark, in concert with Sweden, joined Charles against this confederacy, and sent fleets to the Baltic. They proposed a termination of the war on equitable terms; but these were haughtily refused by the Danish monarch, who despised the youth and inexperience of Charles, and relied too much on the alliance which he had formed with Saxony, Brandenburg, Poland, and Russia.

They are repulsed at Tonningen.

Tonningen, however, resisted all his efforts; and when he ordered the place to be stormed, he had the mortification to see his troops driven headlong from the walls by a handful of Swedes.

Charles defeats the fleet of the allies. A. D. 1700.

In the year 1700, Charles, having intrusted the affairs of the nation with a council chosen out of the senate, set out on the 8th May from his capital, to which he never afterwards returned. He embarked at Carlscrona, and defeated the fleet of the allies. Having made a descent on the island of Zealand, he defeated a body of cavalry that opposed his march, and then proceeded to invest Copenhagen by sea and land. The king of Denmark saw the necessity of either having his capital destroyed, or of doing justice to the duke of Holstein.

Obliges the Danes to make peace.

He chose the latter; and a treaty was concluded on much the same terms as formerly. Charles, being thus at liberty to turn his arms against the other princes who had conspired his destruction, resolved to lead his army against Augustus king of Poland.

Marches against the Russians.

On the road, however, he received intelligence that the czar of Russia was on his march to oppose him, and had laid siege to Narva with an army of 100,000 men. The contest that ensued between Charles and Peter, with the celebrated battles of Narva and Pultava, have been already related under Russia, so that we shall here confine ourselves chiefly to those events in which Peter the Great was not immediately concerned. Peter was the chief support of Augustus, and he took the most active measures to oppose the progress of the Swedish monarch. His want of success, and the subsequent contests between him and Charles, till the decisive battles of Pultava, are related in the same article.

Charles marches against the Saxons, A. D. 1701,

In 1701, as early as the season permitted, Charles, having received a reinforcement from Sweden, took the field, and appeared suddenly on the banks of the Duna, along which the Saxon army was posted to receive him. The king of Poland being at that time sick, the army was commanded by Ferdinand duke of Courland, Marshal Stenau, and General Paykel, all officers of valour and experience. They had fortified some islands in the mouth of the river, and taken every other precaution against an attack; the soldiers were hardy, well disciplined, and nearly equal to the Swedes in number;

and entirely defeats them.

yet Charles, having passed the river in boats with high sides, to screen the men from the fire of the enemy, attacked them with such fury, that they were entirely defeated, and with great loss. This victory was followed by the surrender of all the towns and fortresses in the duchy of Courland. Charles then passed into Lithuania, where every town opened its gates to him. At Birsen, an army of 20,000 Russians retired with the utmost precipitation on the news of his approach.

Forms a scheme for dethroning Augustus.

Here Charles, perceiving that the kingdom of Poland was greatly disaffected to Augustus, began to project the scheme of dethroning him by means of his own subjects. This scheme he executed with more policy than he ever showed on any other occasion.

Augustus, in the mean time, finding his scheme of peace frustrated, had recourse to the senate; but met with such a rough answer from them, that he determined to apply to Charles. To him therefore he sent his chamberlain; but a passport being forgotten, the ambassador was arrested.

Warsaw taken.

Charles continued his march to Warsaw, which surrendered on the first summons; but the citadel held out for some days. Augustus, finding at last that no dependence was to be placed on the Poles, determined to trust his fortune wholly to the Saxon army and the nobility of the palatinate of Cracow, who offered to support him to the utmost of their power. The Saxon army had now advanced to the frontiers, and Augustus immediately put himself at its head. Being joined by the nobility of Cracow, he found that his forces amounted to 30,000 men, all brave and well disciplined. With these he marched in quest of his enemy; nor did the Swedish monarch decline the combat, though he had with him only 12,000 men.

The Saxons entirely defeated.

Though the Saxons were strongly posted, having their front covered by a morass, besides being fortified with pallisadoes and chevaux de frise, they were attacked with irresistible impetuosity, and entirely defeated.

Cracow taken.

This victory was followed by the loss of Cracow. Charles then set out in pursuit of the flying army, with a design of preventing them from re-assembling; but his horse falling under him, he had the misfortune to break his thigh, by which he was confined six weeks, and thus Augustus obtained some respite. He improved this interval. Having convoked a diet, first at Marienburg, and then at Lublin, he obtained the following resolutions; that an army of 50,000 men should be raised by the republic for the service of the prince; that six weeks should be allowed the Swedes to determine whether they were for war or peace; and that the same time should be granted to the turbulent and discontented nobles of Poland to make their concessions.

Remains of the Saxon army entirely defeated. A. D. 1704.

To counteract the effects of these resolutions, Charles assembled another diet at Warsaw; and while the two assemblies disputed concerning their rights and privileges, he recovered from his wound, received a strong reinforcement from Pomerania, and utterly defeated and dispersed the remains of the Saxon army.

Augustus deposed, and Stanislas raised to the throne.

The ill fortune of Augustus continued still to prevail. In 1704 he was formally deposed by the diet, and the crown was conferred by Charles on Stanislas Lecsinsky, palatine of Posnania. Augustus however did not yet tamely relinquish his kingdom.

Warsaw retaken by Augustus.

His adherents daily skirmished with the Swedes; and Augustus himself, being reinforced by 9000 Russians, retook Warsaw, and had nearly surprised the new king, who lived in perfect security in the city while Charles fought his battles. Count Horn, with 1500 Swedes, vigorously defended the citadel; but at last, finding it no longer tenable, he was obliged to surrender at discretion. The reduction of Warsaw was among the last advantages gained by Augustus in the course of this war. His troops were now composed of Saxon recruits and undisciplined Poles, who had no attachment to his person, and were ready on all occasions to forsake him. Charles and Stanislas advanced with the victorious army; the Saxons fled before them, and the towns several miles round tendered their submission.

Excellent conduct of his general Schullemberg.

The Poles and Saxons were under the command of Schullemberg, a most sagacious and experienced general, who used every expedient to check the progress of the Swedes. With all his conduct and caution he found himself outwitted, and Charles in the neighbourhood of his camp, ready to fall on him, while he thought him at fifty leagues distance.

His engagement with the Swedes.

The Swedish monarch attacked him with a superior army, but entirely composed of horse. Schullemberg had posted his men in such a manner as rendered it impossible to surround them. His first rank, being armed with pikes and muskets, presented a rampart of bayonets; the

History.

second line, stooping over the first, who kneeled, fired over their heads; while the third rank, who stood upon their feet, kept up an incessant fire, by which the Swedish horse were exceedingly galled and put in disorder. Charles lost the opportunity of cutting off the whole Saxon army, by omitting to order his men to dismount. This was almost the first time that infantry had been regularly opposed to cavalry, and the superiority of the former was evident. After the engagement had continued about three hours, the Saxons retreated in good order; which no enemy had ever done before in any engagement with Charles. The Swedes pursued their enemies towards the Oder, and forced them to retreat through thick woods, almost impervious even to infantry. The Swedish horse, however, pushed their way, and at last enclosed Schullemberg between a wood and the river, where Charles had no doubt of obliging him to surrender at discretion, or die sword in hand, as having neither boats nor bridges; but the genius of Schullemberg supplied every defect. In the night he ordered planks and floats of trees to be fastened together, on which he carried over his troops, while the Swedes were employed in dislodging 300 men, whom he had placed in a wind-mill for the purpose of defending his flank, and diverting the attention of the enemy. Charles spoke of this retreat with admiration, and said he had been conquered by Schullemberg.

His fine retreat.

Augustus leaves Poland.

No material advantage however resulted to Augustus, who was again obliged to leave Poland, and fortify the capital of his hereditary dominions, which he expected every moment to see invested. In the mean time, the Russians having recovered their spirits, attacked the Swedes in Livonia with the utmost fury. Narva, Dorpat, and several other towns, were taken, and the inhabitants and garrison treated with great barbarity. An army of 100,000 Russians soon afterwards entered Poland. Sixty thousand Cossacks under Mazeppa entered the country at the same time, and committed every outrage with the fury of barbarians. Schullemberg, perhaps more formidable than either, advanced with 14,000 Saxons and 7000 Russians, disciplined in Germany, and reputed excellent soldiers. Could numbers have determined the event of war, the Swedes must certainly have been at this time overpowered; but Charles seemed to triumph over his enemies with more ease the more numerous they were. The Russians were so speedily defeated, that they were all dispersed before one party had notice of the misfortunes of another. The defeating an army of 40,000 men scarcely obstructed the march of the Swedes, while their astonished enemies looked on these actions as the effects of witchcraft, and imagined that the king of Sweden had dealings with infernal spirits. With these apprehensions they fled beyond the Dnieper, leaving the unhappy Augustus to his fate. Schullemberg, with all his skill and experience, was not more successful. The Swedish general Renschild engaged and defeated him in half an hour, though the Swedes were vastly inferior in number, and their enemies posted in a most advantageous situation. Nothing could be more complete than the victory. This extraordinary victory, indeed, is said to have been owing to a panic which seized the troops of Schullemberg; but it was regarded with admiration, and thought to make the renown of Renschild equal to that of his sovereign. Charles himself was jealous, and could not help exclaiming, "Surely Renschild will not compare himself with me!"

The Russians take several towns in Livonia, and invade Poland.

Astonishing success of Charles against them.

Schullemberg entirely defeated by Renschild.

Charles invades Saxony.

Soon after this victory, which was gained on the 12th of February 1706, Charles entered Saxony at the head of 24,000 men. The diet at Ratisbon declared him an enemy to the empire if he crossed the Oder. But to this declaration no regard was paid: Charles pursued his march, while Augustus was reduced to the condition of a vagrant in Poland, where he possessed not a single town except Cracow. Into this city he threw himself with a few Saxon, Polish, and Russian regiments, and began to erect some fortifications for his defence; but the approach of the Swedish general Meyerfeldt, and the news of the invasion of Saxony, disconcerted all his measures, and plunged him into despair. The Russians indeed were his faithful allies, but he dreaded them almost as much as the Swedes; so that he was reduced to the necessity of writing a letter to Charles with his own hand, begging for peace on whatever terms he thought proper to grant. As he was then at the mercy of the Russians, this transaction was concealed with the greatest care. His emissaries were introduced to the Swedish court in the night-time, and being presented to Charles, received the following answer: that King Augustus should for ever renounce the crown of Poland, acknowledge Stanislas, and promise never to re-ascend the throne, should an opportunity offer; that he should release the princes Sobieski, and all the Swedish prisoners made in the course of the war; surrender Patkul, at that time resident at his court as ambassador for the czar of Russia, and stop proceedings against all who had passed from his into the Swedish service. These articles Charles wrote with his own hand, and delivered to Count Piper, ordering him to finish them with the Saxon ambassadors.

History.

Augustus begs for peace on any terms.

Charles's answer.

After his defeat at Pultava (see Russia) Charles fled in a mean calash, attended by a little troop inviolably attached to his person, some on foot, and some on horseback. They were obliged to cross a sandy desert, where neither herb nor tree was to be seen, and where the burning heat and want of water were more intolerable than the extremities of cold which they had formerly endured. The whole had almost perished for want of water, when a spring was fortunately discovered. They reached Otchakoff, a town in the Turkish dominions, the pacha of which supplied the king with every necessary. It was, however, some time before boats could be got ready for transporting the whole of the king's attendants; by which accident 500 Swedes and Cossacks fell into the hands of the enemy. This loss affected him more than all his other misfortunes. He shed tears at seeing, across the river Bog, the greater part of his few remaining friends carried into captivity, without having it in his power to assist them. The pacha waited on him to apologise for the delay, and was as severely reprimanded by Charles as if he had been his own subject.

Charles arrives in Turkey after his defeat at Pultava.

The king remained but a few days at Otchakoff, when the seraskier of Bender sent an aga to compliment him on his arrival in the Turkish dominions, and to invite him to that city. Here he was treated with hospitality. The Turks practised to its full extent their generous maxim of regarding as sacred the persons of unfortunate princes who had taken shelter in their dominions; and they perhaps regarded him, notwithstanding his misfortunes, as an ally that might be useful to themselves against the Russians. Every one indeed regarded him in his distress. The French king offered him a safe passage from the Levant to Marseilles, from whence he might easily return to his own dominions. But Charles was too obstinate to receive advice. Puffed up with the notion of imitating Alexander the Great, he disdained to return except at the head of a numerous army; and he yet expected, by means of the Turks, to dethrone his adversary the czar. Negociations for this purpose were carried on in the Turkish divan, and it was proposed to escort Charles with a numerous army to the frontiers of Poland; but the revolution which there took place put an end to all such projects. Augustus thought himself no longer bound to observe the treaty which he had made, than when Charles was at hand to compel him. After the battle of Pultava, he entered Poland, and took every measure, in concert with the czar, for the recovery of his kingdom. Stanislas was not able to encounter such enemies, but was obliged to leave his dominions and fly to Bender, in the disguise of a Swedish officer, in order to share the

Is kindly received, and his hopes of conquering Russia begin to revive.

Augustus recovers the kingdom of Poland.

History.

The Danes invade Sweden,

fortune of Charles. It was not in Poland alone that the Swedish affairs began to suffer in consequence of the defeat at Pultava. The Danes invaded the province of Schonen with an army of 13,000 foot and 2500 horse. Only 13,000 Swedish forces remained to defend all the territories possessed by Charles in Germany, and of these only a small part was allotted for the defence of Schonen. The regency of Sweden, however, exerted themselves to the utmost to repel this ungenerous invasion; and having collected an army of 12,000 militia and 8000 regulars, despatched them under General Steenboek into Schonen. Some Saxon troops were incorporated in this army; but among these a prodigious desertion took place, which the general found it impossible to prevent; and thus the Danes gained several advantages, and at last took Christianstadt. Their insolence on this success was so great that the Swedes demanded to be instantly led against them. Here the good fortune of Sweden seemed once more to revive.

but are utterly defeated.

The Danes were driven from a very strong situation, with the loss of 8000 killed and taken prisoners, besides a vast number wounded. The king received the intelligence of this victory with the greatest exultation, and could not help exclaiming, "My brave Swedes, should it please God that I once more join you, we shall conquer them all."

In the mean time, Charles, by means of his agents the count Poniatoffski and Neugebar, used his utmost efforts to procure a rupture between the Porte and Russia.

The Turks declare war against the Russians. A. D. 1711.

For a long interval the money bestowed by Peter on the vizirs and janisaries prevailed; but at last the grand signior, influenced by his mother, who was strongly in the interest of Charles, and had been used to call him *her lion*, determined to support his quarrel with Peter. He therefore gave orders to the vizir to fall on the Russians with an army of 200,000 men. The vizir promised obedience, but at the same time professed his ignorance in the art of war, and dislike to the present expedition. The khan of Crim Tartary, who had been gained over by the reputation and presents of the king of Sweden, had orders to take the field with 40,000 of his men, and had the liberty of assembling his army at Bender, that Charles might see that the war was undertaken on his account. See RUSSIA.

The treaty of the Pruth was most violently opposed by Poniatoffski and the khan of Tartary. The former had made the king acquainted with the situation of both armies; on which he instantly set out from Bender, filled with the hopes of fighting the Russians, and taking ample vengeance. Having ridden fifty leagues post, he arrived at the camp just as the czar was drawing off his half-famished troops. He alighted at Poniatoffski's tent; and being informed of particulars, instantly flew in a rage to the vizir, whom he loaded with reproaches, and accused of treachery. Recollecting himself, however, he proposed a method by which the fault might be remedied; but finding his proposal rejected, he posted back to Bender, after having by the grossest insults showed his contempt of the vizir.

The violent behaviour of Charles did not promote his interest. The vizir perceived that his stay in Turkey might prove fatal to himself, and he therefore determined to remove him as soon as possible.

The grand signior desires him to depart.

Succeeding vizirs adopted the same plan; and at last the grand signior himself wrote a letter to Charles, in which he desired him to depart by next winter, promising to supply him with a sufficient guard, with money, and every thing else necessary for his journey. Charles gave an evasive answer, and determined to procrastinate his journey, as well to gratify his own stubborn temper, as because he discovered a correspondence between Augustus and the khan of Tartary, the object of which, he had reason to believe, was to betray him to the Saxons. When he was again pressed to fix the day of his departure, he replied, that he could not think of going before his debts were paid. Being asked how much was necessary for this purpose, he replied, a thousand purses. A purse, it is to be remarked, consists of thirty sequins.

Mean and unjust behaviour of Charles.

Twelve hundred purses were instantly sent to the seraskier at Bender, with orders to deliver them to the king of Sweden, but not before he should have begun his journey. By fair promises, Charles persuaded him to part with the money; after which, instead of setting out, he squandered away his treasure in presents and gratifications, and then demanded a thousand purses more before he would set out. The seraskier was astonished at this behaviour. He shed tears; and turning to the king told him that his head would be the forfeit of having obliged him with the money. The grand signior, on being acquainted with the shameful behaviour of Charles, flew into a rage, and called an extraordinary divan, where he himself spoke; a practice very unusual for the Turkish monarchs. It was unanimously agreed that such a troublesome guest ought to be removed by force, should other means fail.

The Turks resolve to force him to depart.

Positive orders were therefore sent to Charles to depart; and, in case of his refusal, instructions were given for attacking him in his quarters. Nothing could equal his obstinacy on this occasion: in spite of the menaces of his enemies, in spite of the entreaties of his friends, he persisted in his resolution; and at last determined to resist, with 300 Swedes, being the entire number of his attendants, an army of 20,000 janisaries well armed and furnished with cannon.

His desperate resolution to resist.

At length he was attacked in good earnest; though it must be owned, that even in this extremity, the Turks showed their regard to him, and were tender of his safety. Most of the Swedes surrendered at once, perhaps as thinking it the only method of saving the king's life. This conduct, however, had an opposite effect. Charles became the more obstinate, the more desperate his affairs seemed to be.

Is abandoned by all his followers except forty.

With only forty menial servants, and the generals Hord and Dardorff, he determined to defend himself to the last extremity. Seeing his soldiers lay down their arms, he told the generals, "We must now defend the house. Come," added he with a smile, "let us fight *pro aris et focis*." The house had been already forced by the Tartars, all but a hall which was near the door, and where his domestics had assembled. Charles forced his way through the janisaries, attended by the generals Hord and Dardorff, joined his people, and then barricaded the door. The moment he entered, the enemy who were in the house threw down their booty, and endeavoured to escape at the windows. Charles pursued them from room to room with much bloodshed, and cleared the house in a few minutes.

Fights like a madman, but is taken prisoner with all his followers.

He then fired furiously from the windows, killed two hundred of the Turks in a quarter of an hour, so that the pacha who commanded them was at length forced to set the house on fire. This was effected by discharging arrows with lighted matches into the roof; but Charles, instead of quitting his post, gave orders for extinguishing the fire, and he himself assisted with great diligence. All efforts were however vain: the roof fell in, and Charles, with his few faithful companions, was ready to be buried in the ruins. In this extremity one called out that there was a necessity for surrendering. "What a strange fellow!" cries the king, "who would rather be a prisoner with the Turks than mix his ashes with those of his sovereign." Another had the presence of mind to cry out, that the chancery was but fifty paces off, had a stone roof, and was proof against fire. Pleased with the thoughts of again coming to blows, the king exclaimed, "A true Swede! Let us take all the powder and ball we can carry." He then put himself at the head of his troops, and sallied out with such impetuosity, that the Turks retreated fifty paces; but having fallen in the midst of his fury, they rushed upon him, and carried him by the legs and arms to the pacha's tent. This extraordinary adventure, which savours not a little of insanity, happened on the 12th of February 1713. He was now kept prisoner with all his retinue; and in this situation

History.

he was visited by the unfortunate Stanislas, the dethroned king of Poland.

Begins to think of returning to his dominions.

Charles seemed at last inclined to submit to his fate, and began seriously to think of returning to his kingdom, now reduced to the most deplorable situation. His habitation had been fixed at Demotica, a small town about six leagues from Adrianople. Here he was allowed provisions for his own table and those of his retinue; but only twenty-five crowns a day in money, instead of five hundred which he had received at Bender. During his residence here, he received a deputation from Hesse-Cassel, soliciting his consent to the marriage of the landgrave with Eleonora, princess royal of Sweden; to which he readily agreed. A deputation was also sent him by the regency of Sweden, requesting that he would prepare for returning to his own dominions, which, in his absence, were ready to sink under a ruinous war.

Sets out for Sweden. A. D. 1714.

On the 14th of October 1714, Charles set out for Sweden. All the princes through whose territories he was to pass had given orders for his entertainment in the most magnificent manner; but the king, perceiving that these compliments only rendered his imprisonment and other misfortunes more conspicuous, suddenly dismissed his Turkish attendants, and assembling his own people, bid them take no care about him, but make the best of their way to Stralsund. After this he set out post, in the habit of a German officer, attended only by Colonel During. Keeping the by-roads through Hungary, Moravia, Austria, Bavaria, Wirtemberg, the Palatinate, Westphalia, and Mecklenburg, he arrived on the 21st of November at midnight before the gates of Stralsund. Being unknown, he was admitted with difficulty; but being soon recognised by the governor, the greatest tokens of joy were manifested all over the town.

Distressed situation of Sweden.

Sweden was now in the greatest distress. On the news of the defeat at Pultava, the Danes had invaded Schonen, but were defeated by General Steenboek. This victory did not, however, put an end to the war. The kings of Denmark and Poland, with the czar of Russia, entered into stricter bonds of amity than ever. They dreaded the return of Charles to his own dominions, and apprehended that numberless victories would soon efface the remembrance of Pultava. They determined to make the best use of their time; and perhaps Charles never took a more imprudent resolution than obstinately to remain so long in the Turkish dominions. His return seemed to give new life to the whole nation. Though the number of inhabitants was visibly diminished, the levies which he had ordered were completed in a few weeks; but the husbandmen left to cultivate the earth consisted of the infirm, aged, and decrepid; so that a famine was threatened in consequence of the military rage which had seized all the youth of the kingdom.

The king is unable to retrieve the Swedish affairs. A. D. 1715.

The presence of Charles did not now produce those consequences which the allies had feared. The kingdom was too much reduced to furnish the necessary supplies of men and money; and though the king's courage and military skill were not in the least diminished, the efforts which he made, instead of restoring Sweden to its splendour, served more completely to ruin it. In 1715, Prussia declared against him, on account of his demanding back the town of Stettin, which that monarch had seized. To complete his embarrassment, the elector of Hanover, George I. of Britain, also became his enemy. The forces of Denmark, Prussia, Saxony, and Hanover joined to invest Wismar, while a body of 36,000 men formed the siege of Stralsund; and at the same time the czar, with a fleet of twenty large ships of war, and 150 transports, carrying 30,000 men, threw every part of the Swedish coast into the greatest consternation. The heroism of Charles could not prevail against so many enemies; yet he was still so much dreaded, that the prince of Anhalt, with 12,000 brave troops, did not think himself a match for this furious enemy when at the head of only 2000, till he had intrenched his army behind a ditch, defended by chevaux de frise. It appeared, indeed, that this precaution was not unnecessary; for in the night Charles with his men clambered up the ditch, and attacked the enemy in his usual manner. Numbers, however, at last prevailed, and Charles was obliged to retire, after having seen his favourite Grothusen, General Dardoff, and During, the companions of his exile, killed by his side, he himself being wounded in the breast.

Is encompassed on all sides by enemies.

His desperate valour.

Stralsund besieged,

This rash attempt was made in order to save Rugen, whence the town of Stralsund was supplied with provisions. The place was well fortified, and garrisoned with 9000 men, with Charles himself at their head; but nothing could resist the efforts of the enemy. By the 17th of December it was proposed to give the assault. The attack on the horn-work was desperate; the enemy was twice repulsed; but at last, by dint of numbers, effected a lodgment. The next day, Charles headed a sally, in which he dealt terrible destruction among the besiegers, but was at length overpowered and obliged to retreat into the town. At last his officers, apprehending that he must either fall into the hands of the enemy, or be buried in the ruins of the place, entreated him to retire. A retreat, however, was now almost as dangerous as to remain in the town, on account of the fleets of the enemy with which the sea was covered; and it is thought that this very circumstance induced the king to consent to it. Embarking in a small boat with sails and oars, he passed all the enemy's ships and batteries, and arrived safe at Ystedt in Schonen.

and taken, in spite of the utmost efforts of the king.

Charles invades Norway.

To revenge himself for these losses, Charles invaded Norway with an army of 25,000 men. The Danes were everywhere defeated and pursued with that vigour for which the king of Sweden was so remarkable; but strong reinforcements arriving from Denmark, and provisions failing, he was at last obliged to retire. Soon after this the Swedes lost Wismar; but when every thing seemed hopeless, Baron Goertz, the chief minister and favourite of Charles, contrived to make overtures for a treaty with the czar of Russia, by which the most formidable of all Charles's enemies was taken off. The minister found means to work on the inflexible temper of Charles, by representing to him that the cession of certain provinces to Peter would induce him to assist him in his projects of again dethroning Augustus, and of replacing James on the throne of Britain; which last scheme he had projected out of revenge for the elector of Hanover having seized on the duchies of Bremen and Verden. In consequence of the conferences between the czar and Goertz, the former engaged to send into Poland an army of 80,000 men, in order to dethrone that prince whom he had so long defended. He also engaged to furnish ships for transporting 30,000 Swedes to Germany, and 10,000 into Denmark. This treaty was not however ratified, and the death of Charles put a final stop to all the great prospects of Sweden.

A treaty with the czar of Muscovy projected.

Charles invades Norway.

The king had resolved on the conquest of Norway before he dethroned Augustus; and as no difficulties ever deterred him, he marched his army into that cold and barren country in the month of October, when the ground was covered with frost and snow. With 18,000 men he formed the siege of Fredrickshall, though the severity of the frost rendered it almost impossible to break ground. He resolved to form trenches; and his soldiers cheerfully obeyed, digging into the ground with the same labour as if they had been piercing a rock. On the 11th of December the king visited the trenches in the midst of a terrible fire from the enemy, imagining that his men might be animated by his presence. He took his post in the most dangerous station that he could select, standing on a gabion and leaning with his arm over the parapet, while the enemy were firing chain shot at the very spot where he stood. He was entreated to

His death.

History.

change his station, but he remained obstinate. At last he was seen to fall mortally wounded, but whether by the enemy or by an assassin has been much disputed, and will probably ever remain matter of doubt. He soon afterwards expired.

Account of the Swedish affairs from the death of Charles XII. to the year 1771.

Charles XII. was succeeded by his sister the princess Ulrica Eleonora, wife to the hereditary prince of Hesse. On this occasion the states took care to make a previous stipulation for the preservation of their liberties, and obliged the princess, before entering on the government, to sign a document to this effect. Their first care was to make peace with Great Britain, which the late king intended to have invaded. In order to prevent their further losses by the progress of the Russian, the Danish, the Saxon, and other arms, the Swedes made many great sacrifices to obtain peace from these powers. The French, however, about the year 1738, formed a dangerous party in the kingdom, which not only broke its internal quiet, but led it into a ruinous war with Russia, by which it lost the province of Finland. Their Swedish majesties having no children, it was necessary to settle the succession; especially as the duke of Holstein was descended from the queen's eldest sister, and was, at the same time, the presumptive heir to the empire of Russia. Four competitors appeared; the duke of Holstein Gottorp, Prince Frederic of Hesse-Cassel, nephew to the king, the prince of Denmark, and the duke of Deux-Ponts. The duke of Holstein would have carried the election, had he not embraced the Greek religion that he might mount the throne of Russia. The czarina interposed, and offered to restore all the conquests she had made from Sweden, excepting a small district in Finland, if the Swedes would receive the duke of Holstein's uncle, Adolphus Frederic, bishop of Lübeck, as their hereditary prince and the successor to the crown. This was agreed to; and a peace concluded at Abo, under the mediation of his Britannic majesty. The peace was so firmly maintained by the empress of Russia, that his Danish majesty thought proper to drop all resentment for the indignity offered his son. The prince-successor married the princess Ulrica, third sister to the king of Prussia; and in 1751 he entered into the possession of his new dignity, which proved to him a crown of thorns. The French had acquired great influence in all the deliberations of the Swedish senate, who of late had been little better than pensioners to that crown. The intrigues of the senators forced Adolphus to take part in the war against Prussia; but as that war was disagreeable, not only to the people, but also to the king of Sweden, the nation never made so mean an appearance; and on Russia's making peace with the king of Prussia, the Swedes followed the example. Adolphus died dispirited in 1771, after a turbulent reign of twenty years, and was succeeded by his son Gustavus.

Accession of Adolphus Frederick. A. D. 1751.

Gustavus III. ascends the throne. A. D. 1771.

The most remarkable transaction of this reign is the revolution which took place in the government in the year 1772, by which the king, from being the most limited, became one of the most despotic monarchs in Europe. Ever since the death of Charles XII. the whole power of the kingdom had been lodged in the states; and this power they had much abused. Gustavus therefore determined either to seize on that power of which they made such a bad use, or to perish in the attempt. The revolution was effected in the following manner. On the morning of the 19th of August 1772, a considerable number of officers, as well as other persons known to be attached to the royal cause, had been summoned to attend his majesty. Before ten he was on horseback, and visited the regiment of artillery. As he passed through the streets he was more than usually courteous to all he met, bowing familiarly to the lowest of the people. On the king's return to his palace, the detachment which was to mount guard that day being drawn up together with that which was to be relieved, his majesty retired with the officers into the guard-room. He then addressed them with all that eloquence of which he is said to have been a master; and after insinuating to them that his life was in danger, he exposed to them in the strongest colours the wretched state of the kingdom, the shackles in which it was held by means of foreign gold, and the dissensions and troubles arising from the same cause which had distracted the diet during the course of fourteen months. He assured them that his only design was to put an end to these disorders, to banish corruption, restore true liberty, and revive the ancient lustre of the Swedish name, which had been long tarnished by a venality as notorious as it was disgraceful. Then assuring them in the strongest terms that he disclaimed for ever all absolute power, or what the Swedes call *sovereignty*, he concluded with these words: "I am obliged to defend my own liberty and that of the kingdom against the aristocracy, which reigns. Will you be faithful to me, as your forefathers were to Gustavus Vasa and Gustavus Adolphus? I will then risk my life for your welfare and that of my country." The officers, most of them young men, of whose attachment the king had been long secure, and who did not perhaps perceive the real tendency of his majesty's request, were allowed no time to reflect, immediately gave their assent, and took an oath of fidelity to him. Only three refused. One of these, Frederic Cederström, captain of a company of the guards, alleged he had already, and very lately, taken an oath to be faithful to the states, and consequently could not take that which his majesty then exacted. The king, looking at him sternly, answered, "Think of what you are doing." "I do," replied Cederström; "and what I think to-day I shall think to-morrow; and were I capable of breaking the oath by which I am already bound to the states, I should be likewise capable of breaking that which your majesty now requires me to take." The king having then ordered Cederström to deliver up his sword, placed him under arrest. His majesty, however, apprehensive of the impression which his proper and resolute conduct might make on the minds of the other officers, soon afterwards softened his tone; and again addressing himself to Cederström, told him, that as a proof of the opinion which he entertained of him, and the confidence which he placed in him, he would return him his sword without insisting on his taking the oath, and would only desire his attendance that day. The undaunted captain continued firm; he answered, that his majesty could place no confidence in him, and that he begged to be excused from the service.

Account of the revolution in 1772, by which he became despotic.

Resolution of a Swedish officer.

While Gustavus was shut up with the officers, senator Ralling, to whom the command of the troops in the town had been given two days before, came to the door of the guard-room, and was told that he could not be admitted. The senator insisted on being present at the distribution of the orders, and sent to the king to desire it; but was answered, he must go to the senate, where his majesty would speak to him. The officers then received their orders from the king; the first of which was, that the two regiments of guards and of artillery should be immediately assembled, and that a detachment of thirty-six grenadiers should be posted at the door of the council-chamber to prevent any of the senators from coming out. But before the orders could be carried into execution, it was necessary that Gustavus should address himself to the soldiers; men wholly unacquainted with his designs, and accustomed to pay obedience only to the orders of the senate, whom they had been taught to hold in the highest reverence. As his majesty, followed by the officers, was advancing from the guard-room to the parade for this purpose, some of them, more cautious, or perhaps more timid, than the rest, became, on a short reflection, apprehensive of the consequences of the measure in which they were engaged: they began to express their fears to the king, that unless some person of greater weight and influence than themselves

The king gains over the soldiers.

History.

were to take a part in the same cause, he could scarcely hope to succeed in his enterprise. The king stopped a while, and appeared to hesitate. A serjeant of the guards overheard their discourse, and cried aloud, "It shall succeed. Long live Gustavus!" His majesty immediately said, "Then I will venture;" and stepping forward to the soldiers, he addressed them in terms nearly similar to those which he had employed to the officers, and with the same success. They answered him with loud acclamations. One voice only said, No; but it excited no attention.

Secures the senators, and becomes master of the whole power in the kingdom.

In the mean time some of the king's emissaries had spread a report about the town that his majesty was arrested. This drew the populace to the palace in great numbers, where they arrived as he had concluded his harangue to the guards. They testified by reiterated shouts their joy at seeing him safe; a joy which promised the happiest conclusion to the business of the day. The senators were now immediately secured. They had from the window of the council-chamber beheld what was going forward on the parade before the palace; and, at a loss to know the meaning of the shouts which they heard, were coming down to inquire into the cause of them, when thirty grenadiers, with their bayonets fixed, informed them it was his majesty's pleasure they should continue where they were. They began to speak in a high tone, but were only answered by having the door shut and locked upon them. The moment the secret committee heard that the senate was arrested, they separated of themselves, each individual providing for his own safety. The king then mounting his horse, followed by his officers with their swords drawn, a large body of soldiers, and numbers of the populace, went to the other quarters of the town where the soldiers whom he had ordered to be assembled were posted. He found them all equally willing to support his cause, and to take to him an oath of fidelity. As he passed through the streets, he declared to the people, that he only meant to defend them, and save his country; and that if they would not confide in him, he would lay down his sceptre, and surrender up his kingdom. So much was the king beloved, that some of the people even fell on their knees, and many more, with tears in their eyes, implored his majesty not to abandon them.

Summons an assembly of the states;

The king proceeded in his course, and in less than an hour made himself master of all the military force in Stockholm. In the mean time the heralds, by proclamation in the several quarters of the city, summoned an assembly of the states for the ensuing morning, and declared all members traitors to their country who should not appear. Thither his majesty repaired in all the pomp of royalty, surrounded by his guards, and holding in his hand the silver sceptre of Gustavus Adolphus. In a very forcible speech, he lamented the unhappy state to which the country was reduced by the conduct of a party ready to sacrifice every thing to its ambition, and reproached the states with adapting their actions to the views of foreign courts, from which they received the wages of perfidy. "If any one dare contradict this, let him rise and speak." Conviction, or fear, kept the assembly silent, and the secretary read the new form of government, which the king submitted to the approbation of the states. It consisted of fifty-seven articles; of which the five following were the chief. 1. The king has the entire power of convoking and dissolving the assembly of the states as often as he thinks proper. 2. His majesty alone has the command of the army, fleet, and finances, and the disposal of all offices civil and military. 3. In case of an invasion, or of any pressing necessity, the king may impose taxes, without waiting for the assembly of the states. 4. The diet can deliberate on no other subjects than those proposed by the king. 5. The king shall not carry on an offensive war without the consent of the states. When all the articles were recited, the king demanded if the states approved of them, and was answered by a general acclamation. He then dismissed all the senators from their employments, adding, that in a few days he would appoint others; and concluded this extraordinary scene by drawing out of his pocket a small psalm-book, from which, after taking off the crown, he gave out *Te Deum*. All the members very devoutly added their voices to his, and the hall resounded with thanksgiving.

which accepts a new form of government.

History.

The king makes a good use of his power.

The power which he had thus obtained, he employed for the good of his subjects. He took care that the law should be administered with impartiality to the richest noble and the poorest peasant, making a severe example of such judges as were proved to have made justice venal. He gave particular attention and encouragement to commerce; and being himself a man of letters, was a liberal and enlightened patron of literature and science. He strenuously laboured to introduce into his kingdom the most valuable improvements in agriculture that had been made in foreign countries.

Reforms the army and navy.

But while thus active in promoting the arts of peace, he was not inattentive to the art of war. The fleet, which he found decayed and feeble, he in a few years restored to a respectable footing; and, besides changing the regulations of the navy, he raised a new corps of sailors, and formed them to the service by continual exercise. The army, which, like the navy, had been neglected during the aristocracy, was next to be reformed. The king began by giving cloaks, tents, and new arms to all the regiments. Afterwards, under the direction of Field-marshal Count de Hessenstein, a new exercise was introduced, and several camps were formed, in which the soldiery were manœuvred by the king himself. The sale of military offices, which had been permitted for many years, was entirely suppressed; and the king provided not only for the re-establishment of discipline and good order in the army, but for the future welfare of the individuals who composed it. These warlike preparations were necessary to a plan which he had formed for entirely abolishing the power of the aristocracy, and freeing Sweden from the factions which had long been formed in it by the court of St Petersburg. The change which he had introduced was very inimical to the intrigues of that court; and the Russian ambassador exerted himself openly to bring about a rupture between the king and the discontented nobles. Gustavus ordered him to quit the kingdom in eight days, and immediately prepared for war with Russia. To this apparently rash enterprise he was incited by the Ottoman Porte, at that time unable to oppose the armies of the two empires; and his own ambition, together with the internal state of his kingdom, powerfully concurred to make him lend every assistance to his ancient ally. It is needless for us to enter into a detail of the particulars of that war, the principal circumstances of which have already been noticed under Russia. Suffice it to say, that neither Gustavus Adolphus nor Charles XII. gave greater proofs of undaunted courage and military conduct in their long and bloody wars than were given by Gustavus III. from the end of the year 1787 to 1790, when peace was restored between the courts of St Petersburg and Stockholm. When the court of Copenhagen was compelled, by the means of England and Prussia, to withdraw its troops from the territories of Sweden, the king attacked Russia with such vigour both by sea and land, displayed such address in retrieving his affairs when apparently reduced to the last extremity, and renewed his attacks with such pertinacious courage, that the empress lowered the haughtiness of her tone, and was glad to treat with Gustavus as an equal and independent sovereign.

His conduct in the war with Russia.

A conspiracy formed against the king's life. A. D. 1792.

Sweden now enjoyed peace; but the nobles continued discontented, and a conspiracy was planned against Gustavus under his own roof. He had entered into the alliance that was formed against the revolutionary government of France; and in order to raise an army, which he was to

History.

lead in person, to co-operate with the emperor and the king of Prussia, he was obliged to negociate large loans, and to impose on his subjects heavy taxes. The nobles took advantage of that circumstance to prejudice the minds of many of the people against the sovereign who had laboured so long for their good. On the 16th of March 1792 he received an anonymous letter, warning him of his immediate danger from a plot that was laid to take away his life; requesting him to remain at home, and avoid balls for a year; and assuring him that, if he should go to the masquerade for which he was preparing, he would be assassinated that very night. The king read the note with contempt, and at a late hour entered the ball-room. After some time, he sat down in a box with Count d'Essen, and observed that he was not deceived in his contempt for the letter, since, had there been any design against his life, no time could be more favourable than that moment. He then mingled, without apprehension, among the crowd; and just as he was preparing to retire in company with the Prussian ambassador, he was surrounded by several persons in masks, one of whom fired a pistol at the back of the king, and lodged the contents in his body. A scene of dreadful confusion immediately ensued. The conspirators, amidst the general tumult and alarm, had time to retire to other parts of the room; but one of them had previously dropped his pistols and a dagger close by the wounded king. A general order was given to all the company to unmask, and the doors were immediately closed; but no person appeared with any particular distinguishing marks of guilt. The king was immediately conveyed to his apartment; and the surgeon, after extracting a ball and some slugs, gave favourable hopes of his recovery. But the prognostication of his medical attendants soon appeared to be fallacious, and on the 28th of March a mortification was found to have taken place. He expired on the following day; and on opening his body there were found within the ribs a square piece of lead and two rusty nails.

The king dangerously wounded.

Death of Gustavus III. A. D. 1792.

The king had by his will appointed a council of regency; but convinced by recent experience how little dependence was to be placed on the attachment of his nobles, and aware of the necessity of a vigorous government in times of such difficulty and danger, he appointed his brother, the duke of Sudermania, sole regent, till his son, then a minor, should attain the age of eighteen years. In his dying moments he desired that all the conspirators, except the perpetrator of his murder, might be pardoned.

Accession of Gustavus IV.

The young king, who was about fourteen at his father's death, was proclaimed by the name of Gustavus IV. The regent soon took the most vigorous and active measures to apprehend and punish the projectors and perpetrators of the murder of his brother. A nobleman of the name of Ankarström confessed himself the assassin, and gloried in the action, which he called liberating his country from a monster and a tyrant. He was executed in a most cruel manner on the 17th of May. Other two noblemen, and two officers, also suffered death; but the rest of the conspirators were either pardoned, or punished only by fine and imprisonment.

From the accession of Gustavus IV. till the revolution which has been recently effected in Sweden, few transactions of any importance have occurred. Soon after the king had assumed the administration of affairs, he engaged warmly in the war against France, and till the time of his deposition continued a most faithful ally of Britain. The efforts of the Swedish monarch towards humbling the power of Bonaparte have been already noticed under the articles BRITAIN and FRANCE; and the war with Russia, in which his alliance with Britain had involved him, has been sufficiently touched in the article RUSSIA. This prince seems to have been endowed with amiable qualities; but he was certainly rash and imprudent, and perhaps in some degree tinctured with insanity. He thus materially injured his kingdom, and alienated the affections of his principal nobles, especially of his uncle the duke of Sudermania.

History.

Revolution in favour of the duke of Sudermania. A. D. 1809.

In the beginning of March 1809, the plan which appears to have been concerted between the duke of Sudermania and the principal nobility was carried into effect. The king was arrested; the duke assumed the reins of government, and issued a proclamation, announcing that, under existing circumstances, the king was incapable of conducting the affairs of the nation. Gustavus, now in close custody, was easily prevailed upon to abdicate the government. The diet was assembled; the duke of Sudermania was declared king of Sweden, under the title of Charles XIII.; Prince Augustenberg was chosen crown prince; and various changes were introduced into the constitution, confirming the powers of the diet, and removing what the prevailing party held to be encroachments of the crown during the late and preceding reigns. The people, wearied or disgusted by the late king's folly and rashness, readily acquiesced in all the alterations. Peace was then made with Russia; a measure which had become absolutely necessary, as the military force of the kingdom was completely broken, and no means were left for checking the progress of the enemy. By this peace Sweden lost Finland, a country of peculiar importance to her, on account of the supplies of grain which she was accustomed to draw from it; but in the treaty she reserved the right of yearly importing a certain quantity of grain, duty free. Swedish Finland, with Lapmark, now annexed to Russia, was estimated to contain about 120,000 square English miles, with 895,000 inhabitants. On the 6th of January 1810, peace was also concluded with France, which restored Pomerania.

Sweden was now enjoying tranquillity, when the sudden and unexpected death of the crown prince Augustenberg, in April 1810, became a new source of perplexity. The duke of Sudermania was old and in a feeble state of health; and as there was no person within the kingdom who had any title by blood to the throne, it was necessary, for the security of the new order of things, to choose a successor. The threatening position which the acquisition of Finland gave to Russia induced the noblemen who in concert with the court took a lead in this business, to look for some man of military talents. It happened that Bernadotte, prince of Ponte Corvo, who had lately commanded in the north of Germany, had, by his liberal and kind treatment, gained the peculiar esteem of the Swedish officers and soldiers whom he had made prisoners in Gustavus's ill-concerted operations in Pomerania. He was besides highly respected for his military skill; and had been still further raised in general estimation, in consequence of Napoleon having removed him from his command for his lenity and humanity in the exercise of his power. Some of the Swedish officers, to whom his character was known, first conceived the idea of offering him the succession to the crown. The scheme was for some time kept as secret as possible; but it received so much countenance from the most considerable men, that it was at length opened to Bernadotte himself at Paris. He received it as might be expected, and his friends redoubled their intrigues. The prince of Denmark had been proposed, but the ancient enmity against that country was an invincible obstacle to his success. At length, when every thing was prepared, the diet was called, and Bernadotte was with acclamation elected crown prince by all the four orders, on the 21st of July. Of all the changes in the fortune and station of individuals which arose out of the French revolution, this is perhaps the most singular. Bonaparte seized the royal power and dignity for himself, and by force of arms he compelled some of the weaker states to accept his relations and followers as kings. But it does not appear that he was ever consulted as to Bernadotte's elevation, or had the smallest influence in it, except that

History.

the example given in his own person and that of his followers had contributed to destroy some of the old illusions as to birth and hereditary honours, and had prepared men's minds for great innovations. It was thus that a Frenchman who began his career as a common soldier, was raised to the Swedish throne by the spontaneous choice of a body of nobles, proud of their birth and ancestry.

The appearance of Bernadotte in the Swedish capital was followed by numerous feasts and spectacles. He received congratulations from all the public bodies; and though not immediately called to the throne, was, from the king's infirmities, intrusted with the entire conduct of the government. One of his first acts was to recommend to the diet the introduction of a conscription law like that of France, a measure which certainly hazarded his popularity. It was however adopted; and on this occasion he prevailed with the nobles to make a voluntary surrender of their ancient privilege of exemption from military service, as well as from taxation. Pressed by France and Russia, Sweden, in November 1810, professed her adherence to the continental system, and declared war against Britain. The war however was only nominal, and the British cruisers returned, in most cases, their captures untouched. This state of things continued till Bonaparte was preparing for his great Russian campaign, when the Swedish government, solicited by both parties, and tempted by great offers, at length signed treaties of alliance with Russia and Britain in 1812 and 1813. By these treaties, the two powers mentioned engaged to assist the king in conquering Norway from Denmark. The French, for the purpose of intimidation, had previously seized Pomerania. Bernadotte carried over an army of 30,000 Swedes to Germany in 1813; and being joined by several large bodies of Prussian and German troops, he was encountered by Marshal Ney between Berlin and Leipzig on the 6th September, and, after an obstinate engagement, drove back the French army with the loss of 16,000 men. In the battle of Leipzig, fought on the 18th October, he likewise bore a conspicuous share. After the victory, he continued to act against Marshal Davoust's corps, and against the Danes, till he reduced the latter to the necessity of capitulating. He lost no time in improving this advantage; and by a treaty concluded at Kiel on the 14th January 1814, compelled Denmark to cede Norway, on surrendering to her the possession of Pomerania, and thus securing a great advantage by the exchange of territory. He now advanced to the Rhine; but, satisfied with reducing Napoleon's power, and, from views of interest, most probably adverse to ruining him, he was thought to be rather dilatory in improving his advantages. The success of the allies at length left him at liberty to secure Norway, the prize for which he had fought. As the Norwegians announced their intention of resisting, he crossed the frontier with an army in July, and, by judicious manœuvres, which placed the Norwegian force in his power, he obliged them to capitulate, and obtained possession of the country almost without bloodshed; Norway preserving its ancient constitution, and having states of its own. On the death of Charles XIII. in 1818, Bernadotte ascended the throne as Charles XIV., and was crowned at Stockholm and Drontheim. The subsequent history of Sweden presents few points of special interest. It has been characterized by a rapid and steady advance in prosperity, as will be seen from our account of the present state of the country. Bernadotte and his successors have devoted themselves to the establishment of peace and order among the people, and to the development of the industrial resources of the country, and their labours have been crowned with success. Commerce and the arts and manufactures have made rapid progress, and a very marked change has taken place in the moral and social condition of the people. Charles XIV. died in 1844, in the eightieth year of his age, and was succeeded by his son Oscar I. The present monarch, Charles XV., succeeded his father Oscar in 1859.

Boundaries.

Sweden occupies the eastern and larger portion of that part of Northern Europe known as the Scandinavian peninsula. It is bounded on the N.E. by Russia, from which it is separated by the rivers Tornea, Muonia, and Kongämä; on the N.W. and W. by Norway, the range of mountains and tablelands, which form the watershed of the peninsula, being, for the most part, the boundary between the two countries; on the S.W. by the Cattegat and Sound, separating it from Denmark, the former from Jutland, the latter from the Island of Zealand; on the S.E. by the Baltic; and on the E. by the Gulf of Bothnia. Sweden is thus chiefly bounded by water, and has a coast-line, exclusive of indentations, of more than 1400 miles. Its coasts are indented with numerous bays and inlets, and skirted by an immense number of islands. They are generally of moderate elevation and rocky; but they are sometimes low and sandy, particularly in the north. Connected with the coast of Sweden, it is deserving of notice, that in many parts a gradual elevation of the land has been observed to be taking place. This was remarked by Celsius so early as the beginning of the last century, and attributed by him to a gradual subsiding of the waters of the Baltic. Von Buch, during his travels in Scandinavia, in the early part of the present century, found at several points on the Norwegian coast, above the sea level, marine shells of species still existing in the neighbouring sea; and from this, and information obtained from the inhabitants, he was led to believe that Celsius was correct in averring, that a gradual change was taking place in the relative level of the land and water; but he concluded that it was occasioned by the rising of the land, and not by the subsiding of the waters. This view has since been confirmed by Sir Charles Lyell, who, in 1834, found the marks made on the rocks at water-level, fourteen years before under the direction of the Royal Academy of Sweden, to be then in some parts four or five inches above it. The rise has taken place principally in the north; at Stockholm, it was very slight; and in the south of Scania it was imperceptible.

Coasts.

Surface.

Sweden is about 900 miles in length from north to south, and is in general from 150 to 200 miles in breadth; lying between 55. 20., and 69. 10. N. Lat.; and 11. 15. and 24. E. Long. As compared with Norway, its surface is tame and uninteresting. In general, it rises gradually from the sea to the highlands on the borders of Norway. In the north, where these highlands are most elevated, the slopes are usually steep and irregular; in the central region, they form extensive plateaux; while in the south, where the highlands are of slight elevation, or altogether cease, the country is mostly flat, with here and there low ranges of hills. In the north, the surface is diversified with mountains, glens, and deep valleys, whereas, in the south, it con-

Statistics.

sists mostly of vast sandy plains interspersed with numerous lakes.

Rivers. Sweden is extremely well-watered by numerous rivers and lakes. From the nature of the country, however, the rivers are generally of small size, and not suited for navigation. The longest are in the north, rising in the Kiölen Mountains, flowing generally from north-west to south-east, and falling into the Gulf of Bothnia. The principal of these, beginning with the most northern, are the Tornea, Calix, Lulea, Pitea, Skelleftea, Windel, Umea, Angerman, Indals, Ljusne, and Dal. None of these much exceed 300 miles in length, and with the exception of the Angerman are not navigable for any distance from their mouths. Several of them traverse, or have their sources in considerable lakes; and form in their course beautiful falls and cataracts. Few of the rivers of Southern Sweden are of any considerable size, and notwithstanding the generally flat nature of the country through which they flow, they are little suited for navigation, being impeded by rocks and rapids, and subject to frequent inundations. There are numerous mineral springs in the country, and some of the watering-places, as Medewi, Ramlösa, Loka, &c., are much frequented.

Lakes. The lakes of Sweden are very numerous, and some of them are of great size. The Wener, which, after the Ladoga and Onega, is the largest lake in Europe, has a length of about 90 miles, and a breadth, where widest, of about 56. The Wetter is 82 miles in length by 16 in extreme breadth. The Mälar Lake extends westward from Stockholm, and is nearly 70 miles in length by from 2 to 20 in breadth. The Heilmar Lake, which lies to the S.W. of Lake Mälar, with which it is connected by a canal, is 35 miles in length by 15 in extreme width. In the north, the lakes are usually long and narrow, some of them being 40 or 50 miles long by 4 or 5 wide.

Geology. The geological structure of Sweden is very simple, and the formations few. Granite and gneiss are the prevailing rocks, especially the former, gneiss being less common here than in Norway. It is, however, very rich in mineral products, the most important of which are iron, copper, cobalt, zinc, lead, antimony, gold, silver, alum, nitre, and sulphur. Iron and copper, the two most important of these, will be afterwards more particularly noticed in treating of the mines of the country. Porphyry, marble, alabaster, limestone, millstone, potter's earth, &c., are also found. Coal has been found in the south near Helsingborg, but only to a small extent, and of very inferior quality.

Climate. The climate of Sweden, from the great extent of the country, of course, varies considerably; but it is upon the whole much milder than might be expected from its high latitude. As compared with Norway, its mean annual temperature is about 2° less; but, being protected on all sides from the extreme cold of the arctic regions, its winters are 5° warmer, while its summers are 1° colder. Thus, at Stockholm, the mean annual temperature is 42°; winter, 25°; summer, 62°. The atmosphere is remarkably dry and clear, and is in this respect a striking contrast to that of Norway; the fall of rain at Stockholm being only 17½ inches per annum. At Stockholm, the longest day is 18½ hours; the shortest nearly 6 hours in length. In the north, the whole surface of the country is covered with snow and ice for five or six months in the year; in the central parts, winter seldom lasts more than three or four months; and, in the south, the climate is very similar to that of northern Germany. In the north, about N. Lat. 71°, the limit of perpetual snow is 2300 feet above the level of the sea; at N. Lat. 64°, it is 4650 feet; at N. Lat. 62°, 5100 feet; and at N. Lat. 60°, 5600 feet. The transition from winter to summer is usually rapid, especially in the north, where it often takes place within the space of a few days.

Forests. The forests of Sweden are extensive, covering about two-sevenths of its entire area. The varieties of timber, however, are few. In the north the pine, birch, and fir are the principal trees; in the central parts, the ash, alder, willow, and maple are also common; and in the south, the oak, beech, elm, and lime are met with. In the plain of Scania, the mulberry, chestnut, pear, apple, and walnut trees flourish. Till lately the forests of Sweden were very much neglected, but now more attention is bestowed upon them, and timber constitutes one of the most important articles of export. They likewise furnish almost the sole article of fuel used in the country.

Agriculture. Agriculture, though little favoured by either soil or climate, has lately been making rapid advances. The improvements, however, are as yet chiefly confined to gentlemen possessed of large estates; the peasant farmers still mostly adhere to the old system. In consequence of the uncertainty of the climate, there are on an average of seven years only three years of good crops, three of indifferent crops, and one of entire failure. In the north scarcely one crop out of three succeeds. It is estimated that only $\frac{1}{47}$th part of the entire area of the country is arable. The most fertile tracts lie north of Lake Wener, between Lake Wetter and the Baltic, and in the plain of Scania. In consequence of the improved state of agriculture, and of the increased growth of the potatoe, not only is the annual produce of grain equal to the consumption, but generally there is a considerable surplus for exportation. In 1858 the quantity of grain exported (principally oats and barley) was 546,700 imperial quarters. In 1822 the quantity of grain produced was 5,867,570 tons; in 1847, 8,398,451; in 1850, 8,791,950; and, in 1858, about 11,000,000 tons. Of potatoes, the quantity produced in 1822 was 2,374,205 tons; in 1847, 5,328,503; in 1850, 4,890,311; and, in 1858, about 7,000,000 tons. The principal crops are rye, barley, oats, wheat, potatoes, peas, hemp, flax, &c. In the north, in consequence of the short summer, almost the only grain crop raised is barley, which is sown and reaped in seven or eight weeks. It is grown as far north as 69°. Rye cannot be grown with advantage north of 66°, and oats do not ripen north of 64°. Wheat does not, in general, succeed north of 62°. The cultivation of the potatoe is very general in all parts of the country, and in the north this root supplies the deficiency of corn. From the poverty of the soil, and the short duration of the summer, agricultural operations, especially during harvest, require the labour of a great number of persons, for whom, during the long winter, there is little or no employment. This must ever form a great obstacle to agricultural improvement, especially in the northern districts.

Cattle. The length of the winter is also unfavourable to the keeping of cattle, for though there are considerable tracts of good meadows, yet, as the cattle require to be housed from four to six, or seven months in the year, their number is very limited. The horses and horned cattle are small; but the former are active and spirited, and the latter afford excellent milk and beef. The sheep are generally of an inferior kind, but great pains have been taken to improve them by crosses with the French, English, and Spanish breeds. Towards N. lat. 63°, sheep disappear, and are superseded by goats, which are most numerous in the woodland districts of Dalarne and Nordland. In Lapland the reindeer and dog are the only domestic animals. In 1850 the number of horses in the country was 384,464; of horned cattle, 1,807,909; sheep and goats, 1,725,274; and pigs, 556,288. In 1822 the numbers respectively were—horses, 378,353; horned cattle, 1,484,984; sheep and goats, 1,477,709; pigs, 471,814: showing, in horses, an increase in 28 years of only 2 per cent., in horned cattle 22 per cent.; sheep and goats scarcely 17, and in pigs about 18 per cent, while the population had increased during that period 32 per cent. In 1855 there were 1,921,568 horned cattle, and 1,792,070 sheep in the country.

Statistics.

Wild animals.

Wild animals are numerous, especially in the northern parts. Among the more common of these may be mentioned the wolf, bear, fox, lynx, glutton, elk, deer, hares, &c. Among wild birds are eagles, falcons, capercailzies, woodcocks, partridges. Both the sea and the fresh waters swarm with fish, which afford employment and subsistence to many of the inhabitants. The fresh waters contain perch, pike, salmon, trout, grayling, char, roach, bleak, &c.; but of these the salmon is the most important, and is caught abundantly in almost all the rivers and lakes. The sea-fish include the sturgeon, cod, lamprey, ray, sole, turbot, pilchard, herring, and the stromming, a small species of herring.

Mines.

Next to agriculture, the mines of Sweden are the chief source of her wealth. Iron exists in great abundance, and is esteemed the best in the world. The mountain Gellivara in Lapland, 1800 feet in height, is one mass of the richest iron ore; but its situation, beyond the arctic circle (in lat. 67. 20. N.), far from the sea, and in an unpeopled region, deprives it of value. Iron ore, however, is found in almost every district of Sweden. The largest quantities of iron are produced in Carlstad, Orebro, Gefle, Falun, and Westeräs; but the best iron is obtained from the mines of Dannemora, in the län of Upsala. The quantity of iron ore raised, during the five years ending 1854, averaged about 300,000 tons annually; the quantity of pig-iron manufactured was nearly 140,000 tons; and of bar-iron about 100,000 tons. The quantity of bar-iron exported in 1858 was 59,449 tons, and of wrought-iron 2405 tons. This was, however, an unfavourable year, for in 1857 the quantity of bar-iron exported was 85,556 tons; and, in 1856, 83,281 tons. Next to iron, copper forms the most important of the mineral products of Sweden. The most important copper mines are those of Falun in Dalarne; but mines are also worked at Otvidaberg in Linköping-län, Areskuta in Jemtland, Hakanbo in Nerike, Bastras in Westeräs-lån, and other places. The amount of copper obtained in 1855 was 1671 tons. Gold is found at Falun, and a few other places, but the quantity is too small to pay the expense of working. The principal silver mine is at Sala in Westeräs, and the produce of that metal, in 1850, was over 405,000 oz. Of lead about 130 tons were produced, and of nickel 320 tons.

Manufactures.

Manufacturing industry has of late years been making great progress in Sweden. The manufactures of cotton, woollen, linen, and silk stuffs, sailcloth, cutlery, and hardware, paper, glass, earthenware, are all actively carried on. At Motala is a large establishment for the manufacture of steam-engines, iron steamers, &c., employing about 800 men, besides a branch establishment at Norrköping, where 400 more are employed. A very large paper-mill has also recently been established at Motala. Near Hudiksvall extensive saw-mills have recently been erected by an English company at a cost of upwards of L.52,000. The best native cutlery is produced at Eskilstuna, but it is much inferior to the British manufacture. Ship and boat-building is carried on to some extent at most of the ports. The distillation of brandy has of late much decreased, in consequence of a rise in the rate of duty, and other restrictions. In 1835 there were no fewer than 85,172 small, and 670 large distilleries; whereas, in 1855, there were only 3456 small, and 397 large; and, in 1858, 2477 small, and 326 large distilleries. The quantity of spirits produced in 1858 was 5,031,958 gallons, 3,442,749 gallons of which were made in the large distilleries. The amount of revenue derived from the distilleries in 1858 was L.293,530. Little or none of the brandy distilled in Sweden is exported, being almost entirely consumed at home. Domestic manufactures are largely carried on, for which the long winter nights are very favourable. The peasantry make not only their own clothes, but likewise their own furniture and agricultural implements. The following table gives the number of the several kinds of manufactories, the number of workmen employed therein, and the value produced thereat in 1851:—

Manufactories.	Number.	Workmen.	Value.
Cotton and linen	31	1,023	L.55,463
Cloth	156	4,377	470,369
Silk	17	805	75,805
„ ribbon	11	101	4,023
Yarn, linen, and cotton (by machine)	14	2,175	273,291
Sailcloth	12	1,148	31,191
Stockings and socks	18	372	11,332
Sugar	21	679	391,986
Tobacco	79	1,277	134,816
Paper	91	1,299	76,839
Leather	519	1,686	109,721
Dyeing	444	1,639	54,386
Calico printing	20	138	7,370

Rope	23	175	6,904
Clocks and watches	137	313	2,915
Playing cards	11	86	2,994
Paper hangings	14	128	5,668
Chemical manufactories of colours and acids	20	63	4,050
Carriages	19	127	6,676
Chemical tinder-boxes	7	311	5,737
Mechanics workshops	23	857	35,313
Linen yarn spinners	1	118	9,244
Various smaller works	699	2,073	58,222
Total	2,537	23,248	L.2,025,467

In 1854 there were 2413 manufactories employing 25,082 persons, and producing goods to the value of L.2,121,525. The amount of taxes paid by manufacturers on account of their businesses was L.3893.

Trade.

The trade of Sweden is only now beginning to develop itself, having been kept back by the unwise restrictions imposed upon it by the government. These having now, in some measure, been relaxed, commerce is beginning to progress. In 1842 the total value of the imports was L.1,438,130; of the exports, L.1,620,802: in 1849, imports, L.2,126,750; exports, L.2,195,500: 1852, imports, L.2,420,750; exports, L.2,304,833: 1854, imports, L.4,369,750; exports, L.4,400,000: 1856, imports, L.5,880,250; exports, L.5,135,166: and, in 1857 (an unfavourable year) imports, L.4,738,333; exports, L.4,357,417. At the close of the year 1854, the total number of sailing vessels amounted to 2783, of 236,296 tons burden, being a decrease of 42 vessels upon the previous year, but an increase of tonnage to the amount of 6044 tons. During the same year 44 foreign built vessels, of 10,548 tons, were naturalized in Sweden. At the close of 1857 the number of merchant vessels belonging to Sweden was 8190, with 295,410 tons. "I may here mention," says the British consul, in his report on the trade of Sweden during the year 1855, "the very great increase that has taken place in the carrying trade of Sweden since the alteration in the navigation laws in 1849. The number of Swedish vessels employed to carry freight from foreign countries to Englane was 28, tonnage 4176; whereas, in 1854, that number had increased to 212 vessels, with a tonnage of 42,198 (in 1858 the number was 351 vessels, with 77,698). I would at the same time remark, that in consequence of the superior education of the masters and mates of Swedish mercantile vessels, the subordination and steadiness of their crews, combined with great care in loading and unloading their cargoes, they and the Norwegians have become the favourite carriers with merchants of all nations. This pre-

Statistics. ference is not to be attributed to a lower rate of freight although they offer that advantage also; but to the confidence reposed in the zeal and intelligence of the masters and crews of those vessels." "The general foreign commerce of Sweden attained an extent during the year 1854 to which it had never reached before, the amount of imports and exports having exceeded that of the preceding year by about 50 per cent., while it more than doubled the average amount of the five previous years. The value of goods exported in 1854 exceeds that of the imports by L.887,166; while, on the other hand, the value of bullion imported into the country exceeds that of the export to an almost equal amount, viz., L.856,083. This unusual circumstance is chiefly caused by the increased exportation of grain. After deducting the importations in 1854, the whole export of wheat, barley, rye, oats, and peas amounted to L.666,666." In 1856 the total imports from foreign countries amounted (as already stated) to L.5,880,250, and the exports to L.5,135,166, a marked contrast to 1846, when the total imports from foreign countries were L.1,717,000, and the exports L.2,073,000. During the last four years very considerable steps have been taken in the direction of free trade, especially as regards the principal object of Swedish industry, iron and steel, upon the export and import of which heavy restrictions were imposed previously to 1856. The commerce and industry of Sweden, during the years 1857 and 1858, were, as might have been supposed, considerably affected by the monetary crisis which prevailed in Europe and America. The following table shows the amount of trade carried on by Sweden with foreign countries during 1857:—

Countries.	Entered.		Left.		Value.	
	Vessels.	Tonnage.	Vessels.	Tonnage.	Imports.	Exports.
					L.	L.
Norway	812	40,004	571	21,166	491,750	147,250

The foreign trade is principally confined to the ports of Stockholm and Gottenburg.

The following table gives the principal exports from the Swedish ports during each of the years ending November 1856, 1857, and 1858:—

Articles.	1856.	1857.	1858.
Bar iron (tons)	83,280	85,556	59,449
Wrought iron ,,	2,540	2,397	2,405
Other metals ,,	3,515	5,140	7,203
Beams and spars (pieces)	596,556	632,990	544,252
Deals and planks (doz.)	1,014,637	1,129,285	943,892
Deal and batten ends ,,	146,942	148,456	94,448
Masts and poles ,,	12,236	15,646	14,188
Grain of all kinds (qrs.)	355,563	309,784	546,736
Tar (gals.)	1,464,787	1,043,252	860,623

The trade of Sweden with the United Kingdom has within the last few years been rapidly increasing. The following remarks from the report already quoted bear upon the year 1854—"The value of the import trade, which in 1845 amounted to L.200,916 and in 1850 increased to L.277,666, has since risen without interruption. No preceding year however shows so important an increase as that of 1854, when the value of the imports, which in 1853 amounted to L.472,750, rose to L.772,000, in consequence of the increased importation of almost every article. The most remarkable increase is to be observed in the importation of cotton yarn, which more than doubled that of any preceding year. The importation of coal has increased by nearly three hundred per cent. during the last ten years, and the importation of raw cotton from Great Britain, which in the year 1850 amounted to 1,649,160 lbs., had risen in 1854 to 6,675,915 lbs. The value of the exports to Great Britain, which in 1853 amounted to L.1,182,166 (exclusive of the silver coin which was sent to England in that year), rose in 1854 to L.1,924,416, or nearly as much as the whole exports of Sweden in the year 1845. This important increase is chiefly attributable to the unusually great exportation of grain, which amounted to 244,040 quarters, or 131,495 more than the exportation of the preceding year, as well as to the high prices obtained for grain. The export of timber and tar was also much greater in 1854 than in any former year." The following tables give the value of the principal articles of commerce between Sweden and the United Kingdom:—

Exports.

Roads.

The internal commerce of Sweden is very considerable, and enjoys several advantages. The roads throughout the country are generally good, and for four or five months in the year the whole country is covered with snow, which renders the conveyance of goods by sledges easy and expeditious. The great extent of sea-coast also affords great facilities for internal trade as there are few provinces that are not washed by the sea. The most important canal of Sweden is the Gotha canal which connects the Cattegat and Baltic, and was completed in 1832. It traverses Lakes Wener and Wetter, and has a total length of 260 miles. Another canal connects the river Arboga, which flows into Lake Mälar, with Lake Hielmar. The Södertelge Canal connects Lake Mälar with the Baltic, while the Strömsholms canal unites it with the mineral region of Dalecarlia, terminating in Lake Barken. On this lake is situated the town of Smedjebacken, which is almost entirely composed of forges and ironworks. The first railway constructed in Sweden—that between Nora and Orebro, 23 miles in length—was opened on 5th March 1856, and since that time several others have been opened or are in course of construction. A branch line from Dylta, on the Orebro-Nora line, 12 miles long, connects these towns with Arboga, and a short line connects the two towns of Malmö and Lund. A line between Stockholm and Gottenburg is in course of formation, and is open for traffic from Gottenburg to Toreboda, a distance of about 113 miles. The railway between Gefle and Falun is nearly completed, and is open for traffic for two-thirds of its length.

Canals.

Railways.

Inhabitants.

The inhabitants of Sweden are Swedes, Fins, and Laplanders. The Swedes are a branch of the same family as the Danes and Norwegians, and speak a dialect of the same language, considerably modified, however, in consequence of the long political separation and international enmity of the two nations. Books are translated from the one language to the other, but the language of the peasantry in Norway and Sweden does not differ more than broad Scotch and Cockney English. The roots of the words, construction and idioms, are the same in both, or have a common origin. The Fins are supposed to have at one time occupied the whole country, and to have been driven to the forests and fastnesses of the North by an irruption of Goths some centuries before our era. They are now few in number, and are to be found as colonists, here and there, in some of the northern provinces. The Laps also inhabit the north, but they are said not to amount to more than 4000.

In 1751, the population of Sweden amounted to 1,785,727; in 1800, it was 2,347,303; in 1830, 2,888,082; and in 1850, 3,482,541. Sweden is divided into three large districts, viz., Norrland in the north, Swealand or Sweden Proper in the centre, and Götaland or Gothland in the south; and into 24 läns or provinces, which with their areas and populations at the end of 1850 and 1855 were as follows:—

Läns.	Area in English square miles.	Population.		Chief Towns.	Population.
		1850.	1855.		1855.

Most of these läns have other names, as Westeras, Westmanland; Nyköping, Södermanland; Carlstadt, Wermland; Fahlun, Kopparberg; Halmstads, Halland; Carlskrona, Blekinge; Wexio, Kronsberg; Lynkoping, Östergothland; Mariestad, Skaraborg; Wenersborg, Elfaborg; Wisby, Gottland; Hernosand, Westernorrland; Ostersund, Jemtland; Umea, Westerbottens; Pitea, Norrbotens. The following are the other towns having in 1855 more than 2000 inhabitants:—Eshilstuna (4031) in the län of Nyköping; Norrkoping (17,116) and Wadstena (2236) in Lynköping; Westervik (5038) in Calmar; Carlshamn (5214) in Carlscrona; Lund (7254), Ystadt (5056), Landscrona (4833), and Helsingborg (4473) in Malmö; Warberg (2360) in Halmstadt; Uddewalla (3859) in Gottenburg; Boras (2815) in Wenersborg; Lidköping (2883), and Skara (2096) in Mariestadt; Christinshamn (2002) in Carlstadt; Sala (3308) and Arboga (2387) in Westeras; Hudiksvall (2266) and Söderhamn (2183) in Gefleborg; and Sundsvall (3661) in Hernosand. At the beginning of 1859 Stockholm had 101,502 inhabitants, Gottenburg 30,576, Norrkoping 18,062, Malmö 16,823, and Carlscrona 14,513. The population of the 90 towns of Sweden had increased from 378,394 in the end of 1855 to 398,142 in the beginning of 1859. In 1855, the male population was 1,764,118, the female 1,875,214; in 1850, males 1,687,248, females, 1,795,293. Of the male population in 1850, 10,074 were engaged in trade and commerce; 12,566 in the merchant service; 37,808 in manufactures; 55,465 in arts and handicrafts; 40,514 in the army and navy; 8917 landed proprietors; 166,308 owners and cultivators of land; 40,621 tenants; 96,810 peasants on private land; 17,026 peasants on crown land; 80,215 able-bodied cottagers, &c.; 832,145 sons of peasants, labourers, &c., above 10 years of age; 2664 gardeners, &c.; 3430 islanders and fishermen; 25,232 domestic servants; 5530 clergymen, professors, and masters of universities and public schools.

Classes.

The people of Sweden are divided into four classes—the nobility, clergy, burghers, and peasants. The aristocracy of Sweden is among the oldest in Europe, and consists of about 2400 families, numbering in all about 11,000 persons of both sexes. They at one time exercised

Nobles.

Statistics. great power and possessed a fifth part of the kingdom, but now their landed possessions are estimated at under L.6,000,000, which gives an average of less than L.2500 to each family. Hence many of this class are very poor; yet so great is their pride and so absurd are their notions as to what may compromise their personal dignity, that as a class they repudiate all commercial or industrial pursuits, and prefer remaining in a state of penury rather than make an effort to relieve themselves by means which their false ideas proclaim to be derogatory. Every office in the state, about the court, and in the army, is eagerly sought for by the aristocracy, while appointments that require any deep knowledge of the sciences, or demand profound study, are generally left to those of more plebeian birth. Not that this arises from any want of capacity in the higher ranks, but from their strict adherence to the rules and traditions of caste.

Clergy. Next in order after the nobility is the clergy, at the head of whom is the archbishop of Upsala; besides whom there are eleven bishops. There are in all nearly 1300 beneficed clergymen, while about 1900 more are attached to the universities and other educational establishments, or are not invested with full pastoral charges, the whole with their families amounting to about 15,000 persons male and female. The fixed revenues of the church are derived from property valued at about L.85,000; but independent of this, the clergy receive incomes from tithes, official grants, and some casual sources which produce sufficient funds to give a comfortable and even liberal stipend to every incumbent. The established religion is Lutheran, and the clergy as a whole, are a highly educated, intelligent, and respectable body of men. Charges of immorality are seldom brought against them, and even complaints of laxity of principle are not frequent. They conscientiously discharge the routine duties of their office, but they possess little of that true spirit of Christianity by which alone the preaching of the gospel can be made effectual. Baptism and confirmation are indispensable to the holding of any office, or even to the possession of civil rights. A Swede cannot marry before being confirmed; neither can he take oath as a witness in any court. Hence it is that the sacred ordinances of religion have come to be generally regarded as mere forms, necessary to the enjoyment of certain privileges, and true religious feeling and pure morality are at a very low ebb. A religious spirit, however, has been manifesting itself lately in certain parts of Sweden; and a dissenting sect known as Läsere or readers, from their reading the Scriptures, are becoming numerous, especially in the north. They meet with great opposition from the clergy, for though Protestant, the Established Church in Sweden is an eminently persecuting church, and as such is supported by the civil laws. The exercise of other religious worships is indeed permitted under certain restrictions, but no one but a member of that church can hold any office, and dissenters are debarred from the enjoyment of many privileges; while every proselyte from the national creed is subject to fine, imprisonment, confiscation of property, and even to banishment. In 1856, certain proposals were laid before the diet in the royal speech, for the purpose of granting some degree of toleration to other sects, and in particular for the abrogation of the punishment of banishment for apostacy; but such was the influence of the clergy that the measure was negatived in the houses of assembly. The archbishop and bishops are nominated by the king from a list of candidates presented to him by each diocese. Literary, scientific, or administrative talents are qualifications quite as likely to assist their possessor to a bishopric as any amount of piety or deep theological lore. The Swedish clergy possess an unlimited control over the national education of the country which is under the immediate direction of each diocesan consistory, a body invested with considerable powers, composed of the principal clergy, and presided over by the bishop. It appoints all schoolmasters, disposes of many clerical offices, and presents pastors to nearly all the livings not in the royal gift. It also unites judiciary with administrative powers, judging in all causes relating to the spiritual concerns of the church, or education, adjudicating in cases where the clergy are guilty of any dereliction in their ecclesiastical duties, and deciding in complaints against the parochial assemblies.

Burgesses. The third class is the burgesses, in which there are about 70,000 persons of both sexes possessing real property to the amount of about L.3,000,000. They are members of guilds or handicrafts in the cities, or iron manufacturers, or have been in the magistracy. The privileges secured to this class have acted very injuriously upon the industry and trade of the country. Connected with every trade or craft is a guild or corporation, the members of which are by law secured in the possession of certain important rights and privileges. The fourth order, that of peasants, comprises in all about 2,250,000 persons, and possesses landed property to the value of about L.15,000,000.

Peasants. These peasants are a well-educated, intelligent, prudent, and industrious class of people. They are all land-owners, and by their wealth they are gradually absorbing much of the land that is passing from the hands of the nobility. It is calculated that between 1831 and 1841 land to the value of L.1,500,000 was sold or mortgaged from the demesnes of the Swedish nobility.

Besides these four orders there are upwards of 1,200,000 persons in Sweden without any representatives in the legislature. These consist chiefly of the labouring population, but they also include a numerous body possessing considerable landed and personal property, members of the learned professions, distinguished literary and scientific men, and others who have amassed fortunes by their talents and industry. (See *Danes and Swedes*, by C. H. Scott, London, 1856; from which work we have principally derived the preceding account of the several classes of the people.)

The Diet. The diet or parliament of the kingdom is composed of representatives of each of the four orders. The chief of every noble family has by right a seat in the diet, and has even the power of appointing a substitute in case of non-attendance. Usually, however, not more than 400 attend the meetings of the diet. This arises partly from the inability of many of them to bear the expenses; and also from a feeling of pride which leads them to abstain from taking a part in public affairs. The clerical order is represented at the diet by 72 members, of whom the archbishop of Upsala, the eleven bishops, and the *pastor primarius* of Stockholm, are *ex officio* members, the others being elected by and from the clergy of the dioceses. Among these are included a certain number of lay professors from the universities and the academy of sciences; but those from the last must be neither of noble blood nor hold any but purely civil rank. The clergy are the most independent and influential of the four estates, and hence they exercise a great influence over the proceedings of the diet. The burgesses rank as the third order, and elect 102 representatives to the diet. To be eligible for election the candidate must belong to the order of burgesses, be twenty-five years of age, and profess the Lutheran faith. The peasants, or fourth order, are represented at the diet by 150 members. The diet assembles at Stockholm every fifth year, and usually sits for three or four months. The representatives of each of the three lower orders are paid by their constituents during the sitting of the diet. Each body assembles separately for discussion and deliberation, and an ordinary measure is carried if three out of the four orders pass it; but all constitutional questions must receive the sanction of the whole. When a measure is supported or opposed by two of the orders, it is either dropped or submitted for decision to a committee composed of an equal number of members from each order. The king nominates the presi-

Statistics. dent of each of the three orders of nobles, burghers, and peasants, and possesses an absolute veto on all decrees affecting the constitution passed by the diet; but has no controlling power over their deliberations. He has the right to introduce measures for their consideration, but cannot impose new taxes nor contract loans without their sanction.

Government. The government is a hereditary monarchy in the male line. The council of state is nominated by the king, and is composed of ten members, including a minister of justice, a minister of foreign affairs, and the heads of each of the departments of finance, the interior, marine, ecclesiastical affairs, and war. The king cannot decide in any matter of government without consulting the council, except in such as refer to military or diplomatic affairs. The king is Commander-in-Chief of the Forces by land and sea, but no requisition of men or money can be made for purposes of war without the full consent of parliament. Careful provision is made for the impeachment of the Council of State if they are found to have counselled the king to unconstitutional measures, or have themselves transgressed the laws of the kingdom. The liberty of the press is one of the fundamental provisions of the constitution.

The 24 läns of Sweden are subdivided into 117 *faegderier*, or districts, each comprising one or more *härader*, or cantons. At the head of each län is a governor, who is charged with its civil and military jurisdiction and the receipt of the revenue. Every canton is under the superintendence of an executive officer. There are 264 harad courts, or courts of original jurisdiction, with a judge presiding over each. These courts sit three times a year, and 12 peasants are elected by the peasantry of each härad to serve as jurymen for two years. There are three royal judicial courts, viz., at Stockholm, Jönkopping, and Christianstad. The supreme court of justice, or final court of review, is composed of 12 councillors, and presided over by the chancellor of justice.

Education. Elementary instruction is very generally diffused in Sweden. It is reckoned that of the whole population, even including the Laps, the proportion of grown-up persons unable to read is less than one in a thousand. Parents in even the humblest circumstances are able to give instruction to their children in reading and writing; and every adult must give proof of ability to read before he can exercise any act of majority. This general diffusion of elementary instruction is ascribed to the zeal of Gustavus Vasa (1523-1560) and his immediate successors. John III., in 1574, ordered that any nobleman having no knowledge of book-learning should forfeit his nobility. Charles XI., in 1684, required the clergy to have every Swedish subject taught to read, and decreed that no marriage should be celebrated unless the parties had previously taken the Lord's Supper; and that none should be allowed to communicate who could not read and was not instructed in religion. In 1842 a law was passed commanding the erection of a school in each parish; but owing to the sparseness of the population, this was found to be in many cases impracticable, and hence the necessity in many parts for ambulatory schools. According to the census of 1850, there were 143,526 children receiving instruction at the parochial schools; 126,178 at ambulatory schools; 6228 at public schools; 17,465 at private schools, and 128,996 at home; making in all 422,393 children receiving instruction. There are also in most of the towns gymnasia or grammar schools for preparing students for the universities. In 1856 a new law was promulgated, with the view of establishing an efficient system of secondary education. At Stockholm and Gottenburg there are normal schools for the training of teachers. There are two universities in the country, those of Upsala and Lund. The Upsala university was founded in 1477 by Sten Sture the elder. It received its greatest endowments from Gustavus Adolphus, and has continued to be the leading university in Sweden. It has faculties of philosophy, law, medicine, and theology; and in 1859 had 31 professors and 1451 students. The annual expenditure is about L.17,500. The Lund university was founded in 1668, and has also four faculties. The number of students in 1859 was 610; professors, 28; substitutes, 18. The annual expenditure is about L.14,300. Every one, before entering the church or practising either law or medicine, is compelled to take his degree; while candidates for many government offices are required to take degrees in philosophy previous to entering upon a particular study of the sciences necessary to a proper fulfilment of their duties. The examinations are all of a high standard, and well adapted to test the qualifications of the individuals submitted to them.

Crime. The prevalence of immorality and crime in a country like Sweden is not a little remarkable. The general diffusion of education and religious instruction, and the pursuits of the people being chiefly agricultural, would lead one to expect a low rate of crime. Such, however, is very far from being the case. In 1835 the number of persons prosecuted for criminal offences was 26,275, of whom 21,262 were convicted, 4915 acquitted, and 42 under examination; there being thus 1 prosecution for every 114 of the population, and 1 conviction for every 140. The number of prisoners in Stockholm in 1850 was 3394, or 1 to 28 of the population; while in the whole of Sweden the proportion of prisoners was 1 to 261 of the population. This high rate is doubtless in some measure to be accounted for from certain peculiarities in its criminal code. Thus there are many offences of a very venial kind, which cannot with any propriety be called crimes, considered and punished as such in Sweden; but even after making every allowance for such cases, there still remains enough to show that crime in Sweden is unusually high. Illegitimacy is very prevalent in Sweden, especially in Stockholm and the other towns. In Stockholm in 1850 the total births were 3190, of whom 1424, or nearly one-half, were illegitimate; in the other towns the total number of births were 7805, of whom 1538 were illegitimate; while in the country districts, of 99,404 births, only 7358 were illegitimate; making for the whole country a total of 100,079 legitimate, and 10,320 illegitimate.

Army. The Swedish army is composed of four different kinds of troops, viz., the enlisted or regular troops, the *indelta*, the Gothland militia, and the conscription. The regular troops (*värfrade*) amount to about 7692 men, of whom nearly two-thirds are artillery and 1000 cavalry. They usually serve for six years. The *indelta* is composed of men furnished and supported by the landed proprietors. Every holder of a certain amount of crown-land is bound to provide a man, to whom he assigns a croft of land with a cottage, and pays a small annual money allowance. The croft is cultivated by the soldier himself while at home, and during his absence on service by the landholder for his behoof. Once a year during four weeks they are called out for drill. They are retained as long as they are considered fit for service. This force numbers about 33,400 men. The Gothland militia is specially for the defence of that island, and amounts to about 7620 men. The conscription or militia is composed of males between the ages of 20 and 25, all of whom are bound to serve or procure substitutes. They are assembled once a year for drill and exercise, and amount to about 95,000 men. The total force amounts to 144,000 men, besides officers.

Navy. The navy of Sweden consists of 10 ships of the line, 6 frigates, 4 corvettes, 4 brigs, 9 steam-corvettes, 20 war schooners, 77 large and 122 smaller gun-boats, with other crafts, making in all 897 vessels of all kinds. The permanent seamen at command of the government amount to about 8000. They are maintained in the same manner as the

indelta troops, by assignments of land. Including conscripts, the whole naval force may be raised to about 24,000 men.

Revenue. The revenue for each of the three years ending 1860 was estimated at L.1,450,670, of which L.449,140 was from land-tax and other perpetual revenues, and L.1,001,530 from customs, stamps, and other taxes voted at every diet. The ordinary expenditure for each of these years was estimated at L.1,397,726; but besides this there was an extraordinary expenditure extending over the three years of L.1,462,927, which was to be met by reserved funds and others, estimated to amount to L.1,573,609. (D. K.)

SWEDENBORG, Emanuel, was born at Stockholm, in Sweden, in January 1689. His father was bishop of Skara in West Gothland; member of a society for the propagation of the Gospel, formed on the plan of that of England; and president of the Swedish Church in Pennsylvania and London. To this last office he was appointed by Charles XII. who seems to have had a great regard for the bishop, and to have continued that regard to his son. Of the course of young Swedenborg's education we have procured no account; but from the character of the father, it may be supposed to have been pious; and by his appearing with reputation as an author when but twenty years of age, it is proved to have been successful. His first work was published in 1709; and the year following he sent into the world a collection of pieces on different subjects, in Latin verse, under the title of *Ludus Heliconius, sive Carmina Miscellanea quæ variis in locis cecinit.* The same year he began his travels, first into England, afterwards into Holland, France, and Germany, and returning to Stockholm in 1714, he was two years afterwards appointed to the office of assessor in the Metallic College by Charles XII., who honoured him with frequent conversations, and bestowed upon him a large share of his favour. At this period of his life Swedenborg devoted his attention principally to physic and mathematical studies; and in 1718 he accompanied the king to the siege of Frederickshall, where he gave an eminent proof that he had not studied in vain. Charles could not send his heavy artillery to Frederickshall, from the badness of the roads, which were then rendered much worse than usual by being deeply covered with snow. In this extremity Swedenborg brought the sciences to the aid of valour. By the help of proper instruments he cut through the mountains and raised the valleys which separated Sweden from Norway, and then sent to his master two galleys, five large boats, and a sloop, loaded with battering pieces, to be employed in the siege. The length of this canal was about 2½ miles. The execution of this great work, however, did not occupy all his time. In 1716 he had begun to publish essays and observations on the mathematical and physical sciences, under the title of *Dædalus Hyperboreus;* and he found leisure during the siege to complete his intended collection, and also in the same year to publish an introduction to algebra, under the whimsical title of the *Art of the Rules.*

At the siege of Frederickshall he lost his royal patron; but he found another in Ulrica Eleonora, the sister and successor of that hero, by whom, in 1719, he was created a baron. His promotion did not lessen his ardour for the sciences; for he published in the same year *A Method to fix the Value of Money, and to determine the Swedish Measures in such a way as to suppress all the Fractions and facilitate the Calculations.* About the same time he gave the public a treatise on *The Position and Course of the Planets;* with another on *The Height of the Tides, and Flux and Reflux of the Sea;* which, from information gathered in different parts of Sweden, appeared to have been greater formerly than when he wrote.

As Swedenborg continued, under the new sovereign, to hold the office of assessor to the Metallic College, he thought it necessary, for the discharge of his duty, to make a second journey into foreign countries, that he might himself examine their mines, particularly those of Saxony and Harts. During these travels, which were undertaken for the improvement of the manufactures of his native country, he printed at Amsterdam *Prodromus Principiorum Naturalium sive novorum Tentaminum Chemiam et Physicam experimentalem geometrice explicandi; Nova Observata et Inventa circa Ferrum et Ignem, præcipue Naturam Ignis elementarem, una cum nova Camini Inventione; Methodus nova inveniendi Longitudines Locorum terra marique ope Lunæ; Modus construendi Receptacula Navalia vulgo en Dockybynadder; Nova Constructio Aggeris Aquatici; Modus explorandi Virtutes Navigiorum;* and at Leipzig and Hamburg, *Miscellanea Observata circa Res Naturales, præsertim Mineralia, Ignem, et Montium Strata.* This journey was made, and these tracts published, in the compass of a year and a half; and perhaps there has not been another man, Linnæus excepted, who has done so much in so short a time. After his return in 1722, Swedenborg divided his time so equally between the duties of his office and his private studies, that in 1733 he finished his grand work, entitled *Opera Philosophica et Mineralia* and had it printed under his own direction in 1734, partly at Dresden and partly at Leipzig. During the same year he also went to inspect the mines of Austria and Hungary. The work is divided into three volumes folio. The title of the first is *Principia Rerum Naturalium, sive novorum Tentaminum Phænomena Mundi elementaris philosophice explicandi;* of the second, *Regnum Subterraneum, sive Minerale de Ferro;* and the third, *Regnum Subterraneum, sive Minerale de Cupro et Orichalco.* The whole is written with great strength of judgment; and the work is ornamented with plates to facilitate the comprehension of the text.

In the year 1729 he was enrolled among the members of the Society of Sciences at Upsala, and was, probably about the same time, made a fellow of the Royal Academy of Sciences at Stockholm; nor were strangers less willing than his own countrymen to acknowledge the greatness of his merit. Wolfius, with many other learned foreigners, was eager to court his correspondence. The Academy of St Petersburg sent him, on the 17th of December 1734, a diploma of association as a corresponding member; and soon afterwards the editors of the *Acta Eruditorum,* published at Leipzig, recognised in his works some acceptable contributions to useful knowledge.

By many persons the approbation of learned academies would have been highly valued, but by Baron Swedenborg it was considered as of very little importance. "Whatever of worldly honour and advantage may appear to be in the things before mentioned, I hold them," says he, "but as matters of low estimation, when compared to the honour of that holy office to which the Lord himself hath called me, who was graciously pleased to manifest himself to me, his unworthy servant, in a personal appearance, in the year 1743, to open in me a sight of the spiritual world, and to enable me to converse with spirits and angels; and this privilege has continued with me to this day. From that time I began to print and publish various unknown *Arcana,* which have been either seen by me or revealed to me, concerning heaven and hell, the state of men after death, the true worship of God, the spiritual sense of the Scriptures, and many other important truths tending to salvation and true wisdom. (*Short Account of the Hon. E. Swedenborg.*)

Swedenborgians.

After this extraordinary call, Swedenborg dedicated himself wholly to the great work which, he supposed, was assigned him, studying diligently the Word of God, and from time to time publishing to his fellow-creatures such important information as was made known to him concerning another world. Among his various discoveries concerning the spiritual world, one is, that it exists not in space. "Of this," says he, "I was convinced, because I could there see Africans and Indians very near me, although they are so many miles distant here on earth; nay, that I could be made present with the inhabitants of other planets in our system, and also with the inhabitants of planets that are in other worlds, and revolve about other suns. By virtue of such presence, I have conversed with apostles, departed popes, emperors, and kings; with the late reformers of the church, Luther, Calvin, and Melanchthon, and with others from distant countries." (Swedenborg's *Universal Theology*, vol. i. p. 87.) Notwithstanding the want of space in the spiritual world, he tell us, "that after death a man is so little changed that he even does not know but he is living in the present world; that he eats and drinks, and even enjoys conjugal delight, as in this world; that the resemblance between the two worlds is so great, that in the spiritual world there are cities, with palaces, and houses, and also writings and books, employments and merchandises; that there are gold, silver, and precious stones there." "In a word," he says, "there is in the spiritual world all and everything that there is in the natural world, but that in heaven such things are in an infinitely more perfect state. Such was his zeal in the propagation of these peculiar doctrines, that he frequently left his native country to visit distant cities, particularly London and Amsterdam, where all his theological works were printed at great expense, and with little prospect or probability of a reimbursement. "Wherever he resided when on his travels, he was," says one of his admirers, "a mere solitary, and almost inaccessible, though in his own country of a free and open behaviour. He affected no honour, but declined it; pursued no worldly interest, but spent his time in travelling and printing, in order to communicate instruction and benefit to mankind. He had nothing of the precise in his manner, nothing of melancholy in his temper, and nothing in the least bordering on enthusiasm in his conversation or writings." He died at London, March 29, in the year 1772; and after lying in state, his remains were deposited in a vault at the Swedish church, near Radcliff-Highway.

SWEDENBORGIANS. Among the first disciples of the Swedenborgian faith were two clergymen of the Church of England, the Rev. Thomas Hartley, who translated the work on *Heaven and Hell;* and the Rev. John Clowes, translator of the *Arcana Cœlestia.* In December 1783, eleven years after Swedenborg's decease, an advertisement brought 5 persons to meet together for reading and conversation, which number had increased to 30 in 1787. About this time the formation of a definite religious society was commenced; provision was made for public worship; and a system of ministerial ordination was adopted. At the fifteenth conference, held in Manchester in August 1822, there were 8 ministers and 37 delegates, representing 24 congregations. At the census of 1851, the number of congregations was ascertained to be 50, of which the greater number were in Lancashire and Yorkshire. It is considered, however, by members of the body, that the mere number of their chapels gives a very inadequate idea of the prevalence of their opinions; many, they say, ostensibly connected with other churches, entertain the prominent doctrines of the New Church. The principal societies for disseminating the doctrines of the New Church in England are, the "Swedenborg Printing Society," established in 1810, and the "Missionary and Tract Society," established in 1821.

The doctrines held by the New Church of Emmanuel Swedenborg will be seen from the following "Articles of Faith." These were not written by Swedenborg, but were drawn up by order of the Annual Conference of Ministers and Laymen, by whom the affairs of the body, as at present constituted, are managed.

Swedenborgians.

"The Articles of Faith of the New Church, signified by the New Jerusalem in the Revelation, are these:—

"1. That Jehovah God, the Creator and Preserver of heaven and earth, is Love itself and Wisdom itself, or Good itself and Truth itself; that He is One both in Essence and in Person, in whom, nevertheless, is the Divine Trinity of Father, Son, and Holy Spirit, which are the Essential Divinity, the Divine Humanity, and the Divine Proceeding, answering to the soul, the body, and the operative energy in man; and that the Lord and Saviour Jesus Christ is that God.

"2. That Jehovah God himself descended from heaven as Divine Truth, which is the Word, and took upon him human nature, for the purpose of removing from man the powers of hell, and restoring to order all things in the spiritual world, and all things in the Church; that He removed from man the powers of hell, by combats against and victories over them, in which consisted the great work of redemption; that by the same acts which were His temptations, the last of which was the passion of the cross, He united in His humanity, Divine Truth to Divine Good, or Divine Wisdom to Divine Love, and so returned into His divinity, in which He was from eternity, together with and in His glorified humanity; whence He for ever keeps the infernal powers in subjection to Himself; and that all who believe in Him, with the understanding from the heart, and live accordingly, will be saved.

"3. That the Sacred Scripture, or Word of God, is Divine Truth itself, containing a spiritual sense heretofore unknown, whence it is divinely inspired, and holy in every syllable; as well as a literal sense, which is the basis of its spiritual sense, and in which Divine Truth is in its fulness, its sanctity, and its power; thus, that it is accommodated to the apprehension both of angels and men; that the spiritual and natural senses are united by correspondences, like soul and body, every natural expression and image answering to and including a spiritual and divine idea; and thus that the Word is the medium of communication with heaven, and of conjunction with the Lord.

"4. That the government of the Lord's Divine Love and Wisdom is the Divine Providence, which is universal, exercised according to certain fixed laws of order, and extending to the minutest particulars of the life of all men, both of the good and of the evil; that in all its operations it hath respect to what is infinite and eternal, and makes no account of things transitory, but as they are subservient to eternal ends; thus, that it mainly consists with man in the connection of things temporal with things eternal; for that the continual aim of the Lord, by His Divine Providence, is to join man to Himself, and Himself to man, that He may be able to give him the felicities of eternal life; and that the laws of permission are also laws of the Divine Providence, since evil cannot be prevented without destroying the nature of man as an accountable agent; and because, also, it cannot be removed unless it be known, and cannot be known unless it appear; thus, that no evil is permitted but to prevent a greater; and all is overruled by the Lord's Divine Providence for the greatest possible good.

"5. That man is not life, but is only a recipient of life from the Lord, who, as He is Love itself and Wisdom itself, is also Life itself; which life is communicated by influx to all in the spiritual world, whether belonging to heaven or hell, and to all in the natural world, but is received differently by every one, according to his quality, and consequent state of his reception.

"6. That man, during his abode in the world, is, as to his spirit, in the midst between heaven and hell, acted upon by influences from both, and thus is kept in a state of spiritual equilibrium between good and evil; in consequence of which he enjoys freewill, or freedom of choice, in spiritual things as well as in natural, and possesses the capacity of either turning himself to the Lord and His kingdom, or turning himself away from the Lord, and connecting himself with the kingdom of darkness; and that, unless man had such freedom of choice, the Word would be of no use; the Church would be a mere name; man would possess nothing by virtue of which he could be conjoined to the Lord, and the cause of evil would be chargeable on God himself.

"7. That man at this day is born into evil of all kinds, or with tendencies towards it; that therefore, in order to his entering the kingdom of heaven, he must be regenerated or created anew; which great work is effected in a progressive manner, by the Lord alone, by charity and faith as mediums during man's co-operation; that as all men are redeemed, all are capable of being regenerated, and consequently saved, every one according to his state; and

that the regenerate man is in communion with the angels of heaven, and the unregenerate with the spirits of hell; but that no one is condemned for hereditary evil, any further than as he makes it his own by actual life; whence all who die in infancy are saved, special means being provided by the Lord in the other life for that purpose.

"8. That repentance is the first beginning of the Church in man; and that it consists in a man's examining himself both in regard to his deeds and his intentions, in knowing and acknowledging his sins, confessing them before the Lord, supplicating Him for aid, and beginning a new life; that to this end, all evils, whether of affection, of thought, or of life, are to be abhorred and shunned as sins against God, and because they proceed from internal spirits, who in the aggregate are called the Devil and Satan; and that good affections, good thoughts, and good actions are to be cherished and performed, because they are of God and from God; that these things are to be done by man as of himself; nevertheless, under the acknowledgment and belief that it is from the Lord, operating in him and by him; that so far as man shuns evils as sins, so far they are removed, remitted, or forgiven; so far also he does good, not from himself but from the Lord; and in the same degree he loves truth, hath faith, and is a spiritual man; and that the Decalogue teaches what evils are sins.

"9. That Charity, Faith, and Good Works are unitedly necessary to man's salvation; since charity without faith is not spiritual but natural, and faith without charity is not living but dead, and both charity and faith without good works are merely mental and perishable things, because without use or fixedness; and that nothing of faith, of charity, or of good works, is of man, but that all is of the Lord, and all the merit is His alone.

"10. That Baptism and the Holy Supper are sacraments of Divine institution, and are to be permanently observed,—baptism being an external medium of introduction into the Church, and a sign representative of man's purification and regeneration, and the Holy Supper being an external medium of those who receive it worthily, of introduction as to spirit into heaven, and of conjunction with the Lord; of which also it is a sign and seal.

"11. That immediately after death, which is only a putting off of the material body, never to be resumed, man rises again in a spiritual or substantial body, in which he continues to live to eternity; in heaven if his ruling affections, and thence his life, have been good; and in hell if his ruling affections, and thence his life, have been evil.

"12. That *now* is the time of the Second Advent of the Lord, which is a coming not in Person, but in the power and glory of his Holy Word. That it is attended, like His first coming, with the restoration to order of all things in the spiritual world, where the wonderful Divine operation, commonly expected under the name of the last judgment, has in consequence been performed; and with the preparing of the way for a New Church on the earth—the first Christian Church having spiritually come to its end or consummation through evils of life and errors of doctrine, as foretold by the Lord in the Gospels; and that this New or Second Christian Church, which will be the Crown of all churches, and will stand for ever, is what was representatively seen by John, when he beheld the holy city, New Jerusalem, descending from God out of heaven, prepared as a bride adorned for her husband."

In Sweden, Germany, France, America, and the British colonies, the faith of Swedenborg has taken partial root. Richer of Nantes has used his eloquence in favour of the new faith; Moet and Tulk have likewise translated Swedenborg into French. The greatest of his German followers is Dr Tafel, and the greatest of his English disciples is J. J. Garth Wilkinson.

SWEERTS, Jacques Thierri, a Dutch general, born at Gorcum in 1759. At an early age he entered the army, and in 1792 had risen to the rank of colonel. In the following year he served with distinction in the campaign between his country and France; but on the conquest of Holland and the flight of the stadtholder, to whom he was warmly attached, he left the service, and remained in retirement till 1813. On the retreat of the French from Holland, the provisional government raised Sweerts to the rank of general; and in that capacity he did much to bring about the restoration of the Orange family. William Frederick, on his accession, appointed him governor of the palace at the Hague, where he died in 1820.

SWIETAN, Gerard Van, an eminent Dutch physician, was born at Leyden in 1700. He studied at Louvain, and subsequently at Leyden, where he soon became the favourite pupil of Boërhaave. Having graduated in medicine, he was soon after appointed to a professorship, but objection was taken to his being a Roman Catholic, and he was forced to resign his claim. In 1745 he was chosen first physician to Maria Theresa of Austria, and he used all his influence for many years to improve the scientific standing of the city of Vienna. The work by which he is now chiefly know to physicians is his *Commentaria in Hermanii Boerhavii Aphorismos de cognoscendis et curandis morbis*, 5 vols. 4to, 1741–42. Swietan was created a baron of the empire of Austria by Maria Theresa. He died in 1772, and a statue has been erected to his memory in the hall of the University of Vienna.

SWIFT, Jonathan, D.D., Dean of St Patrick's, the most original writer of his own, and perhaps the greatest satirist of any age, was born in Hoey's Court, Dublin, November 30, 1667. Like Pope's, his family was of Yorkshire origin; in the time of Charles I. the representative of one branch had obtained a peerage which expired with him. The first of his own immediate ancestors known to us was a clergyman, rector of St Andrew's, Canterbury, from 1569 to 1592, whose son succeeded him in that living, and whose grandson was the Rev. Thomas Swift, vicar of Goodrich in Herefordshire, renowned for his eccentricity, his mechanical ingenuity, and above all for his stubborn devotion to Charles I., and the persecutions he underwent in consequence. Plundered thirty-six times, ultimately ejected from his living, he died in 1658, leaving his thirteen children a small and greatly impoverished landed estate, and the questionable advantage of a substantial claim on the gratitude of the restored sovereign. More fortunate than most who have kings for debtors, his eldest son Godwin soon obtained the Attorney-Generalship of the Palatinate of Tipperary. This piece of good fortune naturally attracted other members of the family across the channel,—among them Jonathan, one of the youngest of nine brothers, but already husband of Abigail Ericke of Leicester, a lady of descent more ancient and means more limited than his own. A student of law, but never called to the bar, Jonathan appears to have subsisted for some years on windfalls and casual employments. At length (1665) he became steward of the King's Inns (answering to the inns of court in England), an office of small emolument. Two years afterwards he died suddenly, leaving an infant daughter, and a widow pregnant with the future Dean of St Patrick's. So embarrassed had his circumstances been, that although considerable debts were owing to the estate, Mrs Swift was for the moment unable to defray the expense of his interment. Thus Swift's first experience of life was that of a dependant on the charity of his uncles, more particularly of Godwin. It is easy to conceive the effect of perpetual indigence and mendicancy on a spirit like his, and the inevitable bitterness of the situation was aggravated by the grudging manner in which the Tipperary official seemed to dole out his parsimonious help. In fact, the apparently prosperous relative was the victim of unfortunate speculations, and preferred the reproach of avarice to the acknowledgment of the humiliating truth. A virulent resentment became ingrained into the youth's whole nature, and though ultimately acquainted with the real state of the case, he never mentioned his uncle with kindness or respect. Other relatives did more to merit his regard. Yet he took no pride in his Irish connections or nativity, and a singular adventure in his infancy seems to have afforded him a pretext for insinuating that he was really born in England. When he was but two years old, his nurse, a native of Whitehaven, was recalled to that town by an illness in her family. So attached had she become to her charge, as to clandestinely carry him away with her. Mrs Swift was induced to consent to his remaining with her for a time, and the child spent three years in

Cumberland. By his return his education had made considerable progress, and in the next year he was sent to the grammar school at Kilkenny. There can be no question as to the author of *Gulliver* having been a remarkable child, but unfortunately only one anecdote of his school-days has been preserved. It is the story, graphically narrated by himself, of his having once invested the whole of his pocket-money in the purchase of an old horse condemned to the knacker's yard, his momentary triumph over his school-fellows, and his mortification on discovering the uselessness of his acquisition; an anecdote highly characteristic of his daring, pride, and ambition, and from which, instead of the moral he professed to discover, he might have derived an augury of the majestic failure of his life.

In his fifteenth year, and equipped, as is probable, with no more than the literary *supellex* usually brought away from a country grammar-school, Swift was matriculated at Trinity College, Dublin. The history of his residence there is the history of many another youth of parts, fallen upon an unpropitious era in the annals of learning, and restrained, by the very mental superiority which would have triumphed in any worthy competition, from contending for a garland of dead leaves. At that period, the logic of the schoolmen was the beginning, the middle, and the end of Dublin university education. Swift subsequently became as finished a classical scholar as an irregular training would allow; his understanding proved fully capable of apprehending the principles and the utility of those mathematical studies to which his taste by no means naturally inclined; but his reasoning powers must have been less remarkable than was the case, had they allowed him to fancy them assisted by the study actually enforced upon him. He might undoubtedly have accommodated himself to this had he so willed; a stronger proof of his contempt and distaste, therefore, could not well be produced than the ignorance which, on standing for his bachelorship in February 1686, he displayed of the very definition of a syllogism. The degree for some time withheld was at length conferred *speciali gratia*, and the mortifying record stands against his name to this day in the college books. This disgrace, never ascribed to incapacity by any reader of the Dean of St Patrick's, the college contemporaries of poor uncouth Jonathan Swift would have thought it absurd to attribute to any other cause. Swift doubtless incurred the contempt of the whole university; and it is in the ferocity of his wounded pride that we must seek the explanation of the irregularities which marked the latter part of his academical career. Within little more than two years after his humiliation, the future champion of establishments, civil and ecclesiastical, had undergone no fewer than twenty-two penalties for breaches of discipline, besides the degradation of a public apology to the junior dean, Dr Owen Lloyd. Barren as his residence was of university honours, it is by no means likely that his time elapsed in indolence, or that his freaks and irregularities absorbed the whole energy of his mind. His subsequent period of intense study will hardly account for the whole extent of desultory information evinced by his writings, and, if we can rely on a tradition referring the first draught of the *Tale of a Tub* to this epoch, it must be allowed that his mental powers were developed with a very unusual precocity.

In 1688 Swift quitted the university, and, after a brief residence with his mother at Leicester, entered the family of Sir William Temple as amanuensis, on a salary, it is said, of L.20 per annum. A distant relationship between his mother and Lady Temple appears to have recommended him to this post, which his pride must have struggled to accept, and which it hardly suffered him to retain. The relations of patron and dependent are at best delicate and precarious; and if Swift was of all men the first to wince under any slight offered to his dignity, the precise and finical Temple was of all the last to condescend to any abatement of his own. As minister and diplomatist, Temple had rendered great and durable services; if he afterwards abstained from public affairs, it was chiefly from a doubt whether his ungrateful country deserved salvation at such illustrious hands. If he solaced his voluntary ostracism by a comparison with the elegant retirement and lettered ease of Cicero, it did not therefore occur to him to compare his obscure Irish secretary with the Roman orator's amanuensis Tiro, who had, at least, invented short-hand. We who know that in the patron's place the dependent would have governed the nation, need not be surprised at finding, full twenty years afterwards, the iron of servitude still rankling in the latter's haughty soul. He nevertheless made himself useful to his employer, who on one occasion rendered him the medium of a confidential communication to King William, who had consulted Temple on the bill for triennial parliaments, then sanctioned by both branches of the legislature. Swift did his best to enforce Temple's arguments in favour of the measure, and was in after life wont to refer to the failure of his rhetoric as the most useful lesson his vanity had ever received. Struck, it would seem, rather by the physical than the mental endowments of the robust young Irishman, William offered him a troop of horse, a proposal which appears to have been subsequently commuted into a promise of church preferment. Swift had already proceeded to the degree of M.A. at Oxford, and the execution of his design to embrace the ecclesiastical profession was hastened by a quarrel with Temple, occasioned by the latter's reluctance to contract any definite engagement to provide for him. Throwing up his employment, he passed (1694) over into Ireland, but found his views impeded by the refusal of all the bishops to ordain him without some certificate of the regularity of his deportment while in Temple's family. Five months passed ere he could bring himself to solicit this favour from his old patron, which he ultimately did in a letter submissive in appearance, but charged to the full with smothered rage and intense humiliation. Forgiveness was easy to one in Temple's place and of Temple's disposition, and he not only despatched the requisite testimonials, but added a recommendation which obtained for Swift the living of Kilroot, in the diocese of Down and Connor. His residence here was not fated to be of long duration. Temple, who knew his value and had not parted with him willingly, soon let him understand that a return was open to him, and Swift, whose resentment was cooled by time and soothed by the discovery of his indispensableness, lent an unreluctant ear to the overture. He continued to reside with Sir William till the latter's death in 1698; nor does their intimacy appear to have been troubled by any further disagreement. A story representing his return from Ireland as a flight necessitated by a disgraceful action, has been fully exposed as a crazy calumny invented long after his death; another ascribing it to a generous relinquishment of his living in favour of a more needy clergyman, would seem, like more than one other tradition respecting him, to be less supported by any convincing testimony than by his Irish biographers' ideas of the abstract fitness of things.

Lord Macaulay has justly pointed out the familiarity with public affairs acquired by Swift at Moor Park as one main cause of his subsequent distinction as a politician, and here, too, he laid the foundation of his literary renown. Report asserts him to have read regularly for eight hours every day; and we have his own authority for his having, as early as 1691, "written and burned, and written again, more on all manner of subjects than perhaps any man in England." His fortitude was probably more commendable than his fecundity; at least the only relics of these early days belong to a species of composition in which he was little qualified to excel. Nature had denied him the poet's eye, the poet's

ear, and the poet's soul; nor would he, probably, have sought the laurel from a generation less hopelessly unfeeling, unimaginative, and unmusical. At a period, however, when the merit of the poet was rated by his intellectual vigour, Swift might climb without much fear of a fall. If his strains were no better poetry than the effusions of Pomfret and Stepney, they were at all events much better prose, and if tried simply by the standard of his other works, are frequently entitled to no inconsiderable praise. Some pieces, such as *Baucis and Philemon*, are models of easy familiar elegance; the conception of others is highly ingenious; another class, of which the *Petition to Harley* may be considered as the type, blend the grace of idyl with the grace of comedy. Nothing can be more perfect in its kind than the *Description of a City Shower*, unless it be the *Grand Dispute respecting Hamilton's Bawn;* and Swift's satirical and epigrammatical powers could only gain point by submitting to metrical restraint. Poetry worthy of the name he did not and could not write; and his only serious attempt in this direction—the luckless series of *Pindaric Odes*—is chiefly memorable for the severe and unforgiven remark it called forth from his kinsman Dryden—"Cousin Swift, you will never be a poet." Swift's first prose composition betrayed his resentment. In the *Battle of the Books*, a satirical contribution to the controversy on the *Letters of Phalaris*, written, or rather purloined from a French prototype, about 1697, his sarcasm for the first and last time recoiled upon himself. The satire against Dryden and Bentley wants, indeed, nothing but truth to be excellent; but the picture of the former in his monstrous helmet, and the latter in his patchwork mail, yield in ludicrousness to the idea of the author of the *Pindaric Odes* presuming to ridicule the author of *Absalom and Achitophel*, and the inglorious student of Trinity College, Dublin, entering the lists against the pride of Trinity College, Cambridge, on a question of classical scholarship. It is, however, to his credit that his learning was somewhat greater than that of any other writer on his side, and his pretensions incomparably less.

Swift's next literary labour, though accomplished with credit, proved less serviceable to his fortune than he had anticipated. This was his edition of Temple's posthumous works, a charge bequeathed to him as a valuable legacy. They appeared with a dedication to King William, which was to have made the editor a prebendary. A petition to this effect miscarried, as he always believed, through the negligence or ill-will of the nobleman who undertook to present it. He may have been mistaken, as William's esteem for Temple, notoriously not very great, still surpassed his regard for Swift and complimentary dedications. Be this as it may, he had become too important to be overlooked, and soon obtained the post of secretary and chaplain to Earl Berkeley, one of the Lords Justices of Ireland. The better half of this appointment, however, escaped him on his arrival in that country, his secretaryship being transferred to a Mr Bushe, on the pretext of the incompatibility of such a post with clerical functions. Bushe, indeed, seems to have been much better qualified to realise the popular ideal of a dispenser of official patronage; for when Lord Berkeley had at length an opportunity of recompensing Swift's disappointment by the gift of the deanery of Derry, the secretary's influence was successfully exerted in favour of another clergyman, who had gained his interest by the judicious outlay of a thousand pounds. With bitter indignation Swift threw up his chaplainship, but was ultimately reconciled to his patron by the presentation to the rectory of Agher, in Meath, with the united vicarages of Laracor and Rathbeggin. For the first time in his life he might now call himself his own master, and had an opportunity of exhibiting, free from suspicion of external constraint, that stern regard to duty which constituted the noblest and not the least prominent feature of his character. In an age of general laxity—in a priest of an alien church, whose most energetic servants commonly succumbed to the mortifying conviction of their uselessness, and the detestation they excited among the people for whom they laboured—the parishioners of Laracor found a clergyman more censurable for the ostentatious discharge than the easy neglect of his duty, and heard, or might have heard, service three times a week. The energy, however, which probably gained the respect, certainly failed to influence the convictions of his Catholic flock. We have his own authority for reckoning his average congregation at "half a score;" and on one occasion his clerk Roger was his only auditor. In fact, his exertions in the pulpit were more meritorious than his achievements; he entirely lacked the fire, the self-oblivion, the expansive geniality of the orator. He himself characterised his discourses as "pamphlets;" and if meant to imply their arid and argumentative character, the criticism is indisputably just. It must be added that they are no models for pamphleteers even, and his resolution to exchange theology for politics must appear fully justified on a comparison of these inconclusive essays with another performance of the same period. The *Discourse on the Dissensions in Athens and Rome*, written in the Whig interest, and intended as a dissuasive from the pending impeachment of Somers and three other noblemen, received the honour, extraordinary for the maiden attempt of a young politician, of being universally attributed to Somers himself, or to Burnet, the latter of whom found a public disavowal necessary. Three years later appeared a more remarkable work. Clearness, cogency, masculine simplicity of diction, are conspicuous in the pamphlet, but true creative power told the *Tale of a Tub*. "Good God! what a genius I had when I wrote that book!" was his own exclamation in his latter years. Johnson correctly signalises a distinction between the style of this and of his other humorous writings; at the same time, the difference lies rather in accidentals than essentials. Its merits and faults are the merits and faults of youth—the youth of a Titan, who extravagates and luxuriates in the wantonness of strength, and in careless magnificence showers away the energies which maturity would have circumscribed within a single channel, and directed to a definite end. Viewed simply with reference to its literary characteristics, the work may be called a prose *Don Juan;* and as in that marvellous hybrid between epos and satire, ostentatious planlessness, laxity of structure, and digression for digression's sake, become ultimately somewhat fatiguing. As the fascination of Byron's poem for the general reader is summed up in Julia and Haidee, so, of all the humorous ideas lavished in the *Tale of a Tub*, the three supernatural coats and Lord Peter's quintessential loaf have alone taken a firm hold of the popular imagination. Either, it is true, is sufficient for one man's fame. As to the charges of profanity drawn down upon Swift by the reckless exuberance of his humour, it is easier to understand how they should have come to be made than why his biographers should have condescended to refute them.

Before the publication of the *Tale of a Tub*, Swift had taken a step destined to exercise a most important influence on his life, by inviting two ladies to Laracor. Hester Johnson, a dependent of Sir William Temple's, whose acquaintance he had made in the latter's family, and whom he has immortalised as "Stella," came over with her *chaperon*, Mrs Dingley, and was soon permanently domiciled in his neighbourhood. The melancholy tale of Swift's attachments will be more conveniently narrated in another place, and is only alluded to here for the sake of chronology. Meanwhile the sphere of his intimacies was rapidly widening. He was a frequent visitor to London, and counted Pope, Steele, and Addison among his friends. The success of his pamphlet gained him ready access to all Whig circles; but already his confidence in that party was shaken,

and he was beginning to meditate that change of sides which has drawn down upon him so much but such wholly unjustifiable obloquy. The true state of the case may easily be collected from his next publications—*The Sentiments of a Church of England Man*, and *On the Reasonableness of a Test.* The vital differences among the friends of the Hanover succession were not political, but ecclesiastical. From this point of view, Swift's sympathies were entirely with the Tories. As a minister of the Church, he felt his duty and his interest equally concerned in the support of her cause; nor could he fail to discover the inevitable tendency of Whig doctrines, whatever caresses individual Whigs might bestow on individual clergymen, to abase the whole Establishment, by dispelling the last gleams of that aureole of mystic reverence so irrecoverably dimmed at the Reformation. Utterly incapable of either rising to an elevated conception of religion, or of regarding the interests of the Church from a cosmopolitan point of view, he considered her as a corporation, and advocated her cause in the spirit of an attorney. One of his pamphlets, written about this time, contains his recipe for the promotion of religion, and is of itself a sufficient testimony to the extreme materialism of his views. Censorships and penalties are among the means he recommends; and to him the city owes in great measure the fifty new churches of which it is now a problem how to get rid. His pen was exerted to better purpose in the *Argument against Abolishing Christianity*, a piece of irony most consummate and inimitable.

From February 1708 to April 1709 Swift was in London, urging the claims of the Irish clergy to an increased endowment upon the Godolphin administration. His having been selected for such a commission shows that he was not yet regarded as a deserter from the Whigs, although the ill success of his representations probably helped to make him one. By November 1710 he was again domiciled in London, and in the first pages of his remarkable *Journal to Stella* we find him depicting the decline of Whig credit, and complaining of the cold reception accorded him by Godolphin, whose penetration had doubtless detected the precariousness of his allegiance. Within a few weeks he had become the lampooner of the fallen treasurer, the bosom friend of Oxford and Bolingbroke, and the writer of the *Examiner*, a journal established as the exponent of Tory views. He was now a power in the state, the intimate friend and recognised equal of the first writers of the day, the associate of ministers on a footing of perfect cordiality and familiarity. By his own account, his credit had procured the fortune of more than forty deserving or undeserving clients; and the envious but graphic description of his demeanour preserved to us by Bishop Kennet,[1] attests the real dignity of his position no less than the airs he thought fit to assume in consequence. The cheerful, almost jovial, tone of his letters to Stella evinces his full contentment; nor was he one to be moved to gratitude for small mercies. To understand this extraordinary influence, never since vouchsafed to a politician precluded by his profession from serving his party with his voice as well as his pen, two or three circumstances peculiar to the time must be taken into account. Since the age of Anne, the immense extension of the area of politics has necessitated a proportionate division of labour among political writers. No one pen could discuss, no single understanding embrace, the various subjects of which the press now takes cognisance. Every influential journal possesses a large staff of contributors, and must represent some nice shade or peculiarity of opinion. In Swift's time journalism was a more simple matter. Daily papers merely reported the news of the day; the higher class journals appeared weekly, and were then entirely occupied with a single essay, or, in our present parlance, leading article. The sole authorship of such a publication was consequently quite possible to a writer of moderate industry, and the enlistment of such a partisan in that day corresponded to the establishment of a new weekly organ in ours. Till Swift's accession to their cause, moreover, the preponderance of intellect had been decidedly against the Tories. To have found a writer capable of combating and even overthrowing Addison and Steele, was for the ministry of that day what the miraculous advent of a new *Times*, antipodal to the old in all but talent, would now be to an administration powerfully assailed by that journal. Given Swift's indispensableness to the ministers, he had it in his power to determine the nature of his social relations with them; and it will readily be inferred that he was not the man to rest contented with anything short of precise and almost ostentatious equality. Here, again, the circumstances of the time were in his favour. Like the France of Louis Philippe, the England of Anne was the paradise of political adventurers. Ancient names were erased or eclipsed, old notabilities ostracised, the leading men held positions to which they could not have aspired at a more settled period, and which fresh adventurers were preparing to occupy in their turn. This community of character, of history, and of destiny, engendered a frank and genial tone in political circles. Men were quick to discern and esteem in others the qualities which had wrought out greatness for themselves. As officers and privates become intimates on the field of battle, so servility and assumption were forgotten in the excitement of the time.

Great as was Swift's merit towards his party as conductor of the *Examiner*, it was surpassed by that belonging to him as author of the two famous pamphlets, *The Conduct of the Allies*, and *The Barrier Treaty*, devoured rather than read by the nation. Here, again, circumstances were highly favourable to him. For eight years the great captain of the age had fed the country with a succession of triumphs, till exultation had become satiety. One last poignant and exquisite relish remained—to be told that all these conquests had been made for ungrateful allies, and that England was the worst used as well as the most victorious nation upon earth. To have profited by Marlborough's genius was much; to have found a pretext for disowning obligation even more. The victor of Blenheim's private character was more assailable than his military conduct, and it was easy for Swift to extenuate the popular ingratitude which must soon have manifested itself, with a justification or without. The necessity of peace had, indeed, become as clear as the futility of expecting peace at the hands of Godolphin and Marlborough; so that Swift unquestionably rendered his country a service, while he wreaked his fury on the fallen statesmen with the sinister exultation of a morose and unbelieving nature, delighting in nothing more than the abasement of great achievements and great names.

Generous men like Oxford and Bolingbroke cannot have been unwilling to reward so serviceable a friend, especially when their own interest lay in keeping him in England. Notwithstanding, therefore, some dubious expressions in Swift's letters, natural to the deferred hope, we need not doubt their having actually used their best efforts to obtain for him the vacant see of Hereford. Swift, however, had formidable antagonists in the Archbishop of York, whom the *Tale of a Tub* had scandalized, and who had previously frustrated the instances of Godolphin for his promotion, and in the Duchess of Somerset, whom he had inconsiderately lampooned. Charles the Second had not been more amenable than Anne to the influence of female favourites, and it must be considered a proof of the strong interest made for Swift, that she was eventually persuaded to appoint him to the deanery of St Patrick's, Dublin, vacant by the

[1] Kennet particularly notices his zeal in procuring subscribers for the works of "one Mr Pope (a Papist")."

removal of Bishop Sterne to Dromore. In June 1713 he set out to take possession of his benefice, from which he was speedily recalled by the dissensions between the chiefs of his party. His exertions in behalf of the Irish clergy, it should be observed, had been fully successful with the Tory ministry, and his disgust was not small on finding the gratitude of his clients incommensurate with their obligations.

He found affairs in a desperate condition on his return. The Queen's demise was evidently at hand, and the same instinctive good sense which had ranged the nation on the side of the Tories, when Tories alone could terminate a fatiguing war, rendered it Whig when Tories manifestly could not be trusted to maintain the Protestant succession. In any event the occupants of office could merely have had the choice of risking their heads in an attempt to exclude the Elector of Hanover, or of waiting patiently till he should come and eject them from their posts; yet they might have remained formidable, could they have remained united. To the indignation with which he regarded Oxford's refusal to advance him in the peerage, the active secretary added an old disgust at the treasurer's pedantic and dilatory formalism, as well as his evident propensity, while leaving his colleague the fatigues, to engross for himself the chief credit of their administration. Their schemes of policy diverged as widely as their characters; Bolingbroke's brain teemed with the wildest plans, which Oxford might have more effectually discountenanced had he been prepared with anything in their place. Swift's endeavours after an accommodation were as fruitless as unremitting. There is no necessity so evident, no community of interest so radical, no entreaty so powerful, as to reconcile an able man to one whom he despises, or a proud man to one by whom he feels himself despised. Swift's mortification was little likely to temper the habitual virulence of his pen, which rarely produced anything more acrimonious than the attacks he at this period directed against Burnet and his former friend, Steele. One of his pamphlets against the latter (*The Public Spirit of the Whigs*) was near involving him in a prosecution; some invectives against the Scotch having proved so exasperating to the peers of that nation, that they repaired in a body to the Queen to demand the punishment of the author, of whose identity there could be no doubt, although, like all Swift's writings, except the *Proposal for the Extension of Religion*, the pamphlet had been published anonymously. The immediate withdrawal of the offensive passage, and a sham prosecution instituted against the printer, extricated Swift from his danger.

Meanwhile the crisis had arrived, and the discord of Oxford and Bolingbroke had become patent to all the nation. Foreseeing, as is probable, the impending fall of the former, Swift retired to Upper Letcombe, in Berkshire, and there spent some weeks in the strictest seclusion. This leisure was occupied in the composition of his remarkable pamphlet, *Free Thoughts on the State of Public Affairs*, which indicates his complete conversion to the bold policy of Bolingbroke. The utter exclusion of Whigs as well as Dissenters from office, the remodelling of the army, the imposition of the most rigid restraints on the heir to the throne,—such were the measures which, by recommending, Swift tacitly admitted to be necessary to the triumph of his party. If he were serious, it can only be said that the desperation of his circumstances had momentarily troubled the lucidity of his understanding; if the pamphlet were merely intended as a feeler after public opinion, it is surprising that he did not perceive how irretrievably he was ruining his friends in the eyes of all moderate men. Bolingbroke's daring spirit, however, recoiled from no extreme, and, fortunately for Swift, he added so much of his own to the latter's MS., that the author was obliged to recall a production which might not improbably have cost him his liberty and his benefice. This incident but just anticipated the revolution which, after Bolingbroke had enjoyed a three days' triumph over Oxford, drove him into exile and prostrated his party, but enabled Swift to perform the noblest action of his life. Almost the first acts of Bolingbroke's ephemeral premiership were to order him a thousand pounds from the exchequer, and despatch him the most flattering invitations. The same post brought a letter from Oxford, soliciting Swift's company in his retirement; and, to the latter's immortal honour, he hesitated not an instant in preferring the solace of his friend to the offers of St John. When, a few days afterwards, Oxford was in prison and in danger of his life, Swift begged to share his captivity; and it was only on the offer being declined that he finally directed his steps towards Ireland, where he was very ill received. The draught on the Exchequer was intercepted by the Queen's death.

Oxford was not the only friend for whom Swift proved capable of entertaining a fraternal regard; his intimacy with Pope and Arbuthnot was creditable to all three. At the epoch of the fall of Marlborough they had joined in writing *The History of John Bull*, of which, however, by far the largest share belongs to Arbuthnot, whose broad, genial humour, better adapted to conciliate the reader's sympathy than to overawe him by a display of intellectual power, is as unlike as possible to Swift's scathing thunderbolts, and deluges of gall and vitriol. On one chapter, indeed, that recommending the education of all blue-eyed children in depravity for the public good, it is impossible to avoid the verdict, *Aut Decanus aut Diabolus*. Some time before the fall of the Tory administration, the three friends were again united in writing *Martinus Scriblerus*, a satire whose pleasing geniality again betrays Arbuthnot's principal share in its composition. Swift may have contributed one of the digressions, and two passages in ridicule of his old enemies the mediæval logicians. In the masterly *Treatise on the Bathos*, the finical but intense touch of Pope is very observable. Swift's literary partialities occasioned several other satirical pamphlets, such as the cruel attack on John Dennis: he is more agreeable, though not more amusing, when following the bent of his own humour in ridiculing the impostures of the almanac-makers and the eccentricities of Whiston, and otherwise treading with no unequal pace in the track of "Eupolis atque Cratinus, Aristophanesque poetæ." Many of his best poems belong to this period; a more laboured work, his *Memorial* to Harley, recommending the regulation of the English language by an academy, is chiefly remarkable as evincing the deference paid to French taste by the most original English writer of his day. To sum up the incidents of this eventful section of his life, it was during it that he lost his mother and sister; the first, always most tenderly beloved and dutifully honoured, by death; the second by an imprudent marriage, which, though making her a liberal allowance, he never forgave.

Swift's misfortunes had hitherto been no other than may well befall whoever embarks on the tempestuous ocean of politics, but the real tragedy of his life was now at hand. We have already mentioned his invitation of Hester Johnson and Mrs Dingley to Ireland. Both before and after his elevation to the deanery of St Patrick's, these ladies continued to reside in his vicinity, and superintend his household during his absences in London. Such an intimacy could not but originate unfavourable surmises, nor would the most charitable easily conjecture why, with his evident delight in the society of Stella (a dark-haired and symmetrical beauty, endowed with excellent sense and charming temper, and not more brilliant of eye than wit, albeit a grievous offender against all rules of orthography), he did not at once secure it to himself by the simple expedient of matrimony. It may, perhaps, appear in the sequel

Swift.

that his conduct was not incapable of explanation, but it proved none the less the fatal embitterment of his life, and Stella's, and yet another's. During his long residence in London, he had involuntarily kindled a consuming passion in the breast of Esther Vanhomrigh, the Vanessa of his poetry and correspondence, daughter of a deceased commissioner of stores, and then residing in Bury Street, with her mother and sister. The relation he in the first instance assumed towards this young lady was, without doubt, that of an instructor and literary mentor. Instinct might suggest, were experience silent, the facility with which the teacher's interest and the pupil's affection may glide into emotions of a warmer cast. In this instance, the lovers were matched like coin and die. Of genuine love, at least of the pure essence of the passion, disengaged from all alloy of duty or personal advantage, Swift was constitutionally incapable. The finest and most exquisite emotions were dead in him, or had never lived. His breast never admitted, or rather never needed to exclude, any feeling incapable of expression in precise language, or of vindicating itself at the bar of reason.[1] To him a wife would have been nothing more than a friend in a peculiar relation, for which, after all, he could see no necessity, and he probably found Stella and Vanessa's cravings for a closer bond both puzzling and vexatious. So remarkable a deficiency in one portion of the mental organisation supposes an excessive development in some other. In Swift, the atrophy of the affections was compensated by the excrescence of intellectual pride. The surest way to his heart was to suffer him to domineer, and, like most of her sex, Vanessa was a born idolatress. Her character, sufficiently unfolded in the letters first published by Sir Walter Scott, is that of a being all compact of enthusiasm and imagination. These were the genii that had first reared her a splendid image of masculine perfection, and then filled up the abyss between her ideal and Swift. If no submission could disarm his tyranny, neither could any severity satiate her passion for martyrdom. If his arrogance rejected the idea of sacrifice for another's sake as humiliation, her fervour would have cooled before a shrine that required no victim. She speaks of his frowns with rapture, and reserves her agonies for his indifference. Such intensity of passion may well have captivated a mind formed to appreciate impetuous strength; such self-abandonment may have momentarily eclipsed the quiet self-devotion of the absent Stella. In the earlier part of his journal, addressed to the latter, Swift lays bare his feelings with an impassioned unrestraint which renders it the best authority for his character in our possession. The concluding portions are comparatively frigid; Vanessa's advances were clearly not discouraged as they should have been. Yet his regard for Stella was not extinct, nor his ties such as he could break without infamy. For fourteen years Stella had cheered, comforted, amused him. For fourteen years she had lived on patiently in the hope of one day becoming his wife, careless of the slur her equivocal position was casting on her reputation. That nothing might be wanting to his obligations, he had already (in 1706) been the means of her declining an advantageous offer of marriage; his understanding would not allow him to overlook his duty, or his conscience to acquiesce in its non-performance. If, while a mysterious obstacle prevented his marriage, his weakness allowed him to become irremediably entangled with Vanessa, the misery of his victims cannot have surpassed his own. He probably hoped that his return to Ireland would enable him to break off the connection, but he hoped in vain. Vanessa's mother died, and she followed him. Thus was he involved in the most miserable embarrassment; still for a time he continued to temporise. At length, unable to bear any more Stella's mute reproach, and his own consciousness of wrong, he gave a reluctant consent to a private marriage, which was accordingly performed in the Deanery garden by the Bishop of Clogher. This was in 1716. At the same time, he insisted on their union being kept a strict secret, justifying a demand really dictated by tenderness for Vanessa, and probably by another reason which he did not explain, on the most futile and frivolous pretexts. Never more than a nominal wife, the unfortunate Stella commonly passed for his mistress till the day of her death, bearing her doom with uncomplaining resignation, and consoled by unquestionable proofs of the permanence of his affection, if his strange feeling for her deserves the name. Meanwhile, his efforts were directed to soothe Miss Vanhomrigh, to whom he addressed *Cadenus*[2] *and Vanessa*, the best of his poems, and for whom he sought to provide honourably in marriage, without either succeeding in his immediate aim or in thereby opening her eyes to the hopelessness of her passion. In 1717, probably at his instance, she retired from Dublin to Marley Abbey, her seat at Celbridge. For three years she and Swift remained apart, but in 1720, on what occasion is uncertain, he began to pay her regular visits. Sir Walter Scott found the Abbey garden still full of laurels, several of which she was accustomed to plant whenever she expected Swift, and the table at which they had been used to sit was still shown. But the catastrophe of her tragedy was at hand. Worn out with his evasions, she at last (1722) took the desperate step of writing to Stella, demanding to know the nature of her connection with him, and this terminated the melancholy history as with a clap of thunder. Stella replied by the avowal of her marriage, sent her rival's letter to Swift, and retired to a friend's house. Swift rode down to Marley Abbey with a terrible countenance, petrified Vanessa by his frown, and departed without a word, flinging down a packet which only contained her own letter to Stella. Vanessa died within a few weeks.

Five years afterwards (January 1727) Stella followed her to the grave. Two months of intense agony, spent by Swift in seclusion in the south of Ireland, had procured his forgiveness; and the anguish which the gradual decay of her health evidently occasioned him is sufficient proof of the sincerity of his attachment, as he understood it. It is a just remark of Mr Thackeray's, that he everywhere half-consciously recognises her as his better angel, and dwells on her wit and her tenderness with a fondness he never exhibits for any other topic. Yet he could never overcome his repugnance to acknowledge their union till she lay on her deathbed, when he was heard by Mrs Whiteway (his cousin, a lady of fortune and talent, who, though not residing with him, superintended his household during his latter years) to say, *Well, my dear, if you wish it, it shall be owned.* She answered, *It is too late.* A lock of her hair is preserved, with the inscription in Swift's handwriting, most affecting in its apparent cynicism, *Only a woman's hair!*

Though the subject is delicate and invidious to the last

[1] His *debut* as a lover had been unlucky. In 1694, while in Ireland, he had been smitten with a Miss Jane Waryng, whom he straightway proceeded to idealise as "Varina," and woo in the high-flown style of the age. Varina then discouraged his suit on the ground of ill-health, but, two years afterwards, finding her constitution improved, or her matrimonial prospects uncertain, she made him advances in her turn. Swift's mind had also changed, and he could find no better way out of his dilemma than an ill-bred and insulting letter, affecting to accept her proposition on terms which he knew must put further correspondence out of the question.

[2] An anagram of *Decanus*. Some one observed to Stella that this Vanessa must have been an extraordinary woman on whom the Dean could write so finely. "I do not see that," returned Stella, "for" (alluding to one of Swift's satirical pamphlets, a burlesque on Boyle), "all the world knows that the Dean can write finely upon a broomstick!"

Swift.

degree, it would be a cruel offence against Swift's memory to refrain from adverting to the strong probability of the mysterious impediment to his union with Stella having been of a physical and, therefore, an insuperable description. External evidence of this is necessarily wanting, but the internal seems almost to amount to a moral certainty. Without recourse to such a hypothesis, his conduct appears inexplicable. The obstacles he alleged are palpable evasions; his attachment to Vanessa will neither account for his reluctance to contract a marriage with Stella before his acquaintance with her rival, nor for his refusal to acknowledge it after the latter's death. On the supposition alluded to (powerfully corroborated by the entire absence of erotic sentiment from his writings) the grounds of his conduct are sufficiently obvious, and it can only be said that he preferred the ruin of Stella's happiness to an avowal which nothing short of absolute compulsion has ever extorted from any man. It should also be remembered that his natural insensibility to the refinements of passion must have rendered it very difficult for him to realise the misery he was occasioning. His conduct to Vanessa certainly remains unaffected by these considerations, and if there be any to whom the voluntary and enthusiastic homage of beauty is without allurement, these have undoubtedly earned the right to pronounce a severe condemnation. Yet even they should reflect that human actions are properly estimated by their intrinsic character, not by their consequences. Thousands have committed similar errors, unexpiated by similar remorse; but the pangs of *their* Vanessas have proved amenable to time and reason, and their biographers (if any) have taken no cognisance of the matter. The fervour of Vanessa's passion was a terrible misfortune for Swift; let it not be made his crime. Without actually mitigating his culpability, a happier *denouement* would have disarmed the austerity of his censors. It is obvious that on our theory (which is also Sir Walter Scott's), the supposition of a criminal intercourse between Swift and either Stella and Vanessa falls to the ground of itself. On any theory, it is unsupported by evidence, and inconsistent with his character.

During the interval between the deaths of Vanessa and Stella, Swift made three excursions to England, from the last of which he was recalled by the tidings of Stella's illness. The same period witnessed the two greatest literary successes of his life.

While yet hoping to gain an establishment in England Swift had paid little attention to Irish affairs. His residence at Dublin familiarised him with misery and misgovernment, and having begun by hating and despising the Irish, he finished by identifying himself with their cause. In the pamphlet entitled *A Proposal for the Universal Use of Irish Manufactures* (1720) he expressed himself with a boldness that occasioned the prosecution of his printer. The iniquitous conduct of the chief-justice secured a conviction; but public feeling rose to a height that intimidated the government, and no sentence was passed. This proved but the prelude to more momentous incidents. In 1723, a bribe to George the First's mistress obtained for a person named Wood the privilege of coining L.108,000 in halfpence and farthings, and circulating the same throughout Ireland. The Irish Parliament and executive not having been consulted at all, the patent proved as exasperating to the Protestant governing class as to the oppressed Catholics. It was then that Swift sent forth the seven famous letters subscribed M. B., Drapier.[1] These culminating productions of his pamphleteering genius must not be judged with reference to the abstract merits of the question they discussed. Wood was not a villain, or his coinage spurious, or his patent ruinous or even pernicious to the country. Ireland was assailed, not in her pocket, but in her independence, which would have been no less affronted had Wood proposed to distribute his coins at half-price. Under cover of an attack on him, Swift denounced the whole system of government, and first of Irishmen raised the cry, Ireland for the Irish! It elicitted a burst of feeling comparable to that which Charles the First had excited in England by levying ship-money, or James the Second by imprisoning the seven bishops. Soon Swift took a wider range, and denounced abuses without disguise. The public enthusiasm accompanied him, and Walpole was told that it would take 10,000 men to effect his arrest. His printer was an easier victim. Swift visited his prison in disguise, and listened unmoved to the solicitations of the honest tradesman's friends that he would deliver himself by revealing his employer. The might of public opinion soon brought more effectual and honourable relief. Ere long the captive was liberated, the patent withdrawn; and if Ireland suffered more than ever from a want of small currency, she had, at all events, the satisfaction of a victory over the Saxon. The Drapier was toasted at every table,[2] his head was made a sign, medals were struck, and clubs instituted in his honour, and the affection of his countrymen, for once wisely as well as warmly bestowed, never forsook him till his death.

It was in 1726 that *Gulliver* rendered Swift immortal. This, with *Robinson Crusoe* and *Pilgrim's Progress*, belongs to the class of books whose very diffusion reacts against their celebrity. The inimitable simplicity of these works at once brings them into the hands of every child, kindles the rapture with which every child peruses them, and occasions the indifference with which he in after-life confounds them with the other amusements of his infancy. Let the adult reader recur to them, and he will find that, like the miraculous coats in the *Tale of a Tub*, the companion of his boyhood has grown up with his own intellectual stature, and proves as adapted to his maturity as to his nonage. What seemed in *Gulliver* the capricious freak of fancy now appears as the most terrible of satires; the Genie emancipated from the vase. Other satirists have branded human vices; Swift makes war on humanity itself. In Lilliput or in Brobdingnag, in his laughter or his rage, human deformity is still his theme; man the object trampled upon in his passion, or dissected by his more deliberate virulence. The four parts of *Gulliver* are related as strophe and antistrophe, the second and fourth overwhelming with undisguised invective the vices which the first and third had exhibited indirectly, as by a parable. None of them could have been the work of one endowed with any elevation of mind, any perception of the lovely, or any insight into the methods and purposes of Providence; still less of one destitute of a glowing love of rectitude and hatred of evil. It is needless to dilate on the literary merits of a work unrivalled at once for the charm of invention and the deception of reality, whose gaiety can even procure oblivion of the furious sarcasm that lacerates as with a lash of wires. Lucian is left behind, and Voltaire surpassed by anticipation. Yet something of a mechanical character always marks the pro-

[1] Draper.

[2] The following text was popularly applied when Swift appeared in danger of prosecution:—"And the people said unto Saul, Shall Jonathan die, who hath wrought this great salvation in Israel? God forbid: as the Lord liveth, there shall not one hair of his head fall to the ground, for he hath wrought with God this day. So the people rescued Jonathan, that he died not." (1 Sam. xiv. 45.) A confidential servant, entrusted with the secret of the Drapier's identity, once remained so long out on a frolic as to cause serious apprehensions of his having gone to betray his master. On his return, the Dean turned him out of his house, declaring that he would not be intimidated into submitting to insolence from any of his domestics. The man's fidelity was proof against temptation and resentment, and when the danger was over, Swift received him again into his service, and treated him with marked kindness ever after.

ductions of ungenial minds. Gravity in absurdity is the great peculiarity of Swift's humour, and the power of his imagination is less conspicuous in the multiplicity of his ideas than in the inexhaustible variety he contrives to elicit from a single thought.

The Drapier had shaken Ireland, but *Gulliver* amazed all who could read English. Though the publication had been anonymous, the authorship could not remain a secret, and Swift began to hope that he might yet again play a part on the theatre of politics. The journeys to England, already mentioned, had been undertaken with this end in view, the influence on which he principally relied being that of Mrs Howard, the accomplished mistress of George the Second. She seems to have been really desirous of assisting him, but to have wanted the power. It is no disgrace to Swift's penetration that he should have failed to appreciate the tacit understanding established between the royal pair, by which Caroline had, so to speak, bartered her consort's hand for his head, the control over his affections for the management of his affairs. This grand mistake of relying on the mistress instead of the wife, would of itself have proved ruinous to his negotiation, even without the underhand opposition of Sir Robert Walpole, who gave him fair words, but secretly resolved to take good care how he promoted one who might be so formidable. At last his good understanding with the court was destroyed by the audacious forgery of some one who addressed insolent letters to the queen in his name, insisting on the claims of a certain Mrs Barber to her patronage. Full of mortification, he resigned himself to be the *frondeur* of the Irish, instead of the confidant of the English administration. In one viceroy, Lord Carteret, he found a congenial spirit, who frequently attended to his applications in favour of deserving persons, and received and returned his sarcasms with good humour. "You will not put me on such a board, my lord, because you know that I would neither job, nor bribe, nor be bribed, nor waste the public money, nor suffer other people to do any of these things." "What you say," replied Carteret, "is perfectly true, and therefore you must excuse me." At other times his pleasantry was exercised at the expense of the ecclesiastical authorities, whom he hated with all the fury of one who thought he ought to be in their place, and whose attempts to aggrandise themselves at the expense of the inferior clergy he resisted with the ferocity of a tiger and the stubbornness of a mule. "It is quite a mistake," he would say, "to blame the English government for sending us bad bishops; it is invariably careful to select men of the purest morals and most fervent piety. The misfortune is, that as these exemplary prelates cross Hounslow Heath on their way to their dioceses, they are invariably stopped and murdered by the highwaymen, which unprincipled persons assume their robes and their patents, and come over here in their place, to the injury and scandal of true religion among us!" He was also long active as a pamphleteer; one of his productions of this period, the mock proposal to fatten the children of poor persons for the market, being perhaps the most masterly piece of irony he ever produced. He likewise commenced a periodical in conjunction with Sheridan, of which but few numbers were published, and set on foot a scheme for relieving the distresses of the poorer orders by means of small loans, which does not appear to have been unsuccessful, and occasioned many most amusing adventures, which will be found detailed in Sir Walter Scott's *Biography*. His last public appearance was on a financial question, in opposition to a scheme for regulating the gold currency proposed by the real ruler of Ireland, Archbishop Boulter. On the day the measure took effect the cathedral-bells were rung backwards, and a black flag waved from the tower. For a time it was necessary to guard the primate's house, but when no evil effects from his policy were discoverable, the agitation died away. Swift had all his life been subject to violent attacks of giddiness and deafness, occasioned probably by water on the brain, but, as he fancied, by a surfeit of fruit at Moor Park. This year (1736) as he was writing the most virulent of his pieces, the satire against the Irish Parliament entitled the *Legion Club*, the fit seized him so fearfully that on his recovery he determined to lay aside the pen for ever. Nearly all the remainder of his existence was destined to be passed in pain, aggravated by the perceptible decay of his faculties, the consciousness of defeat in the great conflict of his life, a growing distaste for society, and an incapacity for intellectual recreation from the failure of his sight and his obstinate resolution not to wear glasses. It was the peculiar misery of his bodily suffering to engender mental torture, which re-acted on the body in its turn. Sources of consolation open to the weak and humble were closed against his haughty spirit; his austerity rejected the sympathy which his affliction would have commanded; his pride disdained the literary greatness which, in the eyes of most, richly recompensed the disappointments of his life. He permitted, however, the publication of an imperfect edition of his works, and in 1738 sent another anonymous pamphlet into the world, the *Polite Conversation*, written several years previously. It is a satire on the insipidity of commonplace social intercourse, a collection, one would think, of all the vapid trivialities and vulgar proverbs he had ever heard in his life, thrown into a dramatic form with wonderful ingenuity, and garnished with a contemptuous preface. His memory and observation are equally displayed in another work designed for publication at this time, but withheld till after his death, the ironical *Directions to Servants*. The imperturbable gravity of this performance is worthy of *Gulliver*, and the amazement with which we must view the immense accumulation of minute particulars is increased on discovering that it is, after all, only a fragment. During the last days of Anne he had written the history of the *Peace of Utrecht*, subsequently continued to the queen's death, and this he now intended to publish, but was dissuaded by his friends, who dreaded the effect of his revelations, and the uncompromising ferocity of his attacks on the living and the dead. It appeared ten years after his decease, without creating much sensation. The correspondence of his declining years is very interesting, especially his own letters and papers; the latter portion painfully affecting from the evidence of constantly increasing infirmity it contains. Johnson has commented severely on his and his friends' self-satisfaction and contempt for the rest of the world; but this is the universal failing of literary cliques. The poems he wrote between the death of Stella and the interruption of the *Legion Club* are not all calculated to do honour to his memory. Many are trivial, others coarse and extravagantly indecent. A kind of cynicism grew upon him in his latter years, and was increased by the gradual deterioration of his society. As his faculties and political importance declined, he found his equals in station less and less disposed to submit to his despotism, and was driven to tyranize over parasites, for whose amusement he sometimes produced that of which it would be charity to suppose him afterwards ashamed. Yet the *Yahoo* had been an imagination of better days, and quite in keeping with the utter want of refinement which, in strange contrast with the scrupulous attention he paid to his person and apparel, marked both his moral and intellectual character. Some of his best friends, as the witty blunderer Sheridan, he drove from him in his perverseness; others he was near alienating by his freaks, as when he cut down a favourite tree of Sir Arthur Acheson's, and had to purchase his pardon by an elegant apology in verse. Still, and long after he could do no more for Irish liberty by voice or pen, the popular veneration was as strong as ever. His birthday was celebrated by illuminations, and when he was

menaced by the bully Bettesworth, all Dublin seemed to rise as one man in his defence. In Mrs Whiteway he had a most sincere and judicious friend, whose affection he returned, and of whose value, though he sometimes tried her patience, he was fully conscious. Nothing in Lear surpasses the pathos of the last letter he addressed to her.

"I have been very miserable all night, and to-day extremely deaf and full of pain. I am so stupid and confounded, that I cannot express the mortification I am in both of body and mind. All I can say is, that I am not in torture, but that I daily and hourly expect it. Pray let me know how your health is, and your family. I hardly understand one word I write. I am sure my days will be very few—few and miserable they must be.—I am, for those few days, yours entirely, J. SWIFT.

"If I do not blunder, this is Saturday, July 26, 1740."

Early in 1741 it became necessary to place him under restraint, and appoint guardians for his person and property. Much of 1742 was passed in furious madness, aggravated by intense bodily suffering from boils and tumours. Release from pain brought a momentary interval of lucidity. The causes of his insanity were rather physical than mental. After his death his brain was found loaded with water, and an operation, if it had not killed him, would probably have restored his reason. Nothing was attempted, and he quickly sank into a lethargy, which, with a few occasional gleams of consciousness, continued to his death. It is a melancholy comfort to peruse the few affecting anecdotes which go to prove that his faculties were rather suspended than destroyed[1]—

"After the Dean had continued silent a whole year in this helpless state of idiocy, his housekeeper went into his room on the 30th of November in the morning, telling him that it was his birthday, and that bonfires and illuminations were preparing to celebrate it as usual; to this he immediately replied, 'It is all folly, they had better let it alone.'

"Upon his housekeeper removing a knife, as he was going to catch at it, he shrugged up his shoulders and said, 'I am what I am,' and in about six minutes repeated the same word two or three times.

"In the year 1744, he now and then called his servant by his name, and once attempted to speak to him; but not being able to express his meaning, he showed signs of much uneasiness, and at last said, 'I am a fool.' When the same servant was breaking a hard, large coal, he said, 'That is a stone, you blockhead.'

"From this time he was perfectly silent till October 19, 1745, and then died, without the least pang or convulsion, in the seventy-eighth year of his age."

He was interred in his cathedral, with this epitaph, written by himself—"Hic depositum est corpus Jonathan Swift, S.T.P., hujus ecclesiæ cathedralis decani: ubi sæva indignatio ulterius cor lacerare nequit. Abi, viator, et imitare, si poteris, strenuum pro virili libertatis vindicem." With a presentiment of his fate, he had bequeathed his fortune to found an hospital for idiots and lunatics.

As with all authors of genuine merit, Swift's character as a writer is the counterpart of his character as a man. It may be summed up in a phrase—strength without elevation. Nature intended him for the prince of satirists and pamphleteers, and her wisdom was not more conspicuous in what she gave than in what she denied. Satirists and politicians must not see too far. It is not their business to search out principles, but to lash the ephemeral follies, or criticise the no less ephemeral transactions of their own day. Swift has done nothing for the science of politics. The force of his political essays is of genius, but their substance mere shrewdness and common sense. In all his political writings there is hardly anything like a theory, an abstract principle, or a speculation. His suggestions are mere expedients; his expedients coarse and material. Of abstract right, as distinguished from personal integrity, he seems to have had no conception. Disabilities on dissenters seem to him as much in place as saddles on horses. Liberal in his estimate of human action, his views of human opinion are prejudices below the dignity of superstitions. He habitually postpones mankind to his country, his country to his party, and his party to himself. This narrowness of thinking intensified his powers. Like a river in a rapid, his mighty intellect foamed with irresistible force through its contracted channel. To considerations of an elevated nature he is inaccessible, and the antagonist who descends to his own ground is swept away. He overthrows, tramples, breaks in pieces, and tears to tatters. Miserably shorn of some of the highest prerogatives of the human mind, the genius he still possesses cannot be contemplated without awe and admiration. It is like the interrupted pile of Babel—the foundation of a structure that should have reached to heaven. In audacity of demeanour and majesty of port he yields to none of the giants of mind. Milton in his singing robes does not offer a grander image of intellectual force than Swift bespattering ex-ministers, and ringing the changes on bad halfpence. It was as though some sublime spirit, a second Faust, had parted with his better soul for thirty years of uncontrolled dominion. What seems his weakness to us was his strength among his contemporaries. He walked with his age, and did not outrun it. His lip breathed ever in the popular ear; he did not, advanced out of sight, halloo feebly from a distance. Even with us, his narrowness of view redeems his one grand and classical production from disgust. The misanthropy of *Gulliver* would be detestable, were it not so intensely real. Could the book possibly be the production of one of large views or elevated soul, it would be the production of one who had sinned against light, and deliberately sat down to libel and blacken his species. Swift is terribly in earnest, and writes as much in sorrow as in anger. His style is the image of his mind. In conciseness, directness, in plain sense and nervous vigour, it is worthy of the great writers of the preceding generation. But he has not their high thoughts to dress up in appropriate majesty, and disdains to trick out his own petty ones. He writes level to the capacities of his readers, spurning impassioned appeal and metaphor. After Barrow or Taylor, a paragraph of his is like a cathedral after the Reformation—the gorgeous windows shattered, the imposing ritual discarded, the arches blocked up with very comfortable pews. The homeliness of his predilections corresponded to the homeliness of his language; in all his volumes there is not one allusion to Shakspeare. On the other hand, his *Pindaric Odes* are the sole instance he has given of absurdity or affectation. Efforts after sublimity or picturesqueness have sometimes made other writers verbose, meretricious, nonsensical. Swift lay under no temptation to such *dulcia vitia*. Whatever he says is, for him, absolutely and literally, not merely figuratively or transcendentally, true; and so great is the power of earnestness, that his invectives against obscure scoundrels, or diatribes on the passing interests of the day, may even now be read with more pleasure than many a work of genuine imagination. In what may be called his mental build, he is startlingly original; but, strictly examined, his imagination will appear more distinguished for energy than fecundity. The original ideas he does possess are very striking, and he usually makes the most of them, and that with the careless

[1] His last composition was an epigram on a building shown to him when he was taken out for an airing:—

"Behold a proof of Irish sense,
Here Irish wit is seen,
When nothing's left that's worth defence,
They build a magazine!"

Swift.

profusion of a fountain sending forth its waters, not like a gold-beater, covering the amplest possible space with the thinnest possible leaf. Yet he is a master of permutation and combination; he rarely lets an idea go till he has drained it to the very marrow. A thought which with another might have flashed for a moment in an epigram, may with him be heard detonating and exploding throughout a whole pamphlet, and each report adds something to the general effect. Still there is nothing strained or far-fetched about his wit or his argument; he is never ingenious for ingenuity's sake. He is as clear-headed and prompt as copious; each of his numberless strokes falls at the right moment, and in the right place; by the time he has done his adversary (for all his writings are directly or indirectly polemical) is a mangled mass of bruises and blood.

As the characteristic of his writings is vigour without loftiness, so the definition of his moral nature is rectitude without amiability. His virtues were many and great, but coarse, rude, and exaggerated, like well-formed letters blotted by a hasty writer. He possessed the noblest independence of character, but knew not how to assert it without rage against his superiors, and arrogance towards his inferiors and equals. In truth, he had so little faith in excellence, that he hardly believed in his own superiority, unless demonstrated by the envy or the servility of others. The most punctual of men in the fulfilment of all his obligations, he discharged them so harshly and ungraciously that no one, probably, has ever been influenced by his example. Excessively charitable, though frugal and acquisitive,[1] he rarely gave without affronting the recipient. He was one capable of warm attachments, who spoke uncivilly of his friend to his face, and unkindly behind his back; the benefactor of his domestics, and their tyrant; the lover of two women, whose hearts he broke. He possessed not the least delicacy or refinement of sentiment; and his behaviour to others, especially to females, showed that he expected none from them. His virtues were unattractive, his failings repulsive; yet he was capable on occasion of generous deed or magnanimous forbearance. If he sometimes acted as a selfish or cold-hearted man might have done, the reason consisted partly in the overweening self-esteem that blinded him to his own faults, but more in the sluggish imagination that disqualified him from realising the feelings of others. If his frowns and his bitterness brought misery among his intimates, in his writings they were usually employed for the public good. No writer has scourged so many villains, scoffed at so many blockheads, exposed so many impostures, or assailed so many abuses. He was marvellously obtuse on many points of morality and policy; but where he did see evil, he hated it like one who had crossed his ambition. There is something wonderfully massive and sterling in his character; he was above taking pains with his virtues, and allowed himself no affectation but that of some faults he did not possess. His fierceness and austerity of disposition are unspeakably imposing. Others have undergone more romantic vicissitudes of fortune, but few careers are illumined with so wild and tempestuous a splendour. His prosperity is dazzling; his misery appalling. He is not to be thought of without wonder, and reverence, and repugnance, and pity most of all. He is a volcano—fearful in the long suppression of its smouldering fires; amazing in its sudden blaze and gigantic illumination; most awful of all in its silence and ashes, and stupendous, solitary gloom.

Swift's religious sentiments have furnished occasion for much dispute. The prayers found in his handwriting, indeed, sufficiently establish his piety, and the exceptions taken to the levities of his satiric writings can only have originated in a profound ignorance of the nature of humour and humourists. It is impossible, however, to get rid of an indefinable impression of a certain uncomfortableness in his relations towards the established religion. There is no reason to suppose him unconvinced by the external evidences of Christianity, which in his day had hardly been impugned. But no Christian minister has displayed less of the meek spirit of his creed; and the consciousness of a secret disharmony with what he was forced to inculcate and outwardly revere, will probably account for his uneasiness without imputing to him any definite opinion at variance with his station in the church.

Swimming.

In person Swift was tall and commanding, with aquiline features, a swarthy complexion, but an eye "as azure as the heavens." The expression of his countenance was stern in his gayest mood, and when angered his scowl was awful.

Swift was not the man to encourage a Boswell, and his own correspondence is the best authority for his life. Of his contemporaries, we are principally indebted to his indiscriminating panegyrists, Delany and his own nephew Deane, and his detractor, Lord Orrery, whose malevolence is said to be owing to the discovery of the slight value the Dean set on his acquaintance. Hawkesworth compiled the particulars of his life, and published what was the standard edition of his works till the appearance of Sir Walter Scott's in 1814. This edition can hardly be rendered more complete, and is not likely to be soon superseded. The biography prefixed is based on Hawkesworth, but far more copiously and elegantly written. At the same time, it displays more diligence than vigour or penetration, and the author's good-nature has certainly made him too indulgent to his hero. Dr Johnson's biography in the *Lives of the Poets* is the opposite of Sir Walter Scott's in all respects; a condensation of Hawkesworth instead of an expansion; pregnant with acute observations on Swift's private and literary character, but darkened throughout by an antipathy[2] that greatly impairs its value. In our own day, Mr Thackeray has made Swift the subject of an essay, most keen in its criticism, most brilliant in its composition, and full of that geniality and compassion which Swift alone wanted to have been as admirable as formidable, and as happy as famous. (R. G.)

SWIMMING, the art of floating one's self on water, and at the same time making a progressive motion through it. As swimming is not natural to man, it is evident that at some period it must have been unknown among the human race. Nevertheless there are no accounts of its origin to be found in the history of any nation; nor are there any nations so barbarous but that the art of swimming is known among them, and that in greater perfection than among civilized people. It is probable, therefore, that the art, though not absolutely natural, will always be acquired by people in a savage state, from imitating the brute animals, most of whom swim naturally. Indeed so much does this appear to be the case, that very expert swimmers have recommended it to those who wished to learn the art, to keep some frogs in a tub of water constantly beside them, and to imitate the motions by which they move through that element.

Swimming not natural to man.

The theory of swimming depends upon one very simple principle; namely, that if a force be applied to any body, it will always move towards that side where there is the least resistance. Thus, if a person standing in a boat pushes with a pole against the side or any other part of the

Depends on a simple principle.

[1] One of his last acts as Dean was to refuse a bargain which would have profited him to the detriment of his successors.

[2] It is, perhaps, not impossible that Johnson's dislike to Swift may have arisen from his horror of insanity, which he always dreaded for himself, and which he would gladly attribute, in Swift's case, to the perversion of the latter's temper. The resemblance between his own character and Swift's, and the nature of their infirmities, was certainly sufficiently close to alarm him.

vessel in which he stands, no motion will ensue; for as much as he presses in one direction with the pole, just so much does the action of his feet, on which the pressure of the pole must ultimately rest, push the vessel the other way: but if, instead of the side of the vessel, he pushes the pole against the shore, then only one force acts upon it, namely, that of the feet; which being resisted only by the water, the boat begins to move from the shore. Now the very same thing takes place in swimming, whether the animal be man, quadruped, bird, or fish. If we consider the matter simply, we may suppose an animal in such a situation that it could not possibly swim: thus, if we cut off the fins and tail of a fish, it will indeed float in consequence of being specifically lighter than the water, but cannot make any progressive motion, or at least but very little, in consequence of wriggling its body; but if we allow it to keep any of its fins, by striking them against the water in any direction the body moves the contrary way, just as the boat moves the contrary way to that in which the oars strike the water. It is true, that as the boat is but partly immerged in the water, the resistance is comparatively less than when a frog or even any other quadruped swims; but a boat could certainly be rowed with oars though it were totally immerged in water, only with less velocity than when it is not. When a man swims, he in like manner strikes the water with his hands, arms, and feet; in consequence of which the body moves in a direction contrary to the stroke. Upon this principle, and on this only, a man may either ascend, descend, or move obliquely in any possible direction, in the water. One would think, indeed, that as the strength of a man's arms and legs is but small, he could make but very little way by any stroke he could give the water, considering the fluidity of that element. Nevertheless it is incredible what expert swimmers will perform in this way; of which Dr Forster gives a most remarkable instance in the inhabitants of Otaheite, whose agility, he tells us, was such, that when a nail was thrown overboard, they would jump after it into the sea, and never fail to catch it before it reached the bottom.

As to the practice of swimming, there are but few directions which can be given. The great obstacle is the natural dread which people have of being drowned; and this it is impossible to overcome by any thing but accustoming ourselves to go into the water. With regard to the real danger of being drowned, it is but little; and on innumerable occasions arises entirely from the terror above mentioned, as will appear from the following observations by Dr Franklin.

Observations by Dr Franklin.

"1st, That though the legs, arms, and head, of a human body, being solid parts, are specifically somewhat heavier than fresh water, yet the trunk, particularly the upper part, from its hollowness, is so much lighter than water, as that the whole of the body, taken together, is too light to sink wholly under water, but some part will remain above until the lungs become filled with water; which happens from drawing water into them instead of air, when a person in the fright attempts breathing while the mouth and nostrils are under water.

"2dly, That the legs and arms are specifically lighter than salt water, and will be supported by it; so that a human body would not sink in salt water though the lungs were filled as above, but from the greater specific gravity of the head.

"3dly, That therefore a person throwing himself on his back in salt water, and extending his arms, may easily lie so as to keep his mouth and nostrils free from breathing; and by a small motion of his hands may prevent turning, if he should perceive any tendency to it.

"4thly, That in fresh water, if a man throws himself on his back near the surface, he cannot long continue in that situation, but by a proper action of his hands on the water. If he uses no such action, the legs and lower part of the body will gradually sink till he comes into an upright position, in which he will continue suspended, the hollow of the breast keeping the head uppermost.

"5thly, But if in this erect position the head is kept upright above the shoulders, as when we stand on the ground, the immersion will, by the weight of that part of the head that is out of the water, reach above the mouth and nostrils, perhaps a little above the eyes; so that a man cannot long remain suspended in water with his head in that position.

"6thly, The body continued suspended as before, and upright, if the head be leaned quite back, so that the face looks upwards, all the back part of the head being then under water, and its weight consequently in a great measure supported by it, the face will remain above water quite free for breathing, will rise an inch higher every inspiration, and sink as much every expiration, but never so low as that the water may come over the mouth.

"7thly, If therefore a person unacquainted with swimming, and falling accidentally into the water, could have presence of mind sufficient to avoid struggling and plunging, and let the body take this natural position, he might continue long safe from drowning, till perhaps help would come; for as to the clothes, their additional weight while immersed is very inconsiderable, the water supporting it; though when he comes out of the water, he would find them very heavy indeed."

His method of learning to swim,

The method of learning to swim is as follows. The person must walk into water so deep that it will reach to the breast. He is then to lie down gently on the belly, keeping the head and neck perfectly upright, the breast advancing forward, the thorax inflated, and the back bent; then withdrawing the legs from the bottom, and stretching them out, strike the arms forwards in unison with the legs. Swimming on the back is somewhat similar to that on the belly, but with this difference, that although the legs are employed to move the body forwards, the arms are generally unemployed, and the progressive motion is derived from the movement of the legs. In diving, a person must close his hands together, and, pressing his chin upon his breast, make an exertion to bend with force forwards. While in that position, he must continue to move with rapidity under the surface; and whenever he chooses to return to his former situation, he has nothing to do but to bend back his head, and he will immediately return to the surface.

It is very common for novices in the art of swimming to make use of corks or bladders to assist in keeping the body above water. Some have utterly condemned the use of these; Dr Franklin however allows that they may be of service for supporting the body while one is learning what is called the *stroke*, or that manner of drawing in and striking out the hands and feet that is necessary to produce progressive motion. "But," says he, "you will be no swimmer till you can place confidence in the power of the water to support you: I would therefore advise the acquiring that confidence in the first place, especially as I have known several who, by a little of the practice necessary for that purpose, have insensibly acquired the stroke, taught as it were by nature.

and of acquiring confidence.

"The practice I mean is this. Choosing a place where the water deepens gradually, walk coolly into it till it is up to your breast: then turn round your face to the shore, and throw an egg into the water, between you and the shore; it will sink to the bottom, and be easily seen there if the water is clear. It must lie in the water so deep as that you cannot reach it to take it up but by diving for it. To encourage yourself in order to do this, reflect that your progress will be from deeper to shallower water; and that at any time you may, by bringing your legs under you, and standing on the bottom, raise your head far above the wa-

Swimming.

ter: then plunge under it with your eyes open, throwing yourself toward the egg, and endeavouring, by the action of your hands and feet against the water, to get forward till within reach of it. In this attempt you will find that the water buoys you up against your inclination; and it is not so easy a thing to sink as you imagined; that you cannot but by active force get down to the egg. Thus you feel the power of the water to support you, and learn to confide in that power; while your endeavours to overcome it, and to reach the egg, teach you the manner of acting on the water with your feet and hands; which action is afterwards used in swimming to support your head higher above water, or to go forward through it."

Swimming a pleasant and useful exercise.

As swimming is a healthy exercise and a pleasant amusement, and as a dexterity in it may frequently put it in a man's power to save his own life and the lives of his fellow-creatures, perhaps of his dearest friends, it can neither be useless nor uninteresting to consider a few of the evolutions which a swimmer must be master of, that he move in any direction without difficulty, without danger, and without being unnecessarily fatigued.

How to turn to the right or left.

There are several different ways of turning one's self in swimming. You may do it in this way: turn the palm of the right hand outwards, extend the arm in the same manner, and make a contrary movement with the left hand and left arm; then, by a gradual motion, incline your head and whole body to the left side, and the evolution will be finished. There is another way, which is easier still. Bend your head and body toward that side to which you are going to turn. If you wish to turn to the left, incline the thumb and the right hand toward the bottom, bend the fingers of the right hand, stretch it out, and use it for driving away the water sidewise, or, which is the same thing, for pushing yourself the contrary way. At the same time, with your left hand, the fingers being close, push the water behind you, and all at once turn your body and your face to the left, and the manœuvre will be accomplished. If you wish to turn to the right, you must do with your right hand what you did with your left, and with your left what you did with your right. You must be careful when turning yourself never to stretch out your legs, and be sure that the water be so deep that you be in no danger of hurting yourself.

How to turn from the belly to the back.

When you are swimming on your belly, and wish to turn on your back, draw your feet in quickly, and throw them before you; stretch out your hands behind you, and keep your body firm and steady. When you wish to turn from swimming on your back, fold your feet at once under your body, as if you were throwing them to the bottom, and at the same instant dart your body forwards, that you may fall upon your belly.

The eyes ought to be turned towards heaven.

In swimming, the eyes ought to be turned towards heaven. This is a most important rule, and to the neglect of it many of the accidents which befall swimmers are owing. For when they bend their eyes downwards, they insensibly bend their head too, and thus the mouth being too deep in the water, may admit a quantity of it in breaking; besides, the more the body is stretched, it covers a greater part of the surface of the water, and consequently its specific gravity is less. Any person who will make the experiment will find it impossible to dive while he keeps his head erect and his eyes fixed on the heavens.[1]

How to swim on the back,

The easiest posture in swimming is lying on the back. When you wish to swim in this posture, lay yourself softly on your back, and raise your breast to the surface of the water, keeping your body extended in the same line. Put your hands easily over the upper part of your thighs, and throw out your legs and draw them in alternately, keeping them within two feet of the surface. In this way you may advance in any direction you please. You may perhaps not like having so much of your head under water; there is, however, no way of swimming so easy, so safe, and so little fatiguing. If you wish to swim with great rapidity, you may use your arms as well as your feet; and you will find this the easiest way of breaking the force of the waves.

and advance forward.

In swimming on the back, one may advance forward as well as backward. For this purpose the body must be kept straight and extended; the breast inflated, so that the hollow of the back may assume a semicircular form. The hands must recline over the upper parts of the thighs. It is also necessary to raise the legs one after another, and draw them in strongly towards the hams, and then leave them suspended in the water. This way of swimming is not only pleasant, but may serve to rest you when fatigued.

How to swim on one side.

When you are tired with swimming on your back and belly, you may swim on one side. When you wish to do this, sink a little your left side and raise your right; you will immediately find yourself on your left side. Move then your left hand without either raising or sinking it; you have only to stretch it and draw it back, as in a straight line, on the surface of the water. Independently of the pleasure which this kind of motion will give you, you will have the satisfaction of seeing both sides of the river.

How to swim on the belly without the assistance of the hands.

It is possible to swim on the belly without the assistance of the hands. For this purpose you must keep your breast erect, your neck straight, and fix your hands behind your head, or upon your back, while you move forward by employing your feet. This way is not without its advantages. It is an excellent resource when the arms are seized with a cramp, or with any indisposition which makes it painful to exert them. This in some cases may be preferable to swimming on the back; for while in that attitude, one cannot see before them without turning every instant. If one of your legs be seized with a cramp, take hold of it with the hand opposite to it, and use the other hand and leg to advance or support yourself.

How to swim with the hands joined.

A very ancient and graceful mode of swimming, is that of swimming with the hands joined. When you wish to put this in practice, join your hands, keeping the thumbs and fingers towards heaven, so that they may appear above the water; then draw them back and push them forwards alternately from your breast. This method of swimming may be useful in several circumstances, but above all if you are entangled with grass or weeds. Your hands will then open a passage for you.

With the hands elevated.

As a person may sometimes have occasion to carry something in his hand in swimming, which he is anxious to preserve from the water, he may swim easily with one hand and hold a parcel in the other, as Cæsar swam with his Commentaries at Alexandria; or one may swim with both hands elevated. To perform this well, the swimmer must raise his breast, and keep it as much inflated as he can, at the same time that he supports the arms above the water. It must not be concealed that this method of swimming is attended with some danger to one who is not dexterous at the art; for if one should imprudently draw in his breast

[1] An interesting question occurs here, which deserves to be considered. Since the body, when spread upon the surface, can be supported with so little exertion, and frequently without any at all, as in swimming on the back, how comes it to pass that a person when drowned sinks and frequently rises again some time afterwards. The reason is this. In the act of drowning, the lungs are filled with water, and consequently the body, being specifically heavier, sinks. It is well known that the human body contains a great quantity of air. This air is at first compressed by the water; and while this is the case, the body remains at the bottom; but as soon as the air by its elasticity endeavours to disengage itself from the compression, the body is swelled and expanded, becomes specifically lighter than the water, and consequently rises to the top.

Swindon || Switzerland.

when his arms are raised, he would immediately sink to the bottom.

How to rise to the surface after diving.

When a man plunges into the water, and has reached the bottom, he has only to give a small stroke with his foot against the ground in order to rise; but an experienced swimmer, if he misses the ground, has recourse to another expedient, which is very pretty, and which has not been much considered. Suppose him at a considerable depth, when he perceives that he cannot reach the bottom. In such a case, he first puts his hands before his face, at the height of his forehead, with the palms turned outwardly; then holding the fore part of his arm vertically, he makes them move backwards and forwards from right to left; that is to say, these two parts of his arms, having the elbow as a kind of pivot, describe very quickly, both the hands being open and the fingers joined, two small portions of a circle before the forehead, as if he would make the water retire, which he in fact does; and from these strokes given to the water there results an oblique force, one part of which carries the swimmer upwards.

SWINDON, a market-town of England, Wiltshire, on a hill 19 miles N.E. by N. of Devizes, and 80 W. of London. It consists of 5 principal streets, which are broad, regular, and neat; and it contains many good buildings. There are a handsome town-hall and market-house, an elegant gothic parish church, other places of worship belonging to Wesleyans and Independents; national, British, and infant schools, a library, and reading-room. Swindon is a principal station of the Great Western Railway, which has a locomotive-engine factory here, employing 1500 hands. In connection with this factory, a new town, called New Swindon, has sprung up, containing a church, schools, and mechanics' institute of its own. Pop. of the parish, 4876.

Swinemunde || Switzerland.

SWINEMÜNDE, a town of the Prussian monarchy, province of Pomerania, near the mouth of the Swine in the Baltic, 30 miles N.N.W. of Stettin. It has broad streets, lined with well-built houses, and contains a court of law, public offices, baths, and assembly rooms. There are here docks; and a harbour, that has been recently enlarged and improved, as it is the port of Stettin. The trade and navigation of the place are considerable. Pop. 5446.

SWINESHEAD, a decayed market-town of England, in the county and 25 miles S.E. of Lincoln. The sea formerly extended up to the town, and there was a harbour near the present market-place. This has become silted up, and Swineshead is now about 2 miles distant from the nearest point of the sea. There are here a free school, several charities, and a large and handsome church. Formerly there was at Swineshead a Cistercian abbey, and it was in this house that King John took refuge, after losing his baggage in attempting to ford the Wash, shortly before his death. Pop. of the parish, 2044.

SWINFORD REGIS, or KING'S SWINFORD, a village and parish of England, Staffordshire, on the Dudley and Stourbridge and Staffordshire and Worcestershire Canals, 3 miles W.S.W. of Dudley. The chief buildings are an elegant modern parish church, a chapel of ease, places of worship of Independents, Baptists, Primitive and Wesleyan Methodists. The parish occupies an extensive area, in a district rich in iron and coal, and contains many iron-works, collieries, potteries, brick and tile works, &c., with a population of 27,301.

SWITZERLAND.

Boundaries

SWITZERLAND (*La Swisse*, *Schweiz*, *Svizzera*), the most mountainous country in Europe, lies between 45. 48. and 47. 49. N. Lat., and 5. 55. and 10. 30. E. Long., having France on the W. between Basle on the Rhine and Geneva on the Rhone, the boundary line being formed by one of the ridges of the Jura Mountains, and by the River Doubs, an affluent of the Rhone. On the S. are Savoy, Piedmont, and Lombardy, from which it is separated by the Lake of Geneva, and high ranges of the Alps. To the E. are the principality of Lichtenstein, the Vorarlberg, and the Tyrol. Canton Ticino and some small portions of the Grisons are on the south side of the main chain of the Alps. On the N. lie Würtemberg, Lake Constance, and Baden. The town of Constance, with a limited tract about it on the south of the lake, belongs to Baden, while the Canton of Schaffhausen, and a small portion of that of Zürich, lie to the north of the Rhine. The greatest length of the country is from E. to W., in Lat. 46. 30., where it is 200 miles in extent; and its greatest breadth,—about the 9th parallel of E. Long.,—is 135 miles. Between Switzerland and Sardinia the boundary line is strongly defined, except towards the west, where the Canton of Geneva is partially surrounded by Savoy, Chablais, and Faucigny, lately ceded by Sardinia to France. Towards the eastern extremity of the Lake of Geneva, where a high range of the Alps terminates on the banks of the lake near St Gingolph, the line runs southward along this range until it reaches the mountain-knot of Mont Blanc. Thence it runs eastward along the higher portion of the Pennine Alps to Mont Rosa, where it turns to the N.E. along the Lepontine Alps to the great mountain-mass enveloping the Pass of St Gothard. From this point it trends southward, and afterwards S.E. to the Lago Maggiore. From this lake the line passes southward to the western arm of the Lake of Lugano, the central portion of which lake belongs to Switzerland, whilst the south-western and north-eastern extremities belong to Lombardy. A tract of land, extending several miles to the south of the lake, is also included in Switzerland. About 4 miles to the east of the town of Lugano commences a mountain-range, which, passing to the north, separates the valley of St Giacomo, belonging to Lombardy, from that of Misocco, which belongs to Switzerland. This range meets the principal chain of the Rhaetian Alps at the Pass of the Splügen. After proceeding a few miles only along this chain, the line extends to the east and south along a lateral range, crosses the valley of Bregaglia a few miles above Chiavenna, and meets the Bernina range, forming the southernmost of the three chains of the Rhaetian Alps. The valleys of Poschiavo and Münster, on the southern side of the range, belong, however, to Switzerland; while that of Livigno forms a portion of Lombardy, so that the line here does not follow the water-parting. From the southern extremity of the valley of Münster, bordering on the Tyrol, the line passes nearly due north, and, crossing the valley of the Inn, meets the central chain of the Rhaetian Alps. Passing S.W. along this, it meets the lateral chain called the Rhäticon, which runs N.W. between the Prätigau, belonging to Switzerland, and the Montafoner valley, which belongs to Austria. The mountains of the Rhäticon terminate on the Rhine to the north of Meyenfeld. Up to the point where it enters the Lake of Constance, the Rhine forms the boundary between Austria and Switzerland. The Lake of Constance separates Switzerland from Bavaria and Würtemberg, the harbour of Lindau forming the chief point of communication with the former, and that of Friedrichshafen with the latter kingdom. The entire length of boundary is 1040 miles, composed as follows,—602 miles of mountains, 235 of plains, and 203 of water.

Political divisions.

The confederation of Switzerland at present consists of twenty-two sovereign states or cantons, the areas of which, with number of inhabitants, and other statistical data, are given in the following table:—

Cantons.	Area in Sq. Miles.	Population in 1816.	Population in 1838.	Population in 1850.	Number of Families.	Number of Proprietors.	Surface.	Chief Industry.	Chief Towns.	Population in 1850.	Remarks.

[1] According to extracts from five volumes published between 1854 and 1858 by command of the federal government, under the title of *Materials for the Statistics of Switzerland*, and kindly furnished by Professor Paul Chaix of Geneva, the agricultural districts, comprising fields, meadows, and vineyards, may be reckoned at 31 per cent. of the whole; forests at 18 per cent.; and mountain-pastures at 20 per cent. Glaciers and snows are calculated to include ·12, lakes ·05, roads ·1, and buildings ·04, being together about ·31 of the entire area of 1732 sq. leagues.

This country was anciently called Helvetia, from its first known inhabitants; its more modern name is supposed to be derived from the canton of Schwytz, the cradle of Swiss independence. Little is known of the inhabitants of Switzerland till about one hundred years before Christ, when the Cimbri, a race of barbarians inhabiting the northern regions of the Chersonnesus Cimbrica, now known as North and South Jutland or Sleswig, crossed the Rhine, and extended their conquests into Gaul. Several of the Helvetian tribes, tempted by the immense spoils gained by the Cimbri, entered into an alliance with them, and carried their united ravages nearly to the mouth of the Rhone. In this extremity, the Gauls applied for assistance to the Romans, who speedily sent a powerful army to their assistance, under the command of the consul, Lucius Cassius. This force, however, was suddenly attacked on the banks of the Lake of Geneva by the Tigurini, a tribe of the Helvetii, led by a young general named Divico. The Romans were totally defeated, the consul and his lieutenant, Piso, left dead on the field, and the survivors only permitted to retreat after they had given hostages and marched under the yoke. Emboldened by this success, Divico rejoined the Cimbri, and with their united forces crossed the Alps and entered Italy itself, where, however, they were defeated by Marius with tremendous slaughter, and the few who escaped sought refuge among the fastnesses of the Helvetian mountains.

The Helvetii defeated by Cæsar.

For nearly half a century after this decisive defeat, the Helvetii confined themselves to their own country. But the recollection of rich pastures and fertile plains outlived the terror of the Roman arms, and made them resolve once more to quit their rocky fastnesses. After spending three years in preparation, they set out with their wives and families, cattle and possessions, led by the same Divico who had commanded their fathers fifty years before. The number who marched out on this expedition is computed at 368,000 souls, of whom 92,000 were able-bodied warriors.

The Roman province of Gaul was at that time under the government of Julius Cæsar, and that consummate general no sooner heard of the emigration of the Helvetians, than he took effectual measures to defeat their plans. After some abortive attempts at negociation, he attacked and defeated them in two engagements, with tremendous slaughter. Their strength and spirit were completely broken, and, overwhelmed with shame and grief, their numbers reduced to scarcely 100,000, they returned to their desolated country and rebuilt their ruined habitations. In order to watch and overawe them, Cæsar erected a fortress at Noviodunum (Nyon), on the banks of the Lake of Geneva, and established several other garrisons in different parts of the country.

Helvetia subjected by the Romans;

The Helvetii were at first the allies of the Roman people, but in the reign of Augustus they were reduced to complete subjection, and their country remained in the condition of a Roman province for upwards of three centuries, and underwent various reverses of fortune, according to the prosperous or adverse fortune of the empire to which it was subject. When the innumerable swarms of barbarians, issuing from the unknown regions of the north and east, overran Italy and destroyed the Roman empire, Switzerland also became their prey. The Goths established themselves in that portion of the country which bordered on Italy; the Burgundians, a tribe of the Wendes, from the shores of the Baltic, fixed their residence on both sides of the Jura, on the Lake of Geneva, and in the Lower Valais, as far as the Aar; and the Allemanni took possession of the country to the eastward of that country, and of great part of Germany.

The Burgundians having been defeated by the Huns under Attila, about the year 450 allied themselves with the Visigoths, a Scandinavian tribe, and adopted the Visigoth chief as their king. They afterwards extended their dominion into Gaul, along the banks of the Rhone and Saone, and gave their name to the fine country which still bears it. After having located themselves in Gaul and in Western Helvetia, a more regular system of society can be clearly traced among them.

The Allemanni, more ferocious than the Burgundians, devastated the valleys of Helvetia, and reduced the country to a wilderness, so that, gradually, vast marshes and forests overspread those parts, at present so beautiful, around the Lakes of Constance and of Zurich.

and by the Franks.

After this state of affairs had continued some time, a new swarm of adventurers obtained the ascendency. These were the Franks, another race from the north, who, after traversing the Netherlands, gained possession of the whole of Gaul, and pouring their resistless myriads into Switzerland, forcibly dispossessed the inhabitants, and at length, after various changes, succeeded in obtaining exclusive dominion over the whole of Rhætia and Helvetia. The Franks introduced into Helvetia the feudal system and other peculiar institutions and laws of the Teutonic tribes. To them also, under Clovis, the inhabitants were indebted for the adoption of Christianity, which contributed powerfully to the progress of civilization, and the revival of the country from its waste and desolate state. Switzerland remained subject to the Franks till after the death of Charlemagne, when, in consequence of the feuds of that monarch's successors, the vast empire which he had founded was entirely dismembered, and Switzerland was portioned out between France, Italy, and Germany. Rhætia and the country between the Lake of Constance and the Rhine, the Aar and St Gothard, in which German was the current language, were united to Suabia; while Geneva, the Valais, Neuchâtel, and the present country of Berne, Soleure, Fribourg, and Vaud, the districts in which Romance was the prevailing language, were united to Savoy, under the denomination of Little Burgundy. But this arrangement was of short duration, for the disorders and confusion produced by the continued wars enabled the provincial governors to throw off all allegiance to their feudal superiors, or to secure real independence while yielding nominal obedience. Switzerland was thus divided into a great number of petty states, generally engaged in hostilities with each other, and seldom uniting among themselves unless when menaced by some great and common danger. Such a case presented itself in the reign of the Emperor Henry I., surnamed the Fowler. An immense horde of barbarians, known by the name of Hungarians, issued from the east and the shores of the Black Sea, and overran Germany and Italy, burning and destroying wherever they came. In order to protect the inhabitants from the fury of these ruthless invaders, Henry built walls around a number of defensible places, to which all, in case of need, might fly for the security of their lives and property. In this manner Zürich, St Gall, Basle, and various other places, rose from petty hamlets to towns of considerable strength and numerous population. About the same period, the bailiffs of the emperor built and fortified Berne, Fribourg, and various other towns. A ninth of the free and nobler class of inhabitants were required to occupy these national fortresses, and they received the same political organization and rights as the more ancient cities of Germany. This was the first foundation of the class of burghers, who in process of time came to be a third estate in the kingdom. In proportion as the wealth and importance of the towns augmented, the citizens were eager to extend their rights and privileges. They availed themselves of every opportunity to purchase their emancipation from the feudal dominion of the bishops, abbots, and monasteries, to whose authority they had long been subjected; and in a short time the burghers were able to bid defiance to the nobles, and even to balance the political weight of the clergy.

Divided into petty states.

History.

Subject to the house of Austria.

The affairs of Switzerland continued in this state, without any material alteration, until the year 1273, when Rudolph of Hapsburg, whose castle was situated in the canton of the Aar, and who, besides possessing manorial rights and great influence in Schwytz, had held the office of imperial bailiff of several towns, was elected Emperor of Germany. This prince, though inhabiting a distant country, continued throughout his life to be strongly attached to Switzerland. He conferred new honours on its nobles, and granted additional privileges to its towns, or confirmed those which they already enjoyed. Rudolph was succeeded by his son Albert, whose ambition and rapacity soon alienated the affections of both his German and his Swiss subjects. Two of the imperial bailiffs, Hermann Gessler and Beringar of Landenberg, who were appointed over the Waldstätten (the three cantons of Schwytz, Unterwalden, and Uri), subjected the inhabitants to every species of insolence and oppression. Gessler, in particular, was guilty of so many acts of wanton cruelty, that he was at length shot through the heart by the famous William Tell, who thus paved the way for the deliverance of his countrymen. Curiously enough, a similar case occurs in ancient Scandinavian history, as recorded by Saxo Grammaticus. Three patriots, whose names are still revered throughout the republic, Werner Stauffacher, from the canton of Schwytz, Walter Furst of Uri, and Arnold Melchthal, from Unterwalden, had formed a conspiracy against the Austrian governors; and their measures were concerted with such wisdom, and executed with so much courage and intrepidity, that they obtained possession of every fortress of any considerable strength or importance. Shortly after this revolt of the forest cantons, the Emperor Albert was murdered by his nephew and some other nobles; but his son, Duke Leopold, marched against the cantons with a powerful army. The Schwytzers waited his arrival at Morgarten, on the slope of the mountain Sattel, and, notwithstanding the disparity of their forces, routed the Austrians with great slaughter on the 15th of November 1315; and it was with no small difficulty that the duke himself escaped, leaving most of his officers, and an immense number of his soldiers, dead upon the field.

The Swiss revolt from the Austrians, A.D. 1315.

The three cantons of Uri, Unterwalden, and Schwytz, having thus by their courage and virtue, achieved their independence, held a meeting on the 8th of December 1315, at which they entered into a solemn compact, and thus laid the foundation of the Swiss Confederation.

In 1332, the inhabitants of Lucerne formed a perpetual league with the Waldstätten; and in 1351 the citizens of Zürich, having thrown off the yoke of the aristocracy, joined the Swiss republic; and, on account of the power and wealth of the town, it was promoted to the chief rank. Glaris came next; Zug joined the confederation in 1352; and Berne in the following year. To the latter, in consideration of its importance, was assigned the second place of precedence.

The above-mentioned eight cantons, Schwytz, Uri, Unterwalden, Lucerne, Zürich, Glaris, Zug, and Berne, remained for more than a century the federative republic of the Swiss. With few interruptions, the republic enjoyed tranquillity until the year 1375, when a mixed English and French army of adventurers, under a French nobleman, Enguerrand de Coucy, a cousin of Leopold of Austria, and married to the English princess Isabella, advanced on the Limmat as far as Wettingen. Surprised, however, at night by the Swiss, they were dispersed, and the Lord de Coucy retreated into Alsace.

Defeat of Leopold, A.D. 1386.

Duke Leopold III. of Austria viewed the extending confederation with jealousy and alarm, and various quarrels having taken place between him and the cantons, hostilities were at length commenced. The duke, with a numerous force, chiefly composed of cavalry, marched rapidly towards the interior of the country, and, on the 9th of July 1386, encountered the Swiss in the neighbourhood of Sempach. The battle was long and fiercely contested, but at length the Swiss patriots gained a complete victory; the duke himself was slain, and more than 600 of the higher and lower nobility, with about 2000 of their less distinguished adherents, were left dead on the field.

Two years after the battle of Sempach, the Austrians took Näfels, a small town in the canton of Glaris. The garrison retreated from the town as far as Mount Rute where they took up a strong position, and awaited the approach of the enemy on the 9th of April. The Austrians maintained the fight for some time with great ardour, but were in the end overthrown and put to flight. The bridge of Wesen, on the Linth, was broken down by the weight of the fugitives, and above 3000 common soldiers, and 183 knights, were slain in the battle, or drowned in the lake and in the river. These defeats induced Duke Leopold IV., in 1389, to enter into a truce with the cantons for seven years, during which the Swiss contrived by various means to extend their territory and to increase their power.

Again defeat the Austrians, A.D. 1388.

This truce was renewed in 1394 for twenty years more, and was faithfully kept on both sides until 1415. At the commencement of the fifteenth century, the house of Austria possessed yet in Switzerland, Aargau, Fribourg, Rapperschwyl, Thurgau, and Winterthur. The house of Savoy owned the Pays de Vaud. The Valais and the valleys of Rhaetia belonged to their feudal nobles. The Abbot of St Gall and the Counts of Toggenburg in the east, and the Bishop of Basle and Counts of Neuchâtel in the west, were powerful neighbours of the eight Swiss Cantons. In the north existed still the independent imperial towns of Basle, Schaffhausen, and Soleure. The year 1415 was famous for the celebrated Council of Constance. About this time the Swiss Cantons carried their arms across the Alps into Italy; but the troops of Savoy, crossing the Simplon to Domo d'Ossola, drove the Swiss garrison away. The cantons of Unterwalden and Uri having next purchased the town and valley of Bellinzona, the Duke of Milan sent the celebrated condottieri Pergola, who, after an obstinate fight at Arbedo, in June 1422, obliged the Swiss to recross the St Gothard. In 1444, Charlès VII. of France sent the Dauphin Louis, at the head of the Armagnacs, composed of soldiers of fortune of all nations, against Basle. The two armies met outside that town, when, after a most desperate fight, in which out of one Swiss division of 1200 men only ten remained alive, the dauphin, struck with surprise at the conduct of the Swiss, concluded a truce and sought their alliance. The house of Austria had, however, gradually lost nearly all their possessions in Helvetia, when, in 1467, Duke Sigismund sold his last remaining property, Wintherthir, to the Swiss, and the patrimonial estates of that house, even the castle of Hapsburg itself, passed into the hands of the stranger.

With the exception of the disputes which took place between the people of the canton Appenzell, and of the Valais and Rhætian Alps, with their lords, and of the civil war which arose between Zürich and Schwytz relative to the right to some lands, no other event of great importance occurred in the history of Switzerland till the year 1474, when Louis XI. of France induced the Swiss to make a diversion in his favour, by falling on the territory of Charles the Rash, Duke of Burgundy, who had advanced to the very walls of Paris, and threatened Louis with the loss of his throne. This unprovoked attack induced the duke to offer terms of peace to the King of France and the Emperor of Germany, with whom he was at the same time at war; and these monarchs accepted his offer, leaving their late allies to meet his whole vengeance as they best might. Peace was no sooner concluded, than Charles

History.

Twice defeat the Duke of Burgundy.

determined to inflict condign punishment on the Swiss for their unjustifiable aggression, and in the spring of 1476 he crossed the Jura with an army of 60,000 men. He encountered the army of the confederates near the town of Grandson, and after a desperate conflict on the 3d of March, was totally defeated with the loss of a thousand men. His camp, with an immense booty, fell into the hands of the Swiss. A few months after, on the 22d of June, he was defeated, with prodigious slaughter, in a second action, near the little town of Morat; and on the 5th of January 1477, when the duke was slain in the battle of Nancy, the states of Upper Burgundy agreed to pay the confederates the sum of 150,000 florins to make peace with them.

These repeated victories procured for the Swiss the reputation of being the best soldiers in Europe; and a considerable number of them were hired to fight the battles of foreigners. The sudden wealth acquired by plunder and pensions excited its possessors to profusion and extravagance; their morals became corrupted, and the simple republican honesty almost disappeared. A spirit of cupidity and pride displayed itself among the rulers, and dissipation and love of plunder among the people; and the Swiss became notorious throughout Europe as the hirelings of any potentate who had battles to fight and gold to squander. Domestic troubles and feuds generally prevailed; the peace and security of the country were disturbed to such a degree by an armed and desperate banditti of disbanded soldiers and idle vagabonds, that in 1480, during the short space of three months, nearly 1500 assassins and robbers were condemned to death.

The confederation strengthened, A.D. 1481.

The confederates had been faithfully supported in their wars by the towns of Fribourg and Soleure, and in 1481 these requested to be admitted into the confederation. Their request was warmly supported by the town cantons; but the mountaineers of the forest cantons objected to it, and the dispute ran so high that, at a general congress of all the confederates, the deputies were at the point of coming to blows, and the confederation was threatened with dissolution. This catastrophe was happily averted by the eloquent remonstrances of a pious hermit, called Nicholas Lóvenbrugger. His simple but pathetic appeal had the effect of removing their differences, and Soleure and Fribourg were received into the Swiss confederation.

Upon the death of Louis XI. of France, Charles VIII. renewed the alliance with the Swiss cantons, and received permission to recruit soldiers among them in exchange for subsidies. The friendship of the confederation was now sought by many sovereigns, among whom the Pope, the Duke of Milan, the house of Austria, and even Mathias of Hungary were prominent. During the Italian wars for the possession of the Milanese and of Naples, Swiss volunteers were extensively used. So great became the importance of the confederation, that their offer of mediation between Charles VIII. and Maximilian of Austria was accepted, when, by the treaty of Senlis in 1493, the county of Upper Burgundy was ceded to Maximilian. Ludovico Sforza, having usurped the Duchy of Milan, the Swiss were offered the districts of Bellinzona, Locarno, and Lugano by Charles VIII. to obtain their assistance in the conquest of the Milanese. The cantons, with the exception of Berne, having accepted the offer, 20,000 Swiss troops joined the French army in Italy.

Independence of Switzerland acknowledged by the emperor, A.D. 1499.

In the year 1497, the Grisons entered into a treaty offensive and defensive with the confederate cantons. This alliance gave great offence to the Emperor Maximilian, who immediately collected his troops, and marched both against the Grisons and their Swiss allies. Battle after battle took place, in all of which, more particularly at Bregentz, Frastenz, Malserheyde, and Dornach, the Austrians were defeated; and the Emperor, having lost 20,000 of his troops in eight months, and finding further exertions useless, concluded a peace with the Swiss at Basle in September 1499, by which he acknowledged their unconditional independence as a nation. This war, called the Suabian war, was the last the Swiss had to sustain for their independence. For three centuries after this date no farther attempts were made against the liberties of the Swiss cantons, which assumed their station as an independent power in Europe. The towns of Basle and Schaffhausen were received into the confederation in 1501, and Appenzell was added in 1513, and completed the number of *thirteen cantons* which have constituted the Helvetic body till within our own times—namely, Zurich, Schwytz, Uri, Unterwalden, the three Waldstätten or forest cantons, Lucerne, Glaris, Zug, Berne, Fribourg, Soleure, Basle, Schaffhausen, and Appenzell. Besides these there were various confederates and associates who were in alliance with the cantons, and entitled to assistance in case of foreign attack. These were the Abbot of St Gall, the city of the same name, the Pays de Vaud, the towns of Mulhausen and Bienne, the Grisons and the Valais, the republic of Geneva, and the county of Neuchâtel.

Thirteen cantons.

In 1513 the Swiss defended Sforza, whom they had the year before installed as Duke of Milan, against France at the battle of Novara, and another Swiss army invaded Burgundy. After the death of Louis XII. of France, Francis I. invaded Italy, and at the battle of Marignano, called the *battle of giants*, defeated the Swiss, who retired across the Alps into their own country, and concluded peace the next year with France. In the subsequent wars of Francis I. in Italy, Swiss troops fought in his ranks, and at the disastrous battle of Pavia, in 1525, the Swiss lost no less than 7000 men.

Reformation.

Switzerland had scarcely obtained rest from her political wars when religious disputes arose among the cantons, and converted into fierce enemies those who had lately fought side by side in defence of their liberties. The unscrupulous sale of indulgences by the agents of Pope Leo X. in Germany, Switzerland, and the other countries, led to a searching inquiry into the whole of the papal system, and caused vast multitudes to renounce altogether the authority of the Church of Rome. In no country did the doctrines of the Reformation create a greater excitement, or meet with more zealous supporters, than in Switzerland. The inhabitants of Zürich, Berne, Schaffhausen, Basle, St Gall, and the Grisons, as well as of many parts in the neighbourhood of Geneva and Neuchâtel, eagerly adopted the opinions of Calvin and Zwingli; while the people of the Waldstätten, and of Soleure and Fribourg, being more secluded and ignorant, and more under the control of the priests, continued staunch in their support of the papal authority. Fierce animosities speedily arose between the reformed and the papal cantons, and various sanguinary wars were carried on for many years. During these internal broils, the territory of the confederation was violated, and their rights infringed without remonstrance; and such was the divided state of the cantons, that Austria, their ancient enemy, might perhaps have subdued them but for the jealousy of the other great powers. To prevent this danger, they, in concluding the treaty of Westphalia in 1648, formally recognised the independence of the Swiss confederation. But though Switzerland was thus secured against the invasion of any of the greater powers, it continued to be torn by internal dissensions. The arbitrary manner in which the large towns levied taxes upon the people of the country, and of the smaller towns and villages, caused great dissatisfaction, especially in the territories of Berne and Lucerne, and at length the peasantry rose up in rebellion against their rulers; and it was not until after considerable bloodshed that the revolt was quelled, and several of the chiefs who were taken alive were tried, condemned, and

Insurrection of the peasants.

History.

Civil war, A.D. 1703.

executed. Scarcely had this insurrection terminated when religious quarrels again broke out between the Protestants and the Romanists. Till near the close of the seventeenth century, Switzerland was distracted by the dissensions arising from this cause; and in 1703, the whole of the Protestant and of the Catholic cantons were openly arrayed against each other, and a civil war of several years' duration ensued. The immediate cause of the war was a quarrel between the people of Toggenburg and their superior the Abbot of St Gall, who had endeavoured in a fraudulent manner to deprive them of their privileges. Zürich and Berne took part with the people, while the Catholic cantons espoused the cause of the Abbot. Several battles were fought, and at length, in 1712, an army of Catholics, 12,000 in number, encountered 8000 Bernois at Vilmergen. The conflict lasted six hours, and in the end the Catholics were completely routed, leaving 2000 of their number dead upon the field. A peace was soon after concluded at Aarau, on terms advantageous to the victors.

French invasion.

From this period till towards the close of the eighteenth century, the state of Switzerland underwent no material alteration; and their internal discords paved the way for external aggression, and rendered them an easy prey to the grasping ambition of the French republic. In 1797, the French government, which had previously interfered in the affairs of Switzerland, manifested a determination to take possession of that country, and evidently sought for a pretence to come to an open rupture. The Swiss government placed their only hope in a passive neutrality, which in the end proved their ruin. For the sake of peace, they submitted with the utmost servility to the imperious and insulting demands of the Directory; but their humiliation did not save them from destruction. The emissaries of France laboured but too successfully to incite dissensions among the people, and the French rulers made these dissensions a pretext for their interference with the constitution of the country. In this way the bailiwicks of Valtelina, Chiavenna, and Bormio, which had been for centuries dependent on the Grisons, but whom the Grisons had obstinately refused to admit to a community of civil and political rights, were incorporated with the Cisalpine republic. Insurrections broke out in several of the cantons, and were rendered triumphant by the assistance of the French arms. Geneva and the Pays de Vaud placed themselves under French protection, and at length the French armies under Brune and Schauenburg, having defeated the Bernese army under D'Erlach in 1798, united Geneva to the French republic, and established the "*Helvetic Republic.*" The inhabitants of Berne, Soleure, Freibourg, and especially of the Waldstätten, made a brave but ineffectual stand in defence of their rights and liberties. The most horrible excesses were committed by the French soldiers; the towns were successively rifled of their public property, and great part of the country was laid waste, and many of the inhabitants reduced to utter destitution. A new constitution was framed by the French directory, which provided that Switzerland should form a single republic, one and indivisible, under a central government to be established at Aarau. The country was divided into twenty-two cantons, and the supreme authority was committed to two councils and an executive directory, in whom was vested the appointment of prefects and other authorities for the various cantons, which were thus transformed into departments, with the loss of their independence as separate states. After this new constitution was established, a treaty was made with France, by one of the articles of which the Swiss republic was bound to furnish to its new ally a force of 16,000 men. Great miseries were suffered by the people, from the excesses of every kind committed by the French troops, and their heavy requisitions and exactions. The small canton of Unterwalden refused to swear fidelity to the new constitution of the Helvetic republic; but after a desperate struggle it was subdued; the inhabitants were massacred without distinction of sex or age; and that district, once peaceful and happy, was left a scene of horrible desolation. During the campaign of 1799, Switzerland was the theatre of the struggle between the armies of Austria, Russia, and France; the Austrians under Hotze; the Russians under Suwarrov and Korsakov; and the French under Massena, Molitor, Soult, and Lecourbe. The mountain cantons were in consequence utterly ruined, a considerable part of the country rendered uncultivated, and the population reduced to little short of actual starvation. The Helvetic directory was suppressed in 1800, and an executive commission substituted in its room; and about seven months after, this commission dissolved the councils and convoked a new legislature. A general diet was called in September 1801, for the purpose of re-organizing the constitution of the country. Meanwhile the treaty which was signed at Luneville between France and Austria guaranteed the independence of the Helvetic republic, and the French troops were consequently ordered to evacuate Switzerland. Their departure was the signal for a general revolt. All the old factions were awakened afresh. The Pays de Vaud formed itself into a single republic; Uri, Schwytz, and Unterwalden took up arms against the Helvetian government; and the towns of Zürich, Basle, and Schaffhausen renounced their allegiance. A civil war appeared inevitable, when Napoleon Bonaparte offered himself as arbitrator between the contending parties, and ordered Marshal Ney to advance with a body of troops to the frontiers of Switzerland to enforce compliance with his mandates. The existing government was dissolved, a provisional government established, and deputies from all the cantons were ordered to assemble at Paris to deliberate upon a constitution for their country. Several months were spent in debates; and Napoleon, after he had heard and reflected on their representations, promulgated an act of mediation, which was drawn up with a view of reconciling opposite factions, and of fairly meeting various interests. It restored the old federative system, but introduced very considerable improvements. The act of mediation was promulgated 19th February 1803; and the Helvetic general government having been dissolved, and the new constitution put in force, the French troops finally evacuated the country.

Swiss republic.

The French

Independence of the republic.

Act of mediation, A.D. 1803.

From that time till 1814 Switzerland enjoyed internal peace; and during the gigantic wars which at that momentous period raged throughout Europe, this country rested in security amid the din of battles and the crash of falling empires, and made rapid progress in the arts of industry and in the career of intellectual and social improvement. On the downfall of Napoleon, the act of mediation was dissolved; but the integrity of the country was guaranteed by the Congress of Vienna in 1815. The territories formerly dependent on the Bishop of Basle, which had been annexed to France, together with Valais, Neuchâtel, and Geneva, were ceded to it as new cantons, and a constitution, based on the act of mediation, was framed for the whole cantons, now amounting to twenty-two. On the 7th of August 1815 the federal compact was finally signed by all the deputies in the diet assembled at Zürich. The deputies then repaired in procession to the cathedral, where they bound themselves by a solemn oath, and in the name of their constituents, to the faithful observance of its enactments.

New constitution, A.D. 1815

During the fifteen years which elapsed from 1815 to 1830, Switzerland enjoyed profound tranquillity. The general condition of the country was prosperous, and education was improved in several districts; but the civil and criminal laws remained in a defective state; the press was under a strict censorship, and various anomalies existed in the institutions of many of the cantons. Petitions were from time to time presented for the revision of the constitution of

Statistics. 1814, but were everywhere rejected by the councils. The first alteration of this state of things took place in the canton of Ticino in May and June 1830, and the example was speedily followed by all the other representative cantons of Switzerland. A new constitution established equality of political rights among all the citizens of the state; the direct system of electing all the members of the legislature, the elections to take place every four years; separation of the three powers, legislative, executive, and judicial; publicity of debates; liberty of the press, subject to fixed laws against libels; inviolability of person and property and the right of petition. No tax to be imposed unless sanctioned by a majority of two-thirds in the great council. The constitution not to be modified until twelve years shall have elapsed from its enactment; and then any alterations proposed in it must be submitted to the approval of the primary assemblies of the people. These alterations in their constitution were peaceably adopted by the most of the cantons; but in some of them popular tumults arose, which were speedily suppressed by the firmness and prudence of the Diet.

In 1834, the tranquillity of Switzerland was endangered by a considerable body of Polish, German, and Italian refugees, who had taken up their residence in Switzerland. In the month of January, some hundreds of these refugees made a sudden attack on the dominions of the king of Sardinia, in expectation of combined attacks and insurrections in other parts of the Sardinian monarchy. The Sardinian government made strong remonstrances to the confederation concerning this violation of the neutrality of the Swiss territory; and the courts of Austria, Prussia, and other German states, whose territories border on Switzerland, joined in these remonstrances. After some negotiations, the matter was brought to an amicable termination by the Swiss governments promising in future to send away from their territory all those who should attempt to disturb the tranquillity of other states.

The new law establishing a system of education for the clergy in 1839 was opposed at first by the Protestants, and the government at Zürich was dissolved. Aargau, in 1844, demanded the expulsion of the Jesuits; and in 1848, in order to effect this, bodies of armed men, called the Free Corps, were organised in several cantons. The Free Corps under Colonel Ochsenbein having invaded Lucerne were defeated, and in 1846 a separate league, termed the Sonderbund, was formed by the seven Catholic cantons for a defence against the Free Corps. In 1847 the Diet passed a resolution declaring the illegality of the Sonderbund and the expulsion of the Jesuits. The Federal army, under General Dufour, having, in November of that year, defeated the forces of the Sonderbund at Fribourg and at Lucerne, the Catholic cantons submitted, the Jesuits were expelled, and monasteries suppressed. On the 12th of September 1848, the new constitution was promulgated. With the exception of the attempt of a small aristocratic party to separate Neuchâtel from Switzerland and to incorporate it with Prussia—an attempt which at once called forth the strong opposition of the united cantons, and which led to the entire separation of Neuchâtel from Prussia and its incorporation into Switzerland—the cantons have since maintained their internal tranquillity and external independence. During the late contest in Italy, between Austria on the one hand and France and Sardinia on the other, Switzerland maintained the strictest neutrality. (For farther notice see GOVERNMENT, &c.)

Physical features. The physical features of Switzerland are remarkable, and for beauty and grandeur are unsurpassed by those of any other country in Europe, being a singular assemblage of lofty mountains, glaciers, valleys, ravines, rivers, and lakes. Two groups of mountains are spread over its surface, the Jura on the W. and N.W., and the Alps on the S.E. and centre. The Jura range is composed of six parallel ridges, lying in a S.W. and N.E. direction, with few interruptions and no spurs. This range extends from the neighbourhood of Geneva along the boundary between France and the Pays de Vaud, and then enters the canton of Neuchâtel, which it almost entirely covers, as well as the N.W. part of Berne, the greater part of Soleure and Basle, and north-western Aargau. The hill of Bœzberg is generally considered as the north-eastern extremity of the Jurassic chain, although some geographers have adopted the names of the Jura of Franconia and Swabia, for the chain which receives in Germany the very undeserved title of Rauhe Alp. The theoretic extension thus given to the Jura as far as the neighbourhood of Ratisbon, is justified by the analogy of direction, geology and fossil remains; but the same may be said for the southern prolongation of the chain to the south-west of Geneva, on both sides of the Rhone as far as Seyssel in France, and the Mont du Chat and Montagne de l'Epine, south-west of Chambery, thus increasing its extent to more than 350 miles, instead of 250 as formerly calculated. Geologically speaking, the Jura is composed of a nucleus of the bluish-grey limestone called liasic, covered with an upper stratum of oolitic limestone of a yellowish hue. Fossil remains are abundant in the latter, and have lately been found in great quantities in the Mormont, where the South-Western Railway has been the cause of a deep cutting at La Sarraz, in the canton of Vaud.

Jura.

The Jura scarcely attains one-third of the height of the Alps, yet, in proportion to its elevation, it is colder. The highest summits occur in the ridge near to Geneva and Lausanne, between the Fort de l'Ecluse and Orbe, partly in French territory. Although most frequently mentioned, through the observations of De Luc and De Saussure, the Dôle, 5453 feet, is not the highest; Mount Tendre, the Colombier, and the Reculet surpass it; and the Crêt de la Neige has been found by the French engineers to be 11 feet higher than the Reculet, 5642 feet. They do not, however, rise into peaks, being but little superior to the general level of the chain, and entirely destitute of the imposing features of the Alps. Passages across the Jura are little inferior in height to the general line of the crests; but in a few cases, such as the gorges by which the Rhone at Bellegarde, the Rhine, and the Doubs at Morteau, emerge from their upper to their lower valleys, the chain is cut through to its very foot, and sometimes presents stupendous chasms. The Perte du Rhône, and the Malpertuis near Billiat, 5 miles lower down, are the most renowned, the whole body of the river being confined, in this portion of its course, between two immense walls, of 600 feet in height, into a channel estimated at from 15 to 50 feet in width.

Alps. From the radiating direction of the ridges, most of them centring in the neighbourhood of the St Gothard, the Alps better deserve the name of a system than of a chain. The main ridge, called the Pennine Alps, forms the boundary between Canton Valais and Italy, and separates the basin of the Upper Rhone on the north from that of the Po on the south. To the south of Mont Blanc, the Alps consist of a number of partly detached groups without well-defined axes. Eastward they are divided into two great ranges, which enclose the valley of the Upper Rhone, and meet at Mount St Gothard, whence four ranges diverge: the Bernese Alps to the west; the Alps of Glaris and the northern Grisons to the north-east; the south-east branch, which forms the southern boundary of the Grisons on the side of Italy; and the south-west branch, connecting the St Gothard with the Pennine Alps. Between these ranges are four large valleys,—those of the Rhone, the Reuss, the Upper Rhine, and the Ticino. There is a remarkable difference in the shape of the Alps, as they cover the central and western parts of Switzerland, and in the Alps of Tyrol

Statistics. and the Grisons, or Rhætian Alps. In the latter, though the summits are inferior in altitude to those of Savoy, Oberland, and Valais, their mass is larger in comparison with the width of the valleys, and is generally raised so high as to have a greater part of its surface covered with snows and glaciers, or unfit for production. In Rhætia the valleys are mere deep alleys, which is the cause of the scanty population. The mean breadth of the highest portion of the Alps does not exceed 100 miles, but it widens considerably as you proceed eastward. Many of the valleys of the Grisons, Engardine, &c., are, however, wide and open, and the character of the country seems to vary accordingly as the geological conformation is crystalline, slaty, or calcareous. The

Glaciers. number of Swiss glaciers are reckoned at 605, of which nine-tenths, or about 540, are in the following cantons: 255 in the Grisons, 155 in Berne, and 130 in Valais. The supply of water they produce is discharged into the basins of the following rivers: 170 glaciers into the Rhine, 15 to the Linth, 25 to the Reuss, 160 to the Aar, 135 to the Rhone, 35 to the Po, and 65 to the Inn.

Natural divisions. M. Franscini, in his *Statistique de la Suisse*, divides Switzerland into five regions, viz., alpine region, of about 6950 square miles in extent, and containing 388,493 inhabitants; the eastern region, of about 1930 square miles, and 564,124 inhabitants; the northern, of about 2130 square miles, and 803,395 inhabitants; the western or Jurassian, of about 2990 square miles, and 517,804 inhabitants; and the Italian or southern, of about 1230 square miles, and 123,924 inhabitants. It may also be divided thus: 1. The alpine; 2. the Jurassic; 3. the southern part of the space lying between these two ranges, in the form of a plain with isolated hills; and, 4. the northern portion, traversed by ridges of moderate elevation.

Tableland. The tableland of Switzerland, lying to the north of the alpine region and east of the Jura, is the finest and most productive of the whole. It slopes from south to north, from the foot of the Alps to the Rhine and the Lake of Constance, and includes the cantons of Vaud and Fribourg, the greater part of Berne, Lucerne, and Aargau, the whole of Zürich, Zug, Thurgau, and part of St Gall. The elevation of this tableland varies from 1200 to 1800 feet above the sea. Its surface is furrowed by numerous valleys, which generally run from south-east to north-west. Each of these valleys is divided by its river, and various ranges of wooded hills follow the course of the streams.

Rivers. Four-fifths of Switzerland belongs to the basin of the

Rhine. Rhine. This river has its rise in the Alps of the Grisons, receives the waters of some of the glaciers of that lofty region, and is at its source, Hinterrhein, at the foot of the glacier, 7268 feet above the level of the sea. Thence it pursues a northerly direction to the lake of Constance, receiving on its left the Tamina from the canton of St Gall, and on its right the Ill from the Austrian territory. It issues from the north-west portion of Lake Constance, at the town of Stein, where it is 1300 feet above the sea; it then flows in a tortuous but generally westerly direction to Basle, passing by Schaffhausen, Waldshut, and Seckingen, receiving the waters of the Thur, the Aar, and the Birs, forming for a direct distance of about seventy miles the northern boundary of Switzerland. At Basle, where it is 821 feet above the sea, it turns abruptly to the north and leaves the Swiss territory. The Falls of the Rhine are celebrated for their grandeur.

Aar. The Aar flows through the lakes of Brientz and Thun, into the Rhine, having previously formed a cataract at Handeck; and receives the waters of the Limmat, Saane, Thiel or Ziel, Emmen, and Reuss. At Aarberg the Aar is 1469, and at its junction with the Rhine 1033 feet above the level of the sea.

Linth. The Linth, a rapid stream, rises in the Alps of Glaris, it then flows through the lake of Wallenstadt, and is called the Limmat: after marking the limits between Schwytz and St Gall, it forms the lake of Zürich, and, flowing through part of the cantons of Zürich and Aargau, enters the Aar below the confluence of the Reuss. Statistics.

The Thur has its sources at Wildhaus, in the mountains Thur. of High Toggenburg, in the canton of St Gall, and enters the Rhine below Rheinau. Its level at its source is 3358, at Bischoffzell 1500, and at its confluence with the Rhine, 1141 feet above the level of the sea.

The Birs has its rise in the Jura, to the east of the pass Birs. of Pierre Pertuis, flows through the cantons of Berne and Basle, and enters the Rhine just above the town of Basle.

The Thiel or Zihl also has its source in the Jura, under Thiel. the name of Orbe, and is at the Lac de Joux 3312 feet above the sea; flows through the Lac des Brenets, where it disappears, and after a great subterranean descent, makes its re-appearance at the spot called "Source of the Orbe," where it is 1459 feet above the sea; it then flows through the lakes of Neuchâtel and Bienne, and soon after, leaving the latter, enters the Aar at an altitude of 1416 feet above the sea.

The Saane has its source in the Bernese Alps, and after Saane. a rapid course of about 70 miles, in which it passes Saanen, Freibourg, and Laupen, enters the Aar a few miles below the latter town.

The Rhone is formed from a glacier below the Pass of Rhone. the Furca, in the north-eastern extremity of the Valais, at a height of 5500 feet above the sea. Descending rapidly to Oberwald, it proceeds in a south-west direction past Brieg and Sion to Martigny, when it turns abruptly to the north-west, and continues in that direction to its entrance into Lake Leman. It issues from this lake at Geneva, below which it receives the Arve from the valley of Chamouni, and quits the Swiss territory near Chanci, the last village of the canton of Geneva.

The Arve does not strictly belong to Switzerland, the Arve. greater part of its course being through Savoy, but it is the most considerable alpine tributary to the Rhone, into which it flows about 1 mile below Geneva. It is at the source, near the village Du Tour, 4277 feet above the sea, has a course of 65 miles, and at its mouth is 1222 feet above the sea-level: it discharges into the Rhone, on the average, 4300 cubic feet of water per second.

The Inn rises in some small lakes near the Maloya Inn. Pass, is fed by the glaciers on the north side of the Bernina range, and, after flowing through the Grisons in a general N.E. direction, leaves the Swiss territory at Finstermünz.

The Ticino issues from Mount Gries, and traverses the Lago Maggiore in Italy.

The Swiss rivers are subject to rises during the summer Ticino. season of sometimes as much as 16 feet. Their lowest waters last generally from the beginning of November to the end of March, their highest state is in the month of June; and from the middle of July to the end of October they preserve their average volume. The Falls of the Rhine are 78 feet in height, those of the Doubs 88 feet, and the underground fall of the Thiel or Orbe, from the valley of Joux to its re-appearance near Vallorbes, 741 feet.

The lake of Geneva or Leman, the great reservoir of the Lakes. Rhone, spreads in the form of a crescent, its northern bank L. Geneva. being about 56 miles in length, and the southern bank about 46. Its breadth near the centre is about 9 miles, but it becomes much narrower towards Geneva. The surface of the lake is 1230 feet above the level of the sea, its greatest depth is about 1100 feet, and its area 340 square miles. It receives several streams, the principal being the Dranse, from the Alps of Savoy, and the Vevayse and the Venoge, from the Swiss side. The lake of Geneva is known to have been frozen over only twice—in A.D. 762 and 805. It is subject to remarkable risings, called *seiches*, of from 4 to 5 feet, lasting about 25 minutes. Several steamers

Statistics.

ply between Geneva, Morges, Ouchy for Lausanne, Vevey, and Villeneuve.

L. Constance.

The lake of Constance, or Boden See, is about 42 miles long and 9 miles wide. It surface is 1300 feet above the level of the sea, its area is about 290 square miles, and its greatest depth is 1800 feet. Numerous steamers navigate this lake.

L. Four Cantons.

The lake of the Four Cantons, or Vier Waldstätter See, is 26 miles in length. The southern part, called the lake of Uri, is a sheet of deep water, 8 miles long, and between 1 and 2 broad, running from south to north between two almost perpendicular ranges of mountains; a narrow channel unites it with the middle basin, which is about 9 miles in length and about 2 wide. Another strait leads from the middle into the western basin, called the lake of Lucerne, the widest and finest of the three. The surface of the lake is 1428 feet above the sea, and its greatest depth is 1000 feet. The country around the Waldstatter See is the cradle of Swiss independence, and many of the localities possess great historical interest from the exploits of its heroes. Steamboats ply between Lucerne and Küssnacht, and Lucerne and Fluellen, the port of Altorr.

L. of Zurich.

The lake of Zürich, formed by the Limmat, is 24 miles long, and from 1 to 2 miles wide. Its greatest depth is 600 feet, and its surface is 1341 feet above the level of the sea. Steamboats run on this lake between Zürich, Horgen, Richterschwyl, Rapperschwyl, and Schmerikon.

L. of Neuchâtel.

The lake of Neuchâtel is about 30 miles in length, and 5 miles broad throughout one-half of its length. It is 1426 feet above the sea, and has a depth of 350 feet. Steamers ply on this lake, and through the Thiel river on that of Bienne, connecting the railways of Yverdon and Nidau.

L. of Bienne.

The lake of Bienne is about 10 miles long and 2 wide; the level of its surface is 8 feet below that of Neuchâtel, and its greatest depth is 217 feet.

L. of Wallenstadt, &c.

Besides these there are several other lakes of considerable extent, such as the lake of Wallenstadt, or Wallensee, an expansion of the Seer, and lately artificially connected with the Linth, 11 miles in length, and 1394 feet above the level of the sea; and the lakes of Brientz and Thun, both formed by the Aar; the latter, 13 miles long, has a depth of 800 feet, and is 1823 feet above the sea. Steamboats ply on this lake, which is much visited by tourists from Berne. The fish these lakes contain are trout, pike, salmon, tench, carp, perch, and a very delicate fish called umber. The collective extent of the twenty-two largest lakes is about 1035 square miles, of which 260 have to be subtracted as being out of the Swiss territory. The remainder, about 775 square miles, is about one-twentieth of the whole country. The variation of level in the lake of Geneva is 6 feet, and in the lake of Neuchâtel 7 feet 5 inches; the lowest state in the latter is in August, while in the former it is in spring.

Metals.

Switzerland receives a considerable supply of metals from abroad, a great portion of which, however, is again exported in a manufactured state. Iron is produced to the amount of about 10,000 tons annually, of which 5000 tons of excellent character is produced by the Bernese Jura, 1900 tons by Soleure, 1100 by Schaffhausen, and 450 tons from Ardon in the Valais. Salt is produced to the amount of 13,000 tons; of which the works at Schweitzerhall, near Basle, yield 11,000 tons, and the remainder by those at Bex; the salt works at Rheinfelden and Kaiser Augst in Aargau have been abandoned. About 250 tons of copper is produced annually, and 500 tons of lead. There are some mines of anthracite coal of a poor quality, at Outre-Rhône, Salvant, Iserable, in Valais, and a few other places. Among the other mineral productions of Switzerland are marble, alabaster, gypsum, slate, granite, and other kinds of building stone; sulphur near Lake Thun; asphalte in the Valais; and particles of gold are found in the sands of some of the rivers, but not in sufficient quantities to pay for the search.

Springs.

The number of mineral springs in Switzerland is very great; there are as many as twenty first-rate watering-places, and a great number of inferior ones. The most frequented are those of Pfeffers and Leuk. The temperature of the springs at the former is 36°·6′ centigrade, or 98 Fahr., and at the latter 50°·6′ centigrade, or 123 Fahr. Those of Baden, Schinznack, St Moritz, Heirnichsbad, Rosenlaui, and Stachelberg, are also well known, and much visited.

Climate.

The observations of Kaemtz on the Rigi, Schöner on the St Gothard, Bravais on the Faulhorn, and Plantamour on the Great St Bernard, show the average diminution of temperature to be of 1° of the centigrade thermometer for about 570 feet of ascension. The temperature of a place does not, however, altogether depend on its elevation, but also upon the proximity of large glaciers, the reflection of heat from adjoining slopes, and in the mobility of the atmosphere. The slopes are heated by ascending currents of warm air from the valleys; the neighbourhood of glaciers has always, and that of lakes very often, a cooling influence, and are subject during the warmest hours of a summer day to a motion of cool air originating in the same cause as that which produces the land and sea breezes on the shores of the ocean. At a height of about 8000 feet the average temperature is not above freezing point. The average temperature of Berne is 45° Fahr., that of Basle 46°, and that of Geneva 46½°.

Animals.

Among the wild animals of Switzerland are the bear, wolf, wild boar, ibex, deer, and game of all kinds; the marmot, ermines, &c. Large birds of prey are common in the mountains, but the chamois is becoming scarce, and bears and wolves are found in some districts only.

Switzerland is distinguished for the extent and excellence of its pastures, and the number of cattle they support, though in opposition to received opinion, the Swiss import more cattle than they export; the numbers of late years having been in the average 72,000 and 50,000; they are, however, imported when young and sold when fat, in addition to which there is greater profit derived from cheese and hides than from selling the cattle themselves, as their keep is not expensive. Early in the spring, on the disappearance of the snow, they are sent into the lower pastures; in the beginning of June they are moved into the middle pastures, and a portion of them ascend into the highest pastures during July and August. The number of cattle in Switzerland is estimated at 875,000; the number of horses at 105,000; that of sheep 405,000; that of goats 376,000; and that of pigs 279,000; the cattle and goats are on the increase, but the horses and pigs are on the decrease.

Agriculture.

In Switzerland agriculture is carried on to the greatest perfection that the climate and soil of such a country will allow. By means of trenches and sluices water is conveyed from the mountains to any required point: extreme care is taken to economise and render available the manure obtained from their herds; and great judgment is shown in the culture of the different kinds of soil. Even apparently sterile and unavailable slopes are made use of, mould being carried up from below and spread upon them in the form of terraces. The use of animal labour in agricultural operations is not extensive, chiefly owing to the rugged surface of the country; and nearly everything is done by hand. The grain crops are inferior in quantity, but the pasturage is extremely good, and its bright verdure such as to render it a distinguishing feature of the country. The vine is cultivated in several localities, and some of the wines produced are of a very good quality. The cultivation of tobacco is undergoing great development, especially in the northern part of Vaud, which yields a cheap though rather indifferent produce. The domestic economy of a Swiss country household is very simple; from their land and cattle they can supply nearly the whole of their wants,

Statistics. and the profits of their dairy afford them the small sums of money they require. The quantity of timber at present exported exceeds L.86,000 in value, but this must ultimately have a very bad effect on the country, as it is so far beyond the rate of growth.

Commerce. Previous to 1852 commerce throughout Switzerland was limited by a number of internal duties, which were exacted at many of the frontiers of particular cantons. From that time, however, a general line of custom-house offices has been drawn round its frontiers, and one general tariff of duties established by the central government, which, though moderate, is very complicated, and shows that the Swiss legislators have derived but little profit from the example given to Europe by England and Sir Robert Peel. Nobody would believe that singing birds have the honour of figuring in the Swiss tariff. Geneva, where free trade had always been practical, suffered very much by the change, but other cantons gained in proportion as they were more or less fettered previously. The national import duties are divided by the federal government, and each canton in proportion to the number of inhabitants. Each canton is at liberty to levy excise duties. The federal revenue and expenditure of Switzerland for each of the years 1855, '56, and '57, is as follows:—

Import duties.

	1855.	1856.	1857.
Revenue,.........	L.642,600	650,000	627,440
Expenditure,....	619,000	643,320	608,240

Transit trade. Since the abolition of internal customs, the transit trade has increased from 391,000 quintals in 1852 to 597,000 in 1856, out of an import trade which amounted in bulk to 1,890,400 quintals in 1840, 2,652,200 in 1849, and 10,297,055 upon an average from 1852 to 1857—a rate of increase greatly beyond that of the population. The progression is the same with regard to value; the imports and exports together amounted in 1842 to L.18,553,643, in 1852 to L.28,452,219, and, on the average, from 1852 to 1855, to L.40,606,177. The last sum gives a proportion of L.16 to each individual; while in Belgium it is L.12; in France, L.4; in the Zollverein, 66s.; in Sardinia, 50s.; and in Austria, 34s. Of the total sum of L.40,666,177, L.14,000,000 should, however, be deducted as only transit trade, reducing the actual amount due to each individual Swiss to L.10, 10s. France and Lombardy receive but little Swiss produce for their home consumption, while Switzerland receives from the former wines, spirits, and corn, and from the latter silk to a large amount.

Railways. The railway system of Switzerland, considering the physical difficulties presented by the country, is very extensive, most of the large towns of the north and central portions being connected by this means. The electric telegraph is also much used, there being a total length of over two thousand miles laid down.

Manufactures. The watches, for the manufacture of which Switzerland is famous, are mostly made at Geneva, Neuchâtel, Val St Imier, the valley of Joux, and the Val de St Croix, in the Jura of Vaud. This branch of industry, together with that of jewellery, employs about 23,000 people, and the number of watches made annually is about 190,000. The value of those exported in 1853 was L.117,000, and L.255,000 in 1857; but though the quantity produced is thus greatly on the increase, the quality is said not to be so good as formerly, owing, it is believed, to the growing immorality of the workmen in the large towns.

The silk manufactures employ a great number of people in the canton of St Gall, and the manufacture of ribbons is carried on at Basle. In addition to the large quantity of silk imported for these branches of industry, a considerable quantity is produced in Switzerland itself. About five-sixths of the raw material imported comes from Lombardy, and about two-thirds of the manufactured fabrics exported passes through France, and the remainder through the Zollverein. The cotton manufactures are very animated, and it is estimated that they employ more than 660,000 spindles. In Zurich there are 330,000 spindles and 76 mills at work; in Argovia, 137,000; in St Gall, 85,000; in Glaris, 62,000; and in Thurgovia, 22,500.

The manufacture of cutlery and cheap mathematical instruments, a great number of which come to the London market, is carried on to a great extent at Aarau and Zurich.

Population. Switzerland forms the centre where three great continental races meet; the Teutonic Swiss occupy the northern cantons, the French the western, and the Italians the canton of Ticino and the southern valleys of the Grisons; while those speaking the language called *Romansch* a dialect somewhat similar to Latin, occupy half the Grisons. Of the whole population 1,680,000, or about two-thirds, speak German; 540,000, French; 130,000, Italian; and 42,000 the Romanic dialects in the Grisons. Notwithstanding these peculiarities of language, and the variety of physical features, they have lived so long together in a state of confederation as to have assumed quite a national character, and may be looked upon as one people. The French language has long been on the increase.

Births and deaths. The annual average of the births in Switzerland during the three years 1850, '51, and '52, was 70,000, being in proportion to the population as 1 to 34. The proportion of the males to the females with regard to the number of births is as 15 to 14, while to the total population it is as 40 to 41; so that, though there are more males born, they are on the average shorter lived than the females. The porportion of illegitimate to legitimate births is as 1 to 18. The annual average of marriages during the same period was 16,270, being in proportion to the population as 1 to 147. The average annual number of deaths during these three years was 55,500, being in proportion to the population as 1 to 43.

Before 1798 Switzerland consisted of a confederation of states of three very different kinds:—1. Thirteen cantons; 2. the subjects or vassals of these cantons; and 3. the allies of these cantons. The federal bond uniting the various cantons was very loose, and there was no permanent sovereign body, or central government, equally acknowledged by all. No important questions could be decided in the general diets, unless it had been previously debated and decided on in the councils of each of the cantons. The subjects of the Swiss were either subjects of certain particular cantons, or common bailiwicks subject to all the cantons. The whole population of the thirteen cantons at the close of last century was about 1,000,000; that of their subjects was about 250,000; and that of their associates and confederates, and the subjects of these confederates, amounted to nearly half a million more. Altogether, the territory belonging to the Helvetic Federal Body contained a population of about 1,700,000.

Government. By the present constitution, promulgated in 1848, the general affairs of the Confederation are intrusted to a National Council, the members of which are elected for three years, and in the proportion of one to 20,000 inhabitants; and the council of the states, composed of forty-four deputies, two for each canton. Formerly these used to assemble at Berne, Zürich, and Lucerne alternately, but Berne is now fixed upon as the regular place of meeting. A president of the Federal Council and six members, to form an executive government, are chosen by the national council and the council of the states together every three years. The two councils also elect the Tribunal Fédéral, consisting of eleven judges, for three years; and conflicts between the cantons, and between them and the federal council, are decided by this high court. Each canton has sovereign authority in its own affairs, with the exception of certain rights which are vested in the federal power, such

Swords || Sybaris.

as the declaration of war, the conclusion of peace, custom-house duties, post-office, telegraphs, &c. The form of government is *republican*, and is vested in assemblies elected by the people, all the male population, above a certain age, having a vote, without respect of property qualification. The cantons are subdivided into 177 districts and 3059 communes. The general desire seems to be towards a greater amount of centralization than formerly, but it is still thwarted by the private interests and jealousies of separate cantons. They have, however, recently adopted a national coinage and system of measures; the coinage being the same as that of France.

Army. There is no *standing* army in Switzerland, but every able-bodied man, up to a certain age, is called out for a short period in every year and drilled. The number of the *élite*, or those who are supposed always to be in readiness for service if required, is 77,000; the reserve, 43,000; and the landwehr, 57,000; making thus a total of 177,000 men in the event of an emergency. In the winter of 1856, when threatened by Prussia, they placed on foot, within a few months, an army of 200,000 men, well provided with artillery, and proposed to encounter one of the first powers in Europe. The Swiss are very skilful marksmen, devoting a great deal of time to rifle practice, and holding annual matches near one or other of the great towns, at which all the best shots compete for a prize. (N. S.)

Sydenham.

SWORDS, a market-town of Ireland, on the right bank of a river of the same name, in the county and 8 miles north by east of Dublin. It is for the most part very meanly built; and has a Gothic church, a Roman Catholic chapel, a small court-house, and an endowed school. There is neither trade nor manufactures, and the place is in a very decaying condition. Here stands one of the remarkable round towers of Ireland, about 80 feet high. Pop. 1294.

SYBARIS, a celebrated ancient city of Magna Græcia, near the west shore of the Gulf of Tarentum, between the mouths of the rivers Sybaris and Crathis. It seems to have been the earliest Greek colony in this part of Italy; for it is said to have been founded in 720 B.C., by colonists from Helice in Achaia. Situated as it was in a fertile plain, the new settlement rapidly rose to a high degree of prosperity, and became a large and populous city. Contrary to the custom of most of the Greek states, settlers from other countries were freely admitted at Sybaris; and this was very probably one cause of its size and prosperity. Its wealth and luxury were proverbial, and have probably been much exaggerated by ancient writers. But there is no good reason to doubt that Sybaris had attained, in the sixth century B.C., a greater amount of power and riches than had been reached by any Greek state before. Its territories extended to the opposite shore of the peninsula, where it founded the colonies of Laus, Scidrus, and Posidonia; and, according to Strabo, it was mistress of twenty-five dependent cities, most of them probably towns in the interior. Numerous details are given by ancient writers about the magnificence and luxury of the Sybarites; but besides the intrinsic absurdity of many of these tales, it is a suspicious circumstance that these accounts are given with so much minuteness, while we are told so little of the history of the city, with the exception of these events that led immediately to its fall. One of these wonderful stories relates how Sminclyrides, a citizen of Sybaris, went to court Agarista, daughter of Clisthenes, tyrant of Sicyon, followed by a train of more than 1000 of his own personal attendants, including cooks, fishermen, &c. Unfortunately, with all this equipage, he did not find favour with the young lady or her father, although he surpassed and astonished all Greece with his magnificence and luxury. There is probably very little truth in these accounts of Sybaris; and as little in the assertion of Strabo, that it could bring into the field an army of 300,000 of its own citizens.

It seems to have arrived at its greatest prosperity soon after 580 B.C.; but towards the middle of that century political dissensions rose to a violent degree. The government had been for a long time oligarchical, probably in the hands of the wealthier classes; but a democratic party, under a leader called Telys, at length succeeded in gaining the upper hand, and compelled a number of the opposite party to go into exile. The aristocratic city of Crotona afforded a refuge to the fugitives; but Telys and his supporters demanded to have them given up. This demand having been refused, led to a declaration of war against Crotona on the part of the Sybarites. The two armies met near the river Trais, where the Sybarites, though more than three times the number of their enemies, were totally defeated with great loss. The Crotonian army pursued the fugitives to the very gates of Sybaris, which they took without further resistance. Determined to carry out their vengeance to the very last, they laid the city in ruins, and turned the course of the Crathis into it, so that it should never more be inhabited. This happened in 510 B.C. Those who survived its ruin took refuge in the colonies of Laus and Scidrus; and when they attempted, in 452, to rebuild the city, they were driven away by the Crotoniats, a little more than five years after. On this they applied for assistance to the Spartans, but without success; afterwards, however, they obtained the aid of the Athenians, who resolved not only to restore these settlers, but to send colonists of their own along with them. The result of this was the foundation of Thurii, near the site of the ancient city; but Sybaris itself never was restored. No traces have yet been discovered of its remains.

SYDENHAM, a hamlet and chapelry in the parish of Lewisham, Kent, 4 miles from Deptford, and 8 miles S.S.E. from London, lies partly in a deep and pleasant valley, and partly on a considerable hill, environed by much agreeable scenery, which, spite of railroads, still retains somewhat of its rural character. Houses, however, are rapidly springing up on every side, and Sydenham will soon form a portion of suburban London. There are here (1.) a station on the London and South Coast Railway, bringing the metropolis within twenty minutes' ride; and (2.) at Lower Sydenham, a station on the London and Southborough Road branch of the Mid Kent Line. — Situation and statistics.

The population of Sydenham, in 1841, was 2915; in 1851 it had increased to 4501. In the former year there were 516 inhabited houses, 40 uninhabited, and 20 building; in the latter, the inhabited houses numbered 801; the uninhabited, 47; houses building, 28. In 1640 a mineral-spring, afterwards known as the Sydenham Wells, was discovered in this vicinity. Its properties were mildly cathartic, and resembled those of the Epsom waters; but it has long ceased to be recommended by the faculty, or made use of by invalids. The poet Campbell was a resident at Sydenham from 1804 to 1821. His house was situated on Peak Hill, looking towards Forest Hill. He left Sydenham for lodgings at 62 Margaret Street, Cavendish Square, on assuming the editorship of the *New Monthly Magazine*. The living of Sydenham is a perpetual curacy in the patronage of the Earl of Dartmouth, valued at L.248 yearly. The church, a neat and graceful edifice, is dedicated to St Bartholomew.

Crystal Palace. The Crystal Palace is situated within the Sydenham district, and a branch from the London and Brighton Railway diverges at

Sydenham. the Sydenham station to a terminus within the palace grounds. Its site forms a portion of an estate of 290 acres, known as *Penge Place* (purchased by the Crystal Palace Company in 1852), and from its great elevation commands a fine view of the cloudy roofs of the great metropolis, and extensive prospects in Kent and Surrey. The building itself is a great improvement upon the structure of glass and iron which enshrined, in 1851, the industrial exhibition of all nations in Hyde Park, and must be regarded as a satisfactory monument of the engineering skill and mechanical enterprise of the England of the nineteenth century. The Hyde Park building was marked by too great a monotony, and its elevation was disproportionate to its length; but in the Sydenham palace an agreeable effect is produced by the three transepts, by the lofty arch of the centre, and the recesses in the garden front. The dimensions are given by the authorities as—length, 1608 feet; greatest width, 384 feet; general width, 312 feet; area, including wings, 603,072 feet; height of nave, from ground floor, 110 feet 3 inches; height of central transept from ground-floor, 174 feet 3 inches; height of central transept from basement, 197 feet 10 inches; area occupied by the galleries, 261,568 feet. The girders which support the galleries and roof work are of cast-iron, and 24 feet long. The first gallery is reached by a flight of stairs, 23 feet high; the upper gallery, by spiral staircases, about 40 feet in height. If all the columns made use of in this superb structure were laid out in a straight line, they would extend $16\frac{1}{2}$ miles. The iron employed amounts to 9641 tons, 17 cwt., and 28 lb.; the superficial quantity of glass used is 25 acres, and weighs 500 tons. The colonnade leading from the palace to the railway station is 720 feet long, 17 feet wide, and 18 feet high, consuming, so to speak, 60 tons of iron, and 30,000 superficial feet of glass.

The palace is heated by hot water, on a system designed by its principal architect, Sir Joseph Paxton, who had formerly submitted it to the test of experience at Chatsworth. On this point it will be sufficient to state, that the hot water pipes employed, if placed in a straight line, would reach 60 miles; and that the boiler-houses erected in the basement story contain 22 boilers, each holding 11,000 gallons of water.

The interior. The interior of the palace presents many objects of attraction, blending together, perhaps too confusedly, the beauties of art and the wonders of mechanical industry. How far the palace may advantageously be made use of as a grand educational agency, working at a definite object, it is not now our province to inquire; but in spite of many errors of judgment, and, as it seems to us, of taste, there can be no doubt that it exercises a considerable and a beneficial influence upon the minds of its visitors, and that its general tendency is to enlarge their comprehension, refine their ideas, and quicken their perceptions. The most attractive features are, probably, the *Courts;* those portions of the building which are devoted to the illustration of architecture, domestic and ecclesiastical, in its various stages of progress. In these the curious visitor may observe a reproduction of the houses of the Greeks, Romans, and Pompeians; and a visible embodiment of the distinctive features of the Byzantine art; English, German, and French mediævalism; the Renaissance style, the Elizabethan, and the Italian. The Alhambra, the glories of old Thebes and Memphis, and the wonders of Nineveh are also illustrated—in miniature, it is true, but with considerable effect and commendable accuracy. The arrangement of these details were confided to such authorities as Messrs Digby Wyatt, Owen Jones, Penrose, Layard, Bonomi, J. B. Waring, and George Scharf, jun., names which may reasonably be accepted as a guarantee for historical fidelity and general excellence.

Sculpture. Not the least praiseworthy feature of the internal arrangement is the exhibition of fine sculptures from the antique, and copious illustrations of the genius of modern art. The master-pieces of the artists of the old classic world; of the greatest geniuses of France, Germany, and England, are here brought before the eye of the spectator in such juxtaposition that he may, if he will, contrast with ease their relative excellences, the elegance of Canova with the severe grandeur of Thorwaldsen, and the ideal beauty of Baily with the classicism of Gibson. From Paris and Munich, from Florence and Venice, from Rome and Milan, experienced emissaries have procured casts of world-famous statues, and accurate copies of notable frescos, monuments, screens, ornamental arches, or richly-decorated doorways, which, if we accept the well-known axiom of Keats, that "a thing of beauty is a joy for ever," must amply repay the visitor to the Crystal Palace for any fatigue his perambulations of its magnificent corridors may entail.

The gardens. The palace and its grounds occupy an area of about 200 acres, and it may be noted, says the official *Handbook*, that, in the formation of the gardens, the same uniformity of parts is adhered to as in the building itself; that is to say, the width of the walks, the width and length of the basins of the fountains, the length of the terraces, the breadth of the steps, are all multiples and submultiples of the one primary number of eight. Thus, an harmonious combination is effected, which the spectator admires and acknowledges, though ignorant of its cause.

The length of the upper terrace is 1576 feet; its width, 48 feet. The central flight of steps, and the grand central walk, are each 96 feet wide. The lower terrace is 1664 feet in length, and 512 feet in width. The total length of the garden front of this terrace is 1896 feet; of the central walk already alluded to, 2660 feet. The gardens exemplify the more attractive features both of the Italian and English styles, and from their gradual slope are susceptible of infinite effects of light and shade, while commanding, from almost every point, the richest prospects imaginable of the surrounding country.

The water-works. The water-works claim from us a word of passing notice. There are two series of fountains—the upper and the lower; the upper consisting of nine basins, of which the central is of superior dimensions; the lower, of the iron water-temples, from which twelve cascades pour down a volume of water, extending a distance of 600 feet; and the two great fountains, into whose basins this volume rushes in a sort of cataract, 120 feet in breadth, and 30 feet in fall. The smaller fountains in the upper series fling their columns of spray to a height of 90 feet, the central fountain attains an altitude of 150 feet: the iron water-temples are 60 feet in height. The basins of the great fountains, the largest in the world, are 704 feet long, with a diameter of 418 feet. A great central column mounts in each to the astonishing altitude of 280 feet, each column composed of 50 2-inch jets. The whole system of fountains provides for the action of 11,788 jets, making use of 120,000 gallons of water per minute. To Sir Joseph Paxton is due the credit of their construction.

Admission to the palace is gained by yearly tickets, at one guinea each; and day-tickets, one shilling each, on every day but Saturday, when their price is two shillings and sixpence.

SYDENHAM, THOMAS—the greatest name in English practical medicine—was born in 1624 at Winford Eagle, Dorsetshire, where his father, William Sydenham, had a fine estate. He was a commoner of Magdalen Hall, Oxford, 1642, but was obliged to leave that city when it became a royal garrison, not having taken up arms for the king, as the students of those days generally did. In 1649, after the garrison delivered up Oxford to the Parliamentary forces, he returned to Magdalen Hall, and was created Bachelor of Physic on the Pembrokean creation, when Lord Pembroke became chancellor of the university, and honorary degrees were conferred. This was in April 1648. He had not previously taken any degree in arts. He then, on submitting to the authority of the visitors appointed by the Parliament, was made by them (at the intercession of a relative) Fellow of All Souls, in the room of one of the many ejected Royalists. He continued for some years earnestly prosecuting his profession, and left Oxford without taking any other degree. He was also, according to his own account, in a letter to Dr Gould, fellow-commoner of Wadham College in the year Oxford surrendered. It is not easy to understand why he went to Wadham, as he was not a fellow but a fellow-commoner—equivalent to a gentleman commoner in Cambridge—unless it was that, on returning to Magdalen Hall, he found himself, as a Parliamentarian, more at home in Wadham—where the then head was John Wilkins, Cromwell's brother-in-law—a man of genius and of a keen scientific spirit, and afterwards and still famous as Bishop of Chester—one of the founders of the Royal Society, which first met at Oxford; and author, among other works, of a discourse on a *Universal Language* and of an *Inquiry as to the best Way of Travelling to the Moon;* a man of rare parts and worth, and of a liberality in religion and science then still rarer, being according to Anthony Wood, "an excellent mathematician and experimentist, and one as well seen in the new philosophy as any of his time;" such a man would be sure to cordialise with Sydenham, who was of the Baconian or genuine Empiric school; and who, in the "new philosophy," saw the day spring of all true scientific progress. It is not clear when Sydenham settled in Lon-

don, or more properly speaking in Westminster, it certainly was before 1661. In 1663 he was admitted a licentiate of the College of Physicians of London, he never was a fellow; his degree of doctor of medicine was taken at Cambridge in 1676, long after he was in full practice, his college being Pembroke; his diploma is signed by Isaac Barrow. His reason probably for taking a Cambridge degree may have been that his eldest son was a pensioner at that college.

Sydenham's elder brother, William, was a distinguished soldier and politician during the Commonwealth. This, along with his own likings, and his love of the new philosophy, prevented him, during the reigns of the second Charles and James, from enjoying court favour. It has often been doubted whether Sydenham actually served in the army of the Parliament; but from an anecdote known generally as Dr Lettsom's, but which appears first in a curious old controversial book by Dr Andrew Brown, the *Vindicatory Schedule*, published two years after Sydenham's death, it is made quite certain that he did.

Before settling in London he seems, on the authority of Desault, to have visited Montpelier, and to have attended the lectures of the famous Barbeyrac. After this he devoted himself to his profession, and became the greatest physician of his time, in spite of the court, and of the College of Physicians; by one of whose fellows—Lister—he was called "a miserable quack." He suffered for many of the later years of his life from the gout, his description of which has become classical, and died in his house, Pall-Mall—or as he spells it, Pell-Mell—in 1689. He lies buried in St James, Westminster, with the following noble because true inscription:—"*Prope hunc locum sepultus est Thomas Sydenham, medicus in omne ævum nobilis, natus erat, A.D.* 1624; *vixit annos* 65." His works, which became rapidly popular during his lifetime, and to an extraordinary extent soon after his death—there were upwards of twenty-five editions in less than a hundred years—consist chiefly of occasional pieces, extorted from him by his friends, and often in the form of letters, none of them are formal treatises, and all are plainly the result of his own immediate reflection and experience. One is greatly struck at the place he occupies in the writings of all the great medical authors at the end of the seventeenth and beginning of the eighteenth centuries. Morton, Willis, Boërhaave, Gaubius, Bordeu, &c., always speak of him as second in sagacity to "the divine Hippocrates" alone. Boërhaave never mentioned him in his class without lifting his hat, and called him *Angliæ lumen, artis Phœbum, veram Hippocratici viri speciem.* His simple, manly views of the nature and means of medicine as an art seem to have come upon the profession like revelations; it was as if the men in Plato's cavern, who had been all their lives with their backs to the light, studying their own shadows, had suddenly turned round and gazed on the broad face of the outer world, lying in sunshine before them.

All Sydenham's works are in Latin, and though from his education and tastes, and the habits of his time, and also from the composition of the *Processus Integri*—brief notes left by him for his sons' use, and published after his death—there is little doubt he could have written them in that tongue, there seems every likelihood that he was assisted in this by his friends Drs Mapletoft and Havers. There are three English translations—one by Dr Pechey, another by Dr Swan, to which is prefixed a life by Samuel Johnson, among his earliest performances, and published by Cave, and the last, the Sydenham Society's edition, by Dr Latham.

This, we believe, is nearly all of a personal kind we know, or are likely to know of this great and good man—his private tastes and worth we can only infer from his associates. He who had the right and the honour to call John Locke *conjunctissimus*, and who lived on cordial terms with Boyle and all the best men of his time, was not likely to be otherwise than a man of moral excellence as well as intellectual greatness; and from his own unstudied writings we cannot but be sure that he was a most affectionate father, a warm and faithful friend, and a lover of truth and liberty for their own sakes—a man of keen, generous, habitual humanity and tenderness to suffering, and a man profoundly and pervadingly religious. Not that he is ever a moraliser, or given to be didactic, or given to public religiosity; his clear, manly, modest nature would despise this as much as it did any other quackery or nonsense; but his sense of God—of our constant relation to him as our Maker and Judge—of the law of duty—is felt throughout everything he writes, and at times breaks out into the noblest acknowledgments. We do not know how to exemplify his characteristic spirit and manner, better than in the first sentence of his preface to his first work, or "*Opusculum*" as it was called—"*Observationes Medicæ circa Morborum Acutorum Historiam et Curationem.*"

"He who sets himself to the work of curing men would do well to ponder again and again these four things. 1*st*, That he must himself some day render an account to the supreme Judge of the lives of the sick committed to his care. 2*d*, That whatsoever of art or of science he has by the divine blessing attained to, is to be directed in the main to the glory of God in the highest, and to the welfare of the human race; for it were an unworthy thing that their celestial gifts should be made to serve avarice or ambition. Moreover, 3*d*, that he has taken upon himself the charge of no ignoble or contemptible creature; for that we may estimate the worth of the human race, the only begotten Son of God became man, and thus enriched by his own dignity, His nature we assumed. Finally, that he is himself not exempted from the common lot, but is subject to the same laws of mortality and is obnoxious and open to the same calamities and sorrows as are others; so that, being himself a fellow-sufferer, he may the more diligently, and with a more tender affection succour those who are sick."

Here is the key-note of the character and life of this admirable man. We know of no more impressive assertion of the dignity, privilege, and peril of being a healer of men, and we question if there ever was a case in which a man was more truly as good as his word. The religious nature of Sydenham comes more formally and explicitly out in a theological fragment, printed for the first time by Dr Latham; it is taken from a manuscript in the public library of the university of Cambridge. Of this remarkable fragment it has been said by one well qualified to judge, "There is much in it of the spirit both of Locke and Butler—of Locke in the spirit of observation and geniality; of Butler in the clear utterances as to the supremacy of reason, and the necessity of living according to our own true nature."

But we must advert to the more specific qualities of these practical tracts. Besides their broad, accurate, vivid delineations of disease—portraits drawn to the life and by a great master—and their wise, simple, rational rules for treatment, active and negative, general and specific,—there are two great principles continually referred to as supreme in the art of medicine. The first is, that nature cures diseases; that there is a recuperative and curative power, the *vis medicatrix*, in every living organism, implanted in it by the Almighty, and that it is by careful, reverential scrutiny of this law of restoration, that all our attempts at cure are to be guided; that we are its ministers and interpreters, and neither more nor less; and the second, that symptoms are the language of a suffering and disordered and endangered body, which it is the duty of the physician to listen to, and as far as he can to explain and satisfy, and that like all other languages it must be studied. This is what he calls the Natural History of Diseases. With these two central convictions, it is amazing how much error, rubbish, and mischief he exposes and ends. In these respects, the impression in reading him is a very striking one. Here is a man writing nearly two hundred years ago, and yet we have the truth as to hygienic physiology—the duty of living according to the

constitution given us by God, and obeying the laws of health, watching, following, assisting the efforts of nature, all which we now believe and glory in, as a sort of modern gospel of the body,—taught with the same downrightness, authority, earnestness, and unencumbered good sense, as in the pages of Andrew Combe, or Sir John Forbes, or Sir James Clark. It is difficult for us, living as we do in the broad light of our day, to understand all that is implied in an English physician writing and practising in 1680 as Sydenham did; it amounted to a new revelation—to a *restauratio magna* of the entire study and art of treating diseases—and was among the first and the best fruits of the then dawning philosophy of Lord Bacon. What Locke did for the science of mind, for the conduct of the understanding, and for the art of making men reason justly,—what Harvey and Newton did for the sciences of organic and inorganic matter,—Sydenham did for the art of healing and of keeping men whole: he made it in the main observational; he founded it upon what he himself calls "downright matter of fact," and did this not by unfolding a system of doctrines or raising up a scaffolding of theory, but by pointing to a road, by exhibiting a method—and moreover teaching this by example not less than by precept, walking in the road, not acting merely as a finger-post, and showing himself to be throughout a true artsman and master of his tools. The value he puts upon sheer, steady, honest observation, as the one initial act and process of all true science of nature, is most remarkable; and he gives himself, in his descriptions of disease in general, and of particular cases, proofs quite exquisite, of his own powers of persevering, minute, truthful scrutiny. Like most complete men, Sydenham was a humorist. The well-known story of his saying to Sir Richard Blackmore, when he asked him what books he should study medicine in, "Read *Don Quixote*, Sir," is a proof of his sense as well as of his fun; he doubtless meant that medicine, the art of curing diseases, was not to be learned from books. He has acknowledged his obligations to John Locke in a well-known passage quoted by Dugald Stewart:—

"*Nôsti prœterea*," writing to Dr Mapletoft, "*quam huic meæ methodo suffragantem habeam, qui eam intimius per omnia perspexerat, utrique nostrum conjunctissimum Dominum Johannem Lock; quo quidem viro, sive ingenio judicioque acri et subacto, sive etiam antiquis (hoc est optimis) moribus, vix superiorem quenquam inter eos qui nunc sunt homines repertum iri confido, paucissimos certe pares.*"

And Locke, in the preface to the immortal Essay, speaks of Sydenham as "one of the master builders at this time in the commonwealth of learning," in company with "Boyle, Huygens, and the incomparable Mr Newton."

The subjects of his tracts are, as has been said, all practical, and comprehend almost the entire round of the art of medicine; but the best known are those upon acute diseases, —upon fevers, and the "constitutions of years," as in connection with epidemics,—the smallpox,—the gout,—and hysteria. In all these the powers of insight and of description are quite unmatched, making any attempt at improvement in the natural history of disease hopeless enough.

We conclude with one or two selections from his writings, which, to be fully appreciated, must, as has been already said, be read with some understanding of the times he lived in; what a mass of errors and prejudices his art was sunk in; how rampant the hypothesis mania was, and how utterly the practice of his art was overrun with the vilest and silliest nostrums. We must have this in our mind, or we shall fail in estimating the full amount of exact, strong, independent thought, of true courage and uprightness, and of all that deserves to be called magnanimity and virtue, which was involved in his thinking, writing, and practising as he did.

"The improvement of physic, in my opinion, depends, 1*st*, Upon collecting as genuine and natural a description or history of diseases as can be procured; and 2*d*, Upon laying down a fixed and complete method of cure. With regard to the history of diseases, whoever considers the undertaking deliberately will perceive that a few such particulars must be attended to: 1*st*, All diseases should be described as objects of natural history, with the same exactness as is done by botanists, for there are many diseases that come under the same genus and bear the same name, that being specifically different, require a different treatment. The word *carduus* or thistle, is applied to several herbs, and yet a botanist would be inaccurate and imperfect who would content himself with a generic description. Furthermore, when this distribution of distempers into *genera* has been attempted, it has been to fit into some hypothesis, and hence this distribution is made to suit the bent of the author rather than the real nature of the disorder. How much this has obstructed the improvement of physic any man may know. In writing, therefore, such a natural history of diseases, every merely philosophical hypothesis should be set aside, and the manifest and natural phenomena, however minute, should be noted with the utmost exactness. The usefulness of this procedure cannot be easily overrated, as compared with the subtle inquiries and trifling notions of modern writers; for can there be a shorter, or indeed any other way, of coming at the morbific causes, or of discovering the curative indications, than by a certain perception of the peculiar symptoms? By these steps and helps it was that the father of physic, the great Hippocrates came to excel; *his theory* (θεωρία) *being no more than an exact description or view of Nature.* He found that Nature alone often terminates diseases, and works a cure with a few simple medicines, and often enough with no medicines at all. If only one person in every age had accurately described, and consistently cured, but a single disease, and made known his secret, physic would not be where it is now; but we have long since forsook the ancient method of cure, *founded upon the knowledge of conjunct causes*, insomuch that the art, as at this day practised, is rather the art of talking about diseases than of curing them. I make this digression in order to assert, that the discovering and assigning of remote causes, which now-a-days so much engrosses the minds and feeds the vanity of curious inquirers, is an impossible attempt, and that only immediate and conjunct causes fall within the compass of our knowledge."

Or as he elsewhere pithily states it:—

"*Cognitio nostra, in rerum cortice, omnis ferme versatur, ac ad* τὸ ὅτι *sive quod res hoc modo se habeat, fere tantum assurgit;* τὸ διότι, *sive rerum causas, nulla tenus attingit.*"

He was the first to point out what he called the varying "constitutions" of different years in relation to their respective epidemics, and the importance of watching the type of each new epidemic before settling the means of cure. In none of his works is his philosophic spirit, and the subtlety and clearness of his understanding, shown more signally than in his successive histories of the epidemics of his time. Nothing equal to them has ever appeared since; and the full importance of the principles he was the first to lay down, is only now beginning to be acknowledged. His confession as to his entirely failing to discover what made one epidemic so to differ from another, has been amply confirmed by all succeeding observers. He says:—

"I have carefully examined the different constitutions of different years as to the manifest qualities of the air, yet I must own I have hitherto made no progress, having found that years, perfectly agreeing as to their temperature and other sensible properties, have produced very different tribes of diseases, and *vice versâ.* The matter seems to stand thus: there are certain constitutions of years that owe their origin neither to heat, cold, dryness, nor moisture, but *upon a certain secret and inexplicable alteration in the bowels of the earth,* whence the air becomes impregnated with such kinds of *effluvia* as subject the human body to distempers of a certain specific type."

As to the early treatment of a new epidemic, he says:—

"My chief care, in the midst of so much darkness and ignorance, is *to wait a little,* and proceed very slowly, especially in the use of powerful remedies, in the meantime observing its nature and procedure, and by what means the patient was relieved or injured;"

and he concludes by regretting the imperfection of his observations, and hoping that they will assist in beginning a work that, in his judgment, may greatly tend to the advantage of mankind. Had his successors followed in his track with equal sagacity, honesty, and circumspection, our

 knowledge of these destructive and mysterious incursions of disease, would, in all likelihood, have been greatly larger and more practical than it is now.

Sydenham is well known to have effected a revolution in the management of the smallpox, and to have introduced a method of treatment upon which no material improvement has since been made. We owe the cool regimen to him. Speaking of the propriety of attending to the wishes of the sufferer, he says, with equal humanity and good sense:—

"A person in a burning fever desires to drink freely of some small liquor; but the rules of art, built upon some hypothesis, having a different design in view, thwart the desire, and instead thereof, order a cordial. In the meantime, the patient, not being suffered to drink what he wishes, nauseates all kinds of food, but art commands him to eat. Another, after a long illness, begs hard, it may be, for something odd, or questionable; here, again, impertinent art thwarts him and threatens him with death. How much more excellent the aphorism of Hippocrates—'Such food as is most grateful, though not so wholesome, is to be preferred to that which is better, but distasteful.' Nor will this appear strange, if it be considered that the all-wise Creator has formed the whole with such exquisite order, that, as all the evils of nature eminently conspire to complete the harmony of the whole work, so every being is endowed with *a Divine direction or instinct*, which is interwoven with its proper essence, and hence the safety of mankind was provided for, who, notwithstanding all our doctoring, had been otherwise in a sad enough plight."

Again:—

"He would be no honest and successful pilot who were to apply himself with less industry to avoid rocks and sands, and bring his vessel safely home, than to search into the causes of the ebbing and flowing of the sea, which though very well for a philosopher, is foreign to him whose business it is to secure the ship. So neither will a physician, whose province it is to cure diseases, be able to do so, though he be a person of great genius, who bestows less time on the hidden and intricate method of nature, and adapting his means thereto, than on curious and subtle speculations."

The following is frank enough:—

"Indeed, if I may speak my mind freely, I have been long of opinion that I act the part of an honest man and a good physician as often as I refrain entirely from medicines, when, upon visiting the patient, I find him no worse to-day than he was yesterday; whereas, if I attempt to cure the patient by a method of which I am uncertain, *he will be endangered both by the experiment I am going to make on him and by the disease itself; nor will he so easily escape two dangers as one.*

"That practice, and that alone, will bring relief to the sufferer, which elicits the curative indications from the phenomena of the diseases themselves, and confirms them by experience, by which means the great Hippocrates made himself immortal. And had the art of medicine been delivered by any one in this wise, though the cure of a disease or two might come to be known to the common people, yet the art in its full extent would then have required men more prudent and skilful than it does now, nor would it lose any of its credit; for as there is in the operations of nature (on the observations of which a true medical praxis is founded) more of nicety and subtlety than can be found in any art supported on the most specious hypotheses, so the science of Medicine which Nature teaches will exceed an ordinary capacity in a much greater degree than that which mere philosophy teaches."

There is much profound truth in this. Observation, in its strict sense, is not every man's gift, and but few men's actual habit of mind. Newton used to say, that if in any one way he differed from other men, it was in his power of continued attention—of faithful, unbroken observation; his ladder had all its steps entire, and he went up with a composed, orderly foot. It requires more strength and fineness of mind, more of what deserves to be called genius, to make a series of trustworthy observations in Medicine, or any other art, than to spin any amount of nice hypotheses, or build any number of "*castella in aere*," as Sydenham calls them.

It would not be easy to over-estimate the permanent impression for good, which the writings, the character, and the practice of Sydenham have made on the art of healing in England, and on the continent generally. In the writings of Boërhaave, Stahl, Gaubius, Pinel, Bordeu, Haller, and many others, he is spoken of as the father of rational medicine; as the first man who applied to his profession the Baconian principle of interpreting and serving nature, and who never forgot the master's rule, "*Non fingendum aut excogitandum, sed inveniendum, quid natura aut faciat aut ferat.*" He was what Plato would have called an "*artsman*," as distinguished from a teacher of abstract science. But he was by no means deficient either in the capacity or the relish for speculative truth. Like all men of a large sagacious nature, he could not have been what he was, or done what he did, without possessing and often exercising the true philosophizing faculty. He was a man of the same quality of mind in this respect with Watt, Franklin, and John Hunter, in whom speculation was not the less genuine that it was with them a means rather than an end. (J. B—N.)

SYDENHAM, *Floyer*, a translator of Plato, was born in 1710, and graduated in arts at Wadham College, Oxford, in 1734. Between 1759 and 1780 he published translations of the Io, Greater and Lesser Hippias, Banquet, Rivals, Meno, First and Second Alcibiades and Philebus, in 3 vols. 4to. This translation was on the whole a very creditable one; in the more abstruse parts of Plato, the translator often missed the sense, but in the less abstract portions the version is excellent. It was completed in 1804 by Thomas Taylor. The subscribers to a work like this were few, and the learned and laborious, the "candid and gentle" author died in his old age in prison, where he had been incarcerated for a debt contracted for the barest necessaries of life with an eating-house which he frequented. He died April 1st 1787. His other works were —*A Dissertation on the Doctrine of Heraclitus, so far as it is mentioned or alluded to by Plato*, 1775; *Onomasticon Theologicum*, 1784. Out of the facts connected with this melancholy end of Sydenham, the literary fund is said to have taken its rise.

SYDNEY, the capital city of the colony of New South Wales, situated on the southern side of the harbour of Port Jackson, about 7 miles from the entrance to the port; S. Lat. 33. 52., E. Long. 151. 12. It was founded on the 26th January 1788, and named from Viscount Sydney, at that time secretary for the colonies.

Sydney is distinguished as the earliest of the Australian settlements, and was commenced as a convict establishment under the transportation system of the Imperial Government. The resource at command for that system in North America having been gradually cut off, first by a growing preference with the colonists for negro labour, and at last by the separation of the United States, the British authorities turned attention elsewhere, and the reports of Captain Cook directed them to New South Wales. "The first fleet," as it has been called, consisting of 11 vessels, left for the antipodes on 13th May 1787, and arrived at Botany Bay, the intended destination, on the 18th January. But this place proving quite unsuitable, the whole expedition was promptly removed to Port Jackson, a few miles to the northward. This port, one of the finest harbours in the world, was previously thought to be only a boat harbour, and was called after one of Cook's seamen, who had first discovered it. The party, consisting of 1030 persons, including 565 male and 192 female convicts, with 200 soldiers, and some women and children, was landed at Sydney Cove, one of the many beautiful inlets of the harbour, and there they founded the present city of Sydney, with Captain Arthur Phillip, R.N., at their head, as the first governor of the new penal colony.

For a time at first the town was irregularly constructed, and comprised very picturesque and humble edifices, some of which have lingered into present times. The present plan was laid out in 1809. The city is surrounded on three sides by water: to the north, the main harbour called the Stream; to the east, Woolloomoloo Bay; and to the west,

Darling Harbour. It is built partly on high ground, and partly along a hollow, traversed by the principal thoroughfare, George Street. The basis is sandstone, which affords a valuable building material, that is plentifully made use of both in building and paving the town. The soil is light and sterile—a characteristic feature that prevails far beyond the limits of Sydney. On the other hand, the water or harbour scenery is most diversified and beautiful, with numerous inlets, and rocky promontories covered with the natural evergreen vegetation, and thickly interspersed with houses and gardens belonging to the expanding suburbs of the capital.

The harbour is quite landlocked; and large ships may approach close to or even touch the rocky shores on which the town is built. These natural advantages, have given undisputed pre-eminence to Sydney as the great commercial emporium of the colony; and nature has been powerfully seconded by the system of extensive wharf accommodation along Sydney Cove and Darling Harbour. A dry dock, capable of accommodating the largest merchantman, has also been constructed at Waterview Bay, one mile distant from Sydney; and there are, besides, two patent slips at Darling Harbour, the larger of which can take up vessels of from 1500 to 2000 tons. The town and shipping are protected by five forts or batteries on various commanding situations, including the principal ones of Fort Maquarri, Dawes' Battery, and the more recent and imposing erections at Kiribilli Point on the north shore, and Fort Denison on what was originally called Pinchgut Island. There is a large and admirably constructed dry-dock in private hands, on Water View Bay, and another constructed by the government on Cockatoo Island, capable of accommodating the largest class of ocean steamers. There is also a very fine patent slip at Balmain in the hands of a company. The customs-tariff is in general liberally framed, and upon principles of free trade. The duties are levied upon a few principal articles of import, chiefly spirits, wines, and tobacco. The duty on the latter, however, operates protectively upon an inferior colonial production. There is an export duty on gold of 2s. 6d. per oz., as in the adjacent colony of Victoria, the governments of both places having found difficulty in securing by other means a payment for the use of the auriferous soil. The scale of commerce and shipping is large, and has been greatly augmented since the gold discoveries in 1851. The colonial imports in 1850 were L.1,333,413; the exports, L.1,357,784. In 1858 they were—imports, L.6,058,366; exports, L.4,186,277. The apparent discrepancy in the exports arises from the large transit of live stock across the border to Victoria, no account of which can be taken. These figures are for the whole colony of New South Wales, including the Moreton Bay District, which has just been created a separate colony; but nearly the entire of this large commerce is connected with the central harbour of Sydney. The chief articles of export are wool and gold, the latter in annual value above L.1,000,000, having considerably increased since 1858, and the former about one-third to one-fourth more. The shipping inwards for 1858 was 348,984 tons, and outwards 366,825 tons. The colonial revenue for 1858 was L.1,456,451, exclusive of loans for railways, &c., and for 1859 it was L.1,540,550. The public debt on 31st December 1858 was L.2,797,090. The great railway schemes which are being carried out by the colonial government, will soon much increase this amount. Three great railway lines have been projected from Sydney, to the north, to the west, and to the south-west. These have all been commenced, and of the last, proceeding *via* Paramatta towards Goulburn, and intended eventually to reach the Victoria frontier, 34 miles are already finished and in operation. There is telegraphic communication throughout great part of the colony, and particularly to the south-west, where, at Albury on the frontier, 360 miles from Sydney, the telegraph lines from Victoria are united, and thus connect Sydney with that colony, and with South Australia and Tasmania. Already the grand project of telegraphic connection with Europe has been seriously entertained at Sydney, and seems likely to be soon carried out, now that there is almost a continuous line from England *via* Kurachee and Ceylon to the eastern part of Java.

The population of Sydney by the last census in 1856 was 53,118, consisting of 26,220 males, and 26,898 females, while that of the entire colony was, on the same occasion, 268,737. Ten years previously that of the city was 37,203. In 1858, the population of the two electoral districts in which Sydney is divided, was estimated at 53,358, exclusive of the populous and now connected suburbs. Sydney and these numerous offshoots of Paddington, the Glebe, Newtown, St Leonards, &c., may now contain about 75,000 souls. So considerable a place, with a proportionably large export and import commerce, presents a very active scene of life and business. Omnibuses constantly traverse town and suburbs, and many vehicles are despatched from Sydney in all interior directions for the passenger and postal service, while the towns on the sea-coast are connected by steam communication, extending south to Melbourne and Hobart-Town, and north to Moreton Bay, and the newly discovered gold region behind Port Curtis and Rockhampton. The oft interrupted steam postal communication with Britain seems at length permanently settled. The present line is *via* Suez and Melbourne, occupying about 50 days to Sydney, when the short and fast route through France is availed of. This postal service has hitherto been monthly, but it is expected presently to be fortnightly, by arrangement with the contracting steam company (the Peninsular and Oriental), and it is partly with this object in view, partly to avail of the recent telegraphic extensions to Ceylon, that an alteration has just been effected (March 1860), by which Galle has been made the place of call instead of Mauritius. Sydney, however, as standing at the extreme of this postal line, the last place of arrival and the first of departure, and exposed to frequent disappointment in receipt of mails, has of late been dissatisfied with this route, and in conjunction with the New Zealand settlements, which are still more unfavourably situated, has been endeavouring to establish a second and alternate line *via* Panama.

In 1843, Sydney, in common with Melbourne and some other Australian towns, was formed into a municipality under a mayor and corporation. The proceedings of this body having rendered it unpopular, it was abolished some years ago; but the institution has since been restored, and has made itself useful in effecting improvements in sanitary and other departments. The corporation revenues for 1858 amounted to L.55,451, including a government grant of L.10,000, but exclusive of loans; the expenditure was L.66,862. In religious affairs, Sydney is the residence of an Anglican bishop, and a Roman Catholic archbishop. The Australian museum, commenced in 1838 and incorporated in 1853, comprises a good illustration of Australian natural history. The University was founded in 1850, and the same year established by act of council. Its degrees now take rank with those of similar institutions in Britain. In 1858 there were 33 matriculated students. The city has long been lighted with gas. It is now well supplied with water, and a great system of drainage is in progress. The main thoroughfares of Pitt Street and George Street have a carriage-way of 60 feet in breadth; and there are now many handsome shops, churches, and public and private edifices. There are 8 banks, most of which have large capitals, and many branch establishments; and the town is varied on its outskirts by several parks, by a botanic garden, and by the domain surrounding a handsome and spacious Government House.

Shortly after the gold discoveries, the establishment in Sydney of a branch of the royal mint was petitioned

for, and with success. This institution came into operation in May 1855. The coinage is limited to gold, the sovereigns and half-sovereigns to be of equal weight and purity to those of imperial coinage. There has not yet, however, been conceded to it the privilege of an imperial coinage—a circumstance that materially diminishes the advantage of the local mint, and is of constant inconvenience in the commercial relations between Australia and Britain. Meanwhile the adjacent colonies have accepted the coin as legal tender, although not without demur and delay, particularly in the case of Victoria, which objected alike to the invidious non-imperial distinction, and to the fact of the mint having been hastily placed at Sydney, while nearly all the gold was at Melbourne. For a time at first, therefore, the Sydney mint threatened to prove a serious loss to the colony. The works cost L.50,000, and the annual maintenance L.12,000, while the income fell short of the latter sum. There is now, however, an excess of income, but the colony is prohibited by imperial regulation from making the institution a source of profit. The area of the legal tender has been extended to several colonies, Mauritius, Ceylon, and Hong-Kong, which are still imperially administered. Those colonies having free governments to decide in the matter for themselves. The business of the Sydney mint is again threatened by a recent demand of the legislature at Melbourne for a mint there also; and if, as seems reasonable, the imperial privilege will soon be conceded to Australian coin (the branch mint operations being all under imperial appointees, and subjected to regular imperial test), there is a yet further diminution in extent of operations in prospect, because great part of the business hitherto can be regarded as merely the substituting of colonial for imperial coin, in consequence of the latter having more value outside Australia than the former, and being in consequence always preferably taken for export.

The 26th of January is now a distinguished anniversary, which has of late been somewhat regularly celebrated, and with due eclât, in London, where, from the facilities of intercommunication and affection for the parent country, very many colonists can now always be mustered. It is, however, no longer the celebration of a penal settlement, but of a flourishing colony, which has long been entirely self-supporting, and is now possessed of a free constitutional government. The battle of the transition from "convictism" is not altogether a pleasing retrospect. The cessation of transportation to New South Wales, and the removal of the stigma of its being a penal settlement, were but reluctantly conceded by the imperial and colonial authorities, and even by an influential party of colonists under the past regime, who, as employers of labour, found more profit and less annoyance from the assigned convict than from the free immigrants. The league against the transportation system, inaugurated in 1851 at Melbourne, and established also at Sydney, was eventually victorious, and but for the partial revival of the system at Western Australia, these colonies might now have been entirely freed, at all events, from any further criminal admixture, and have been in a fair and rapid way for recovering from the social damage already sustained. As it is, however, the progress has been very marked in the relative diminution of crime, and, to the residents themselves, it is even more evident in the general social aspect. A prosperous colony of the British people, in a temperate latitude, should be a scene comparatively destitute of heinous crime. These colonies, with the widely spread and lingering elements of their original character, cannot assume this position; but the following comparative return of the convictions at the Supreme Court of Sydney gives a good assurance of progressive improvement, even allowing for the effects of irregularity and extravagance that characterized the earlier years of the gold discovery, 1851 to 1853. In 1853, the convictions were 604; in 1854, 637; in 1855, 526; in 1856, 461; in 1857, 395; in 1858, 415.

Sydney is the seat of the Governor-General of the Australian settlements. The supremacy, however, which the Governor of New South Wales legally enjoys with reference to the other colonies has long been, in consonance with understanding, a dead letter, and exists only for certain possible emergencies. The colonial legislature assembles in a handsome edifice of the capital, and consists of a council, at present of crown nomination, and consisting of forty members, besides the president, and an assembly of seventy-six members, including the speaker, elected by the colonists. The former body, the Upper Chamber, or House of Lords, as it were, will, with the view of giving it more independence, probably soon be made elective as well as the other, in obedience to prevailing public opinion, and in harmony with example in the other colonies. The political tendencies, and the religious as well, since self-government has permitted their free devolpment, are all towards a democratic equality; universal suffrage, the ballot, no property qualification, are principles either already adopted or on the eve of being so. The good wages and independent position of all classes, and the absence of local traditional inequalities, render these results natural, suitable, apparently, and probably irresistible. It is pleasant to add, that neither this conceded freedom of political action, nor the tendency to this extreme democratic departure from the home model, have affected the loyal sentiments of the colony. The new constitution was proclaimed in November 1855; but the colony ever since, although actively contentious enough as regards its own political parties, has displayed only an increased deference and loyalty to the parent government, the natural result, indeed, of its having secured at length that free political condition which it had long desired and contended for.

SYENE, now ASWAN. See EGYPT.

SYLBURG, or SYLBURGIUS, *Friedrich*, a very distinguished Greek scholar of the sixteenth century, was born at Wetter near Marburg, in 1536, and hence the frequent addition to his name of Veterensis. He received his education at the University of Jena, where he studied Greek with great ardour, under the renowned Rhodomannus. After leaving college he spent some years in teaching, but disliking the profession he exchanged the ferula for the pen. Sylburg formed a connection with Wechel the printer, in Frankfort-on-the-Main, for whom he engaged to edit works in the Greek language. In 1591 he exchanged his position for one in Heidelberg with the printer Jerome Commelin. In both these situations Sylburg, by his profound knowledge, his great diligence, and his extraordinary industry, became one of the most illustrious names of his century. His society was courted by such great men as Casaubon and De Thou, and he gained from the Landgrave of Hesse an annual pension from the funds of the University of Marburg. Sylburg died at Heidelberg on the 16th of February 1596. He has left a reputation behind him hardly inferior to that of the illustrious family of Stephens. His life and labours will be found recorded in the *Vita Frederici Sylburgii* of J. G. Jung, Berleburg, 1745.

SYLLOGISM. See LOGIC.

SYLVESTER, JOSHUA, an English poet of some celebrity in his day, was born in 1563. He was a species of merchant, or "merchant adventurer" as he styles himself, and being of a roving disposition kept very generally poor. He was engaged chiefly in translating works from the French, and he rendered Du Bartas' poem of the *Divine Weeks and Works* into sweet, fantastical, and rather insipid verse in 1605, which had a great run. This poetical Puritan addressed a lively piece, with an edifying title, on the iniquities of tobacco, to King James VI. in 1615. The

title of the book ran thus: *Tobacco battered, and the Pipes shattered (about their ears that idly idolize so base and barbarous a weed, or at leastwise over-love so loathsome a vanitie), by a Volley of Holy Shot thundered from Mount Helicon.* Sylvester seems to have had considerable powers of versification, but was destitute both of taste and judgment. After firing this "holy shot" from his exalted position, he seems to have betaken himself to a less elevated region, for he died at Middleburg in Holland, in 1618.

SYMMACHUS, QUINTUS AURELIUS, a Latin writer of high reputation during his own time, was born at Rome, being the son of Lucius Avianus Symmachus, who became prefect of the city in the year 364 A.D. The son was carefully initiated in the learning of the age, and soon distinguished himself by his talents and eloquence. He became pro-consul of Africa in 370, and prefect of the city in 384. He likewise appears to have filled the office of *pontifex.* While he held that of prefect, he addressed to Valentinian II., Theodosius, and Arcadius, an elaborate epistle, urging the restoration of the pagan rites and observances. This application produced no effect, but his zeal for the ancient superstition was still unabated; and in 388 or 389, when congratulating Theodosius, he again, in the name of the senate, entreated him to restore the altar of Victory to the senate-house. But the Emperor, who had a more personal reason for being dissatisfied with his conduct, on account of his favourable sentiments towards the usurper Maximus, sent him into exile at a great distance from Rome. His disgrace does not however appear to have been lasting; for he was nominated consul in the year 391. He survived Theodosius, and was employed by his sons Arcadius and Honorius.

Symmachus is chiefly known to posterity as the author of ten books of Epistles, which reflect some light on the history of that era. He seems to have chosen Pliny as his model; but he belongs to a very inferior age of Latinity, and has a due share of the quaintness and affectation by which it is generally characterized. His *relatio* in favour of paganism (lib. x. epist. lxi.) produced a refutation from Ambrose, bishop of Milan, who on that subject addressed two epistles to Valentinian. He was likewise assailed by Prudentius, who composed a poem in two books, *Contra Symmachum Præfectum Urbis.*

The *Epistolæ* of Symmachus are said to have been printed before the close of the fifteenth century, and other very early editions are mentioned. Only 317 Epistles appear in the edition printed by J. Schott, Argent., 1510, 4to. The subsequent impressions include 965, divided into 10 books. The next edition was printed by Froben, Basil, 1549, 8vo. An edition, illustrated with notes, was afterwards prepared by Juretus, Paris, 1580, 1604, 4to. To the annotations of this editor, Lectius added his own, Genev., 1587, 1599, 8vo. The text of Lectius is preferable to that of Juretus. Another edition, accompanied with notes, was published by Scioppius, Mogunt., 1608, 4to. These notes he was accused of having pilfered from the papers of Giphanius.[1] The next editions of Symmachus were those of Pareus, Neapoli Nemetum, 1617, 1628, Francof., 1642, 8vo. He added a *Lexicon Symmachianum* and *Electa Symmachiana.* We have only to mention another edition, Lugd. Bat., 1653, 12mo. Of the orations of Symmachus some fragments were discovered in the Ambrosian Library at Milan by the indefatigable Angelo Mai, and by him have been communicated to the public, Mediolani, 1815, 8vo.

SYMONDS. See SHIP-BUILDING.

SYMPHONY (Ital. *Sinfonia*). Anciently this word had various musical meanings. It now usually signifies a piece of instrumental music for an orchestra, consisting of several movements, and generally performed in a concert-room. The overture differs from the symphony chiefly in the smaller number of its movements, seldom containing more than a short, slow, introductory movement, and an allegro, and being used at the beginning of an opera or a ballet. The word symphony is also used to signify an instrumental passage which usually introduces a piece of vocal music, or is brought in at its close, or occurs during some pause of the voice. Hadyn, Mozart, and Beethoven have produced the finest models of the orchestral symphony in point of originality, beauty, ingenious construction, and skilful instrumentation. For clearness of design and breadth of effect, Haydn's symphonies still remain unrivalled.

SYNÆRESIS (συναίρεσις, *a drawing together*), is a figure by which two syllables are united in one, as *vemens* for *vehemens.*

SYNAGOGUE, a Jewish place of worship. Authors are not agreed about the time when the Jews first began to have synagogues. Some suppose them as old as the ceremonial law, and others fix their beginning to the times after the Babylonish captivity. Jerusalem is said to have contained 480 synagogues. The chief things belonging to a synagogue were—1, the ark or chest, made after the model of the ark of the covenant, containing the Pentateuch; 2, the pulpit and desk in the middle of the synagogue, in which he that was to read or expound the law stood; 3, the seats or pews for the people; 4, the lamps to give light at evening service, and the feast of dedication; 5, rooms or apartments for the utensils and alms-chest. The synagogue was governed by a council or assembly, over whom was a president, called the Ruler of the Synagogue. These are sometimes called Chiefs of the Jews, the Rulers, the Priests or Elders, the Governors, the Overseers, the Fathers of the Synagogue. Service was performed three times a day, namely, in the morning, in the afternoon, and at night. At the time of morning sacrifice, evening sacrifice, and after the evening sacrifice on Monday, Thursday, and Saturday, there was a more forcible obligation upon the people to attend than upon the other days.

SYNALŒPHA (συναλοιφή, *a melting together*), is a contraction of syllables, performed principally by suppressing some vowel or diphthong at the end of a word, on account of another vowel or diphthong at the beginning of the next. As, *ill' ego*, for *ille ego*, &c.

Conticuer' omnes intentiqu' ora tenebant.—VIRGIL.

SYNTAX, the proper construction of the words of a language into sentences and phrases. (See GRAMMAR.)

SYNTHESIS (συντίθημι, I put together), is a species of reasoning, opposed to analysis, which is the logical or formally deductive method, in which the reasoner, from certain assumed data, concludes either formally or materially a proposition of higher generality than any of those with which he set out. It is frequently called the method of composition or combination, in contrast to analysis, which is called the method of resolution. (See LOGIC.)

SYRA (anc. *Syros*), an island of the Grecian Archipelago, belonging to Greece, and one of the Cyclades, eleven miles S. of Andro; about N. Lat. 37. 29.; E. Lon. 24. 55. It is about ten miles in length by seven in breadth, and irregular in its outline, with steep and rugged coasts. The interior is hilly and is chiefly composed of mica slate, and there is abundance of iron and an inferior kind of marble. The soil is in general not very fertile, and there is a deficiency of water; but the island produces wheat, barley, cotton, wine, figs, and silk. Pop. 42,000. The capital is Hermopolis, also called New Syros, at the head of a bay on the east coast, near the site of the ancient city, all traces of which have disappeared. It is the residence of Russian, French, Austrian, and other consul; and con-

[1] *Fabricii Bibliotheca Latina*, tom. iii., p. 208, edit. Ernesti.

tains a handsome new church, a gymnasium, quarantine establishment, &c. Shipbuilding is actively carried on; and there is an extensive trade. About 1500 vessels annually enter and clear from the harbour. This port is the centre of the steam navigation of the Archipelago. Pop. 14,000.

SYRACUSE (anc. *Syracusæ*), a Greek city in Sicily, memorable in ancient history. It was, with the exception of Naxos, the earliest of all the Greek colonies in the island, having been founded by a band of Corinthians under Archias, in the year 734 B.C. The original settlers established themselves on the small island of Ortygia, at the mouth of the capacious bay which afterwards formed the great harbour of Syracuse; and for a long time the city did not extend beyond its narrow limits. The name was most probably derived from the neighbouring marsh or lake of Syraco. The new city rose steadily if not rapidly in power and prosperity; and founded several colonies of its own, among which were Acræ, Casmenæ, and Camarina. But we know little of its history previous to the fifth century, B.C. In the beginning of that century the government was oligarchical, in the hands of a class called the *Gamori*, probably the descendants of the original settlers. Meanwhile a democratic party by degrees grew up, who, in 486, effected a revolution, and expelled the *Gamori* from the city. The latter, however, applied for aid to Gelon, tyrant of Gela, who immediately put himself at their head and took possession of Syracuse. Perceiving the superior advantages of this city over Gela, he resolved to make it his capital; and in order to increase its size and importance, he demolished the neighbouring city of Camarina, and transplanted the inhabitants to Syracuse. Soon afterwards, entering into a war with the Megareans, he defeated them, took and razed their city, and in like manner transplanted the people. Syracuse thus became powerful, and full of inhabitants; and the friendship of Gelon was courted by Athens and Lacedæmon at the time of the Persian invasion. But in the meantime the Carthaginians had entered into a treaty with the Persians; by which it was agreed, that the former should attack the Greeks in Sicily and Italy, in order to divert them from assisting their countrymen at home. Sicily was accordingly invaded by the Carthaginians with a vast army; but they were utterly overthrown by Gelon, as is related under the article CARTHAGE. After this victory, the people out of gratitude obliged him to assume the title of king, which till that time he had refused.

Gelon died in the year 478 B.C., and was succeeded by his brother Hiero, whose character is differently drawn by different historians. He is highly celebrated in the odes of Pindar; and it is certain that his court was the resort of men of letters, whom he treated in the most courteous manner and with the greatest liberality. In 467 B.C. Hiero was succeeded by Thrasybulus; who proving a tyrant, was in ten months dethroned, and a popular government restored, which continued for the space of about sixty years.

After the establishment of free government, Syracuse, along with the other Greek cities in Sicily, made rapid progress in wealth and power; and it was probably about this time that it reached its highest pitch of prosperity. But during this period also it incurred the greatest danger it had yet experienced, in a contest with Athens at the very height of her power. The memorable siege of Syracuse, which in the end proved fatal to Athens, began in the spring of 414 B.C. The Athenians under Nicias landed to the north of the town, and established their naval station at a place called Thapsus. The city had by this time far extended beyond its original limits; the plateau of Achradina to the north of the harbour was densely peopled, but was commanded by the heights of Epipolæ to the west. The latter were at once seized by the besiegers as an important position, and secured by the erection of a fort on a hill called Labdalum. They then proceeded to construct a line of trenches across the plateau in order to shut in the city; and the rapid progress of this work so alarmed the Syracusans, that they made several attempts to stop it by counterworks. These were, however, all destroyed by the Athenians; and their fleet having sailed into the great harbour, they were able to carry the circumvallation down to the shore, leaving only a small part of it towards the north of the plateau in an unfinished state. Hitherto the Athenians had been successful in all their operations, and in all the contests that had taken place in the course of them; but the arrival of Gylippus from Sparta with reinforcements for the Syracusans turned the tide of affairs. He forced his way through the Athenian lines where they were incomplete, and entered the city. Then, directing all his efforts to prevent the completion of the circumvallation, he first surprised the Athenian fort of Labdalum, and afterwards proceeded to intersect their lines by a cross wall running out from that of the city. This he succeeded in carrying out quite beyond the line of circumvallation, so as to render it impossible to enclose the city. Nicias, after an unsuccessful attempt to capture this outwork, wrote to Athens for assistance, and meanwhile strengthened his position on the harbour by fortifying the headland of Plemmyrium which commanded its entrance. But the Syracusans, making a simultaneous attack by sea and land, captured this fort, and subsequently defeated the Athenian ships in the harbour. A strong fleet arriving from Athens under Demosthenes and Eurymedon revived for a time the hopes of the besiegers. They attacked once more the Syracusan outworks on the heights, but were repulsed with great loss. It was now evident that all hope of capturing the city was gone; and the Athenians would have been wise had they immediately raised the siege. But the counsel of Nicias for delay prevailed against that of Demosthenes, and they speedily found their position changed from that of besiegers to being themselves besieged. Their fleet was blockaded in the harbour, and finally destroyed; and the army attempting to retreat by land, after suffering great losses, was forced to lay down their arms. This siege was scarcely ended when a new and formidable invasion by the Carthaginians took place; but the event of that expedition was as unfortunate to its authors as the former had been. (See CARTHAGE.) In the meantime, a considerable revolution had happened in Syracuse. Dionysius, a man of great valour and address, by various insidious stratagems, succeeded in gaining unlimited power, and assumed the title of king of Syracuse in the year 404 B.C. The Syracusans did not tamely submit to their new master; but Dionysius managed matters so well, that their frequent revolts answered no other purpose than more certainly to entail slavery on themselves; and he was allowed to possess the throne without much opposition till his death, which happened in the year 367 B.C. The wars which this monarch carried on with the Carthaginians, and their unsuccessful attack on Syracuse in 397 B.C., are narrated in the article CARTHAGE.

On the death of Dionysius, he was succeeded by his son, likewise called Dionysius. He no sooner ascended the throne, than Dion, his uncle, succeeded in gaining an ascendency over his mind by the help of the philosopher Plato, under whose care he placed the young king. But the courtiers, dreading the effects of the philosopher's instructions, prevailed on the king to banish Dion, and to keep Plato himself in a kind of imprisonment in the citadel. At last, however, he set him at liberty; and Plato then returned to his own country.

In 356 B.C., Dion resolved at once to avenge himself on the tyrant for the wrongs he had suffered at his hands, and to deliver his country from the oppression under which it groaned. He raised a body of troops, landed in Sicily, and

Syracuse. taking advantage of the tyrant's absence, proceeded to Syracuse. On his march he prevailed on the inhabitants of Agrigentum, Gela, Camarina, and other cities, to join him. As soon as he entered the territories of Syracuse, multitudes flocked to him; and as nobody appeared to oppose him, he boldly entered the capital, where he soon found himself at the head of 50,000 men. Dionysius returning to the city, after some attempts at resistance, betook himself to flight. But in 350 B.C. he again made himself master of Syracuse; and being exasperated by his past misfortunes, became more tyrannical than ever. The Syracusans first had recourse to Icetas, tyrant of Leontini; but as the Carthaginians in alliance with this monarch took this opportunity to assail them with a powerful fleet and army, they were obliged to apply to the Corinthians. By them Timoleon, a celebrated commander, was sent to the assistance of the Syracusans, whom he found in a very distressed situation; Icetas being master of the city, the Carthaginians of the harbour, and Dionysius of the citadel. As all parties were equally the enemies of Dionysius, he found it impossible to resist, and therefore surrendered himself to Timoleon in 343 B.C.

After the departure of the tyrant, Timoleon succeeded in expelling both Icetas and the Carthaginians from Syracuse, and obtaining possession of the whole city. By sound of trumpet, he invited the inhabitants to come and assist in demolishing the citadel and other castles, which he called the *nests of tyrants;* after which he caused edifices for the administration of justice to be erected in the place where the citadel had stood. He found the city in a most miserable condition; for many having perished in the wars and seditions, and others having fled to avoid the oppression of tyrants, Syracuse, once so wealthy and populous, was now become almost a desert. Timoleon supplied the city with inhabitants from Corinth and other cities of Greece, and at the same time great multitudes from Italy and the other parts of Sicily resorted thither.

For twenty years the Syracusans enjoyed the fruits of Timoleon's victories; but new disturbances arising, in a short time another tyrant started up, who exceeded all that had gone before him in cruelty and other vices. This was the celebrated Agathocles, of whose exploits against the Carthaginians a full account is given under the article CARTHAGE. He was poisoned by one Mœnon in the year 289 B.C., after having reigned twenty-eight and lived ninety-five years. A succession of tyrants followed, till at last the city being held by two rivals, Tœnion and Sosistratus, who made war within the very walls, Pyrrhus king of Epirus, was invited into Sicily, in order to put an end to these distractions, and to deliver the island from the Carthaginians. He willingly complied with the invitation, and was everywhere received with loud acclamations, as the deliverer, not only of Syracuse, but of all Sicily. As he had a fine army of 30,000 foot and 5000 horse, with a fleet of 200 sail, he drove the Cathaginians from place to place, till he left them only the two strong posts of Eryx and Lilybœum. So sanguine were his anticipations, that he caused his son to assume the title of king of Sicily; but in the mean time, having displeased the Sicilians by his arbitrary behaviour, they deserted from him in such numbers that he was glad to set out for Italy in 275 B.C. After his departure, Hiero, a descendant of Gelon, the first king of Syracuse, first as general and afterwards as king, succeeded, during a long period of peace, in raising Syracuse to a high degree of wealth and prosperity. He preserved internal tranquillity, promoted agriculture and commerce, and adorned the city with many splendid buildings. The most important war carried on by Hiero was with the Mamertines of Messana, whom he reduced to such straits that they were obliged to call in the Romans to their assistance. The consequences of this have been fully related under the articles ROME and CARTHAGE. Hiero, who had allied himself with the Carthaginians, being himself defeated by the Romans, and finding his allies unable to protect him against the power of that republic, concluded an alliance with them, and continued faithful to them even in the time of the second Punic war, when they were in the greatest distress. In his reign flourished the celebrated mathematician Archimedes, whose genius he employed in fortifying the city of Syracuse, by innumerable machines, in such a manner as rendered it almost impregnable by any method of attack known at that time.

Hiero died about 211 B.C. and was succeeded by his grandson Hieronymus; but he imprudently forsook the counsels of his grandfather, and entered into an alliance with the Carthaginians. He was soon afterwards murdered, in consequence of his tyranny and cruelty; and the greatest disorders took place in the city, which Hannibal, though then in Italy, found means to foment, in hopes of keeping the Syracusans in his interest. This indeed he effected; but as his own affairs in Italy began to decline, he could not prevent Marcellus from landing in Sicily with a formidable army, which the Sicilians had no means of resisting. Syracuse was invested in 214 B.C.; but the machines invented by Archimedes baffled all attempts to take it by assault. The immense preparations which the consul had made for taking the city by storm, could not have failed to accomplish his purpose, had not the place been defended by the genius of Archimedes.

The consul, finding himself defeated in every attempt, turned the siege into a blockade, and at last made himself master of Syracuse in 212 B.C. He took the opportunity of a festival, when the soldiers and citizens had drunk plentifully, to make a detachment scale the walls of the quarter called Tyche, in that part of it which was nearest to Epipolæ, and which was ill guarded. He speedily possessed himself of Epipolæ; and the inhabitants of Neapolis as well as of Tyche then sent deputies to offer their submission. Marcellus granted life and liberty to all of free condition, but gave up those quarters of the city to be plundered. The other quarters still held out, and an attempt was made by the Carthaginians to relieve the place, but this proving unsuccessful, they left the citizens to their own resources. The Romans, having obtained by treachery a landing in the island of Ortygia, succeeded in carrying by assault a part of Achradina, and on this the remainder of the city was given up to them. In the confusion of the assault Archimedes was killed.

The city of Syracuse continued subject to the western empire till its fall, when the island of Sicily, being ravaged by barbarian tribes, the capital also underwent various revolutions, till, at last, in the ninth century, it was so destroyed by the Saracens that very few traces of its ancient grandeur are now to be seen. The ancient city, in its most extended condition, was of a triangular form, and consisted of five parts. These were Ortygia, or the Island, which was the oldest part, Achradina, Tyche, Neapolis, and Epipolæ. The circuit, according to Strabo, amounted to 180 stadia, or 22 English miles and 4 furlongs. For an account of the modern Syracuse see SICILIES, *Two*. Its population is 18,000.

SYRIA.

Syria.

SYRIA is a country of high historic and sacred interest. Take it in its full extent, including Palestine, and no country in the world can be compared with it. Even that northern section to which this article is confined has claims on our attention possessed by few lands. Syria was the cradle of commerce. What England is now, Phœnicia, a province of Syria, was thirty centuries ago—"the mistress of the seas." Tyre was the London of antiquity. The merchants of every nation met and traded in her rich marts. Syria was also the cradle of manufacture. Tyrian purple was the garb and symbol of royalty in every land; and Homer tells us that before his day a Sidonian robe was considered a gift of sufficient splendour to propitiate the angry patron-goddess of Troy (*Il.* vi. 288). Damascus, the capital of Syria, is confessedly the oldest city in the world; and while its ancient rivals have been laid in the dust, it still possesses all the freshness and beauty of youth. Antioch, another capital of Syria, was the third city of the Roman empire, and was famous even in the Augustan age for its splendour, its wealth, and the luxurious refinement of its inhabitants; and there, eighteen centuries ago, the name we bear and in which we glory—the name Christian, was invented. The mountains of Syria possess an interest far surpassing those of Greece or Italy. The names of Hermon and Lebanon are household words; and they are bound by sacred ties to all our hearts hold dear.

Notwithstanding all this, the geography of Syria has yet to be written. No regular survey of it has ever been made; the sites of some of its great cities remain unexplored and almost unknown; the picturesque beauty of its wildest glens and mountains has never been fully described; and the abundant resources of its soil and its mines have never been fairly estimated. In the writings of Maundrell, Shaw, Burckhardt, Chesney, Robinson, and Porter, we have all hitherto published, as the result of personal research, regarding the modern geography of Syria.

The name.

The original name of the country, now usually called *Syria* by western geographers, was Aram. This, in fact, is the only name given to it in the Old Testament, but the Hebrew *Aram* (אֲרָם) is generally rendered in the English version *Syria*, probably after the Septuagint Συρία (2 Sam. x. 6; 1 Kings x. 29; xv. 18, &c.) Aram was a son of Shem; and his descendants having peopled a large district, embracing Mesopotamia and north-eastern Syria, gave to this country the name of their progenitor (Gen. x. 22; xxv. 20); just as the family of Asshur, the elder brother of Aram, called their country *Assyria*. The Semitic name Aram is not confined to the sacred writings. It is used by Homer (*Il.* ii. 783); and Strabo states, that those who are commonly named Syrians call themselves *Aramæans* (Αραμμάιους; *Geog.* i.; xiii. 4; xvi. 4; see Reland, *Pal.* p. 46). It is a singular fact, that the name Syria, though known to, has never been adopted by, native writers. The only name generally known among the inhabitants, and used by their authors, is Esh-Sham.

Origin of the name *Syria*.

Some think the name Syria is derived from Tyre, in its Semitic form *Sur*. There can be no doubt that the city of Tyre was from the very earliest period well known to the Greeks; and being the place with which they were best acquainted, and had most intercourse, they naturally gave its name to the country; just as they called the southern part of the country Palestine, from the small maritime province of Philistia (Bochart. *Geog. Sac.* iv. 34). Others suppose that the word Syria is an abbreviation of *Assyria*. Herodotus says, Assyria is the Barbarian and Syria the Greek name (vii. 63). So also Justin represents the Assyrians and Syrians as the same (i. 1); and Strabo several times alludes to this, showing that such was the general opinion of learned men in his day (Bochart. *Geog. Sac.* ii. 3). In fact, by most of the classic writers, the two names were used promiscuously. Upon examining the subject closely, however, it would seem that this confounding of two countries arose from the similarity of the names, and from want of clear and systematic knowledge not only of etymology, but of geography. Assyria unquestionably derived its appellation from the patriarch Asshur, and embraced the country round Nineveh (as Pliny states, lib. ii.), which was afterwards called Adiabane (Bochart. *Geog. Sac.* ii. 3). *Syria*, on the other hand, was the Greek form of *Sur*, and appears to have been applied somewhat vaguely to the whole of Aram, Phœnicia, and Palestine. Some may have prefixed the article, and thus made it *Al*-Syria or *As*-Syria.

Extent and boundaries.

The old country of Aram, the Syria of the Bible, embraced Mesopotamia, and that section of Syria only which lies north of Mount Hermon, and east of the great mountain-range which runs along the coast of the Mediterranean. Mesopotamia was called *Aram-Naharaim*, "Aram of the two rivers" (Gen. xxiv. 10); while the division of Aram west of the Euphrates appears to have been first called by the general name *Aram-Dammesek*, "Aram of Damascus," but was afterwards subdivided, as we shall see (2 Sam. viii. 6). Herodotus, the first writer who uses the name Syria, makes the country extend as far eastward as the ancient Aram, while he stretches it northward over a large section of Asia-Minor, westward to the Mediterranean, and southward to the borders of Egypt (i. 72; ii. 104, 116; Reland, *Pal.* pp. 43, 44). Pliny writes somewhat indefinitely. He says, the part of Syria bordering on Arabia was called Palestine, Judea, Coele, and Phœnice; that in the interior, Damascena; that south of the latter, Babylonia; the part lying between the Euphrates and Tigris, Mesopotamia; beyond (north of) the Taurus range, Sophene; on this side of it, Commagene; and the part adjoining Cilicia, Antiocheia. He thus extends it even farther than Herodotus; but in another place he says, its length from Cilicia to Arabia is 470 miles, and its breadth from Seleucia to Zeugma on the Euphrates, 175; while he affirms that some geographers distinguish Syria both from Phœnicia and Judea (*Hist. Nat.* v. 13). According to Xenophon (*Anab.* i. 4), Syria was separated from Cilicia by a pass called the "Syrian Gates;" but he includes in it Mesopotamia. Strabo's description is more definite (xvi. 2). Syria, he writes, was bounded on the north by Cilicia and Mount Amanus; on the east by the Euphrates and the Arabian Scenitæ, who live on its western bank; on the south by Arabia-Felix and Egypt; and on the west by the Mediterranean. Some of the old geographers speak of Phœnicia as a distinct province (Herodot. iii. 5; Ptolemy, &c.); while others, as Strabo and Pliny, include it in Syria. Jewish writers generally distinguish between Syria and Palestine (Reland. *Pal.* p. 10). Ptolemy confines Syria to what may be regarded as its proper limits (*Hist. Nat.* v.) He says it was bounded on the south by Judea, on the west by the Mediterranean, on the north by Cilicia and Cappadocia, and on the east by the Euphrates as far as Thapsacus, and by the Arabian desert. This is the region which forms the subject of the present article.

The boundaries of Syria may be more definitely stated, as follows:—On the north, a line drawn from the head of the Gulf of Issus eastward to the Euphrates; on the east, the River Euphrates as far as the ruins of Thapsacus, now

Syria.

El-Hummâm, and then a line drawn past Palmyra, and across the plain to the Haurân Mountains; on the south, a line extending from the Haurân Mountains, by the waters of Merom, to the ruins of Tyre; on the west, the "Great Sea." The province thus extends from 33. 15. to 36. 50. north latitude; and from 35. 10. to about 37. 40. east longitude.

Physical geography.

The surface formation or physical structure of Syria is peculiar. The country is divided into a series of longitudinal belts, extending from north to south. There is first a narrow belt of plain along the sea-coast; next to this is a belt of mountains; next follows a long valley; then another but less regular mountain-range; and lastly, a great belt of table-land. These we shall take in order.

1. *The maritime plain.*—This plain commences on the south, at the Promontorium Album, a bold promontory of white limestone which projects into the Mediterranean. From hence to the banks of the river Auwaly (the ancient Bostrenus), a distance of 28 miles, the average breadth of the plain is about a mile. Opposite the sites of Tyre and Sidon the mountains retreat slightly, and the coast also juts out into the sea; the breadth is there increased to some two miles; while in other places the rocky hills almost dip into the Mediterranean. The surface of the plain is undulating, and the soil fertile, composed chiefly of disintegrated limestone, washed down from the heights of Lebanon. The greater part of it is now waste and desolate, but the few spots still cultivated show what it might be. The gardens and orchards of Sidon are almost unrivalled, producing melons, bananas, mulberries, figs, grapes, apricots, and oranges, in addition to the more common fruits and vegetables. Here and there we still meet with a few scattered palm-trees. This little plain constituted the nucleus of Phœnicia. Its coast-line is singularly bare and uniform. Opposite the promontory of Tyre there was formerly an island; it is now a peninsula, having been united to the mainland by Alexander's Mole; on it stood the new city of Tyre. (See Tyre.)

Between the River Auwaly and Beyrout the plain is intersected by several rocky spurs from Lebanon. The promontory of Beyrout is low and sandy. From the base of the mountains to the apex it measures about 3 miles. Vast groves of olives, gardens of mulberries, and orchards of fruit-trees grow upon it; but the drifting sand threatens them all with destruction. The bay of St George, on its northern side, affords, perhaps, the safest anchorage along the whole coast. It derives its name from its being the scene of the fabled contest between England's patron saint and the Dragon.

North of this bay the plain is again broken for a distance of nearly 20 miles by the rugged roots of Lebanon. On approaching Tripolis, it opens out into broad and beautiful fields and orchards. The gardens of Tripolis are more extensive and scarcely less productive than those of Sidon. Northward the plain still expands to a breadth of some 6 miles, sweeping round the gentle curve of a spacious bay, which extends to the rocky islet on which the ruins of Aradus lie, 25 miles from Tripolis. The soil is here exceedingly fertile, though the greater part of it is waste. From Aradus to the base of Mount Casius the plain continues unbroken, varying from 2 to 5 miles in width. Mount Casius interrupts it, rising abruptly from the sea. On its northern side lies the rich alluvial plain of Seleucia, at the mouth of the Orontes, now in part covered with orchards of mulberries and cultivated fields. Then, again, the bold headland called Ras-el-Khanzîr juts into the Mediterranean, separating the plain of Seleucia from that of Issus. The latter is very narrow, low, and marshy. At its northern end is a low promontory over which the road is carried; on the top of the pass are the remains of an ancient arch, and not far distant may be seen traces of a massive wall. This is doubtless the site of the "Syrian Gates" referred to by Xenophon in his description of the march of Cyrus, and is, consequently, the northern limit of our province.

2. *The Mountain Range.*—This range shuts in the maritime plain on the east, and is divided naturally, as well as historically and nominally, into three sections. The southern section is called

Lebanon. The great chain of Lebanon commences on the north bank of the River Litâny, from whose gloomy defile it rises boldly and abruptly. It runs in a north-eastern direction for about 90 miles, and terminates at the pass called in Scripture the "Entrance of Hamath." The breadth of the ridge varies from 15 to 20 miles, and its average elevation is about 7000 feet. Two peaks, Jebel-Sunnîn and Jebel-Mukhmel, rise considerably higher; and on their summits the snow remains in streaks during the whole summer. The latter is the loftiest mountain in Syria, rising about 10,000 feet above the sea. The main body of the ridge is limestone, but along the lower western slopes are thick strata of chalk, and fossils of various kinds everywhere abound. The summits are rounded, bare, and of a greyish-white colour. On the eastern side the descent is rugged and abrupt into the valley of Bukâa, the ancient Coele-Syria; while on the western it is more gentle, and we here see what industry can do even amid the wildest forms of nature, when it has a Syrian soil to work upon and a Syrian climate to aid it. No idea could be formed of the resources or cultivation of Lebanon by looking up from the maritime plains. As the whole range from base almost to summit is cultivated in terraces, nothing meets the eye when turned upwards but rude walls of rough stones, and loffy cliffs of gray rock. But when, on gaining some commanding peak, the eye is turned downward, one can scarcely repress the thought that the wand of an enchanter has been waved over the scene. Stair-like terraces of bright green corn and luxuriant vines, intermixed with long ranges of mulberries, olives, and fig-trees, have taken the place of naked rocks. Those more rugged parts along the lower declivities where cultivation is impossible, are scantily clothed with the oak and the pine. And high up on the side of the loftiest peak, far apart from other trees, still stand in stately, solitary grandeur the little grove of cedars—the last remnant of a sacred forest.

Nusairîyeh Mountains. The pass at the northern end of Lebanon, through which the road leads from the coast to the plain of Hamath, is about 5 miles wide. Beyond it rise the Nusairîyeh Mountains, which run in an unbroken chain northward to the Orontes, constituting the second section of the general chain. They are much lower than Lebanon, not averaging more than 4000 feet. Limestone is the prevailing rock; and thin oak-forests cover nearly the whole ridge. Where the chain meets the Orontes at Antioch, it sweeps round to the west, and terminates abruptly in a singular conical peak, which rises up bare and steep to a height of 5700 feet; this is the Casius of which Pliny tells such wonderful stories. The Nusairîyeh range is the Bargylus Mons of old geographers.

Jawar Dagh. On the north bank of the Orontes the mountains again rise abruptly in huge masses of naked rock. A spur shoots out from them westward, shutting in the plain of Seleucia and terminating in the bold promontory of Ras-el-Khanzîr. This part was formerly called Mons Pieria, from whence the city of Seleucia took its name Pieria. The chain which continues northward is the Amanus of Roman geographers, and is now called in Turkish Jawar Dagh. It has an elevation of about 6000 feet, and its scenery is both wild and picturesque, the lower slopes being furrowed with deep glens and clothed with forests of evergreen oak.

3. *The Great Central Valley.*—This valley runs along

the eastern base of the mountain-chain, and forms the most striking feature in the physical geography of the country. It is the continuation of a wonderful crevasse, which, further south along the course of the Jordan, has for a hundred miles and more a depression varying from 1 foot to 1312 feet below the level of the sea. Between the parallel ridges of Lebanon and Anti-Lebanon this valley extends from S.W. to N.E. about 70 miles in length, and is from 3 to 7 miles in breadth. It is almost perfectly flat; and the soil is in general rich, loamy, and abundantly watered. It is the Coele-Syria of the ancients; and its modern name is *El-Bukâa*, "the Plain." It has an elevation of some 3000 feet above the sea. At its northern end it joins the plain of Hamath, which extends far eastward; but there is still enough of depression along the course of the river Orontes to indicate the proper line of the valley. At Hamath it has again a ridge of hills on its eastern side; and here its course is due north, and it gradually contracts until, sweeping round westward at Antioch, it cuts through the mountain-chain in a sublime gorge, opening a way for the Orontes to the Mediterranean.

4. *The Anti-Lebanon Range.*—Along the east side of the valley of Coele-Syria lies another mountain-range, the Anti-Libanus of old geographers, now called Jebel Esh-Shurky. It rises up on the plain of Jaulân, a few miles east of the waters of Merom, and runs due north for 20 miles, gradually increasing in elevation, and covered with oak-forests. It then joins Mount Hermon, which is the culminating point of the whole range. It is a massive, white, naked, truncated cone, attaining an elevation of nearly 10,000 feet; and is, like the peaks of Lebanon, tipped with perpetual snow. From Hermon, as a centre, several ridges radiate, spreading out like an opening fan from N.E. to E. The ridge on the extreme left is the loftiest, varying from 4000 to 7000 feet in height; it sinks down into the plain of Hamath after a course of about 80 miles. That on the extreme right is much lower; it bounds the plain of Damascus, and extends away beyond Palmyra. All the ridges are bare, and hopelessly barren; though here and there one meets with scanty forests of oak and juniper. The main ridge is limestone, like Lebanon, abounding with fossils; but the lower ridges toward the plain of Damascus are chalky, and in places white as snow. They form a fit home for wild beasts—bears, leopards, wolves, swine, and especially jackals. Between the expanding ridges are several terrace-like plateaus, bleak and arid, though not all barren; and they are intersected by two wild and rich glens—*Abana*, which creates by its abundant waters the noble plain of Damascus, and *Helbon*, famed as of yore for its vintage (Ezek. xxvii. 18). The fullest account of this remote region will be found in Porter's *Damascus.*

Plain of Hamath. At the northern end of the main, or western, ridge of Anti-Lebanon lies the fertile plain of Hamath, extending from the banks of the Orontes to the desert of Palmyra. About 50 miles north of Anti-Lebanon another chain rises up in the same line, not far from the ruins of Apamea. It is made up of several clumps of hills, almost detached; and it runs northwards as far as the parallel of Aleppo. These hills are limestone, in places well wooded, and are intersected by little fertile plains and valleys. They are interesting to the traveller and antiquarian as containing some of the most remarkable ruins in Syria. The southern section is called Jebel-Rîha, the central Jebel-el-Ala, and the northern Jebel-Simân, from its having been the residence of St Simon Stylite.

5. *The Eastern Plateau.*—This plateau continues almost unbroken from the southern limits of the country to the banks of the Euphrates. Its southern section constituted the ancient kingdom of Bashan, and is one of the most fertile tracts in Western Asia. Its surface is flat, with a deep, rich, black soil, and is dotted here and there with little conical and cup-shaped mounds of basalt, evidently extinct craters. It has an average elevation of nearly 2500 feet above the sea. In the very centre of this plain is one of the most remarkable regions in the world, in a physical point of view. It is now named the *Lejah*, or "Retreat," but the Hebrews called it *Argob*, and the Greeks *Trachonitis*, both words being descriptive of its wild, stony character. It is oval in shape, about 25 miles long by 13 wide. Its borders are as clearly defined as a rocky coast-line. The general surface is elevated from 20 to 30 feet above the surrounding plain. It is wholly composed of basalt rock, which appears to have issued from innumerable pores in the earth, and to have flowed out on every side until the plain was almost covered. Before cooling it seems to have been tossed like a tempestuous sea. The crater-like cavities from which the liquid mass exuded are still visible. Deep fissures and yawning chasms intersect the whole like a network; while here and there are huge mounds of shattered rock. The rock is black, filled with air-bubbles, and hard as flint. The aspect of the whole is savage and desolate in the extreme. The very trees that grow among the rocks have a blasted look; yet, strange to say, this forbidding region is thickly studded with deserted towns and villages.

Mountains of Bashan. Away on the eastern border of the plain is an isolated range of volcanic hills, the highest peak of which, called Kuleib, has an elevation of about 5000 feet. Their sides are partially covered with remains of ancient oak-forests, and dotted with the ruins of primeval cities. These are the "Mountains of Bashan" mentioned in the Bible, called Alsadamus Mons by Ptolemy, and Jebel-Haurân by the Arabs. Another isolated and much lower ridge separates the territory of Bashan from Damascus.

The Plain of Damascus, now called *El-Ghûtah*, is celebrated throughout the world for its richness and beauty. It is perfectly flat; and its fertility and surpassing loveliness are wholly owing to the waters of the Abana and Pharpar, which are diffused by innumerable canals and ducts over its surface. On the north of the Ghûtah the low bare ridge which runs eastward from Hermon intersects the great plateau; but beyond this range it again extends arid, bleak, and desolate—fit abode for timid gazelle and wild Bedawy—far away to the banks of the Euphrates. On its western side, in the midst of low, white, chalk-hills, stands Aleppo. Between Aleppo and the Euphrates is a large salt marsh.

The Orontes, now called El'Asy, is the largest river in Syria. Its highest source is in the valley of Coele-Syria, beside the ruins of Lybo, at the base of Anti-Lebanon; but its principal source is 10 miles farther down, at the eastern base of Lebanon. It flows northward towards Hums, the ancient Emesa, where a strong embankment, built many centuries ago, dams up the river, and forms a large lake, called Kades. From hence it flows on in the same general direction through the centre of the valley to the parallel of Antioch, where it turns abruptly westward, and passes through a sublime gorge to the Mediterranean. Before passing Antioch it is doubled in size by a tributary from a lake called Bahr-el-Abiad, lying a few miles northward. Rivers.

The Leontes, now called El-Litâny, is the second river in magnitude. It rises in the plain of Coelé-Syria, near Bâalbek, and receives numerous small tributaries from Lebanon and Anti-Lebanon. At the southern end of the plain it enters a narrow deep ravine, in many places only a few feet wide, and at one spot spanned by a natural bridge. After intersecting the mountain-ridge, it falls into the Mediterranean near Tyre.

The Abana, the Chrysorrhoas of the Greeks and Barada of the Arabs, is a wild mountain-torrent, rising in the very centre of Anti-Lebanon, cutting in succession through three of its parallel ridges, and at length bursting forth from its

rocky barrier, bearing gold in its bosom and scattering emeralds far and wide over the matchless plain of Damascus. About 15 miles east of the city, the river, greatly reduced in size, divides into two branches, each of which feeds a little lake.

The other rivers of Syria are the Pharpar, now called Nahr-el-Awaj, which rises high up on the side of Hermon, flows across the plain of Damascus, and falls into a lake, or rather marsh. The *Lycus flumen*, or Nahr-el-Kelb (the Latin "wolf" having degenerated into the Arab "dog"). Its source is on Jebel-Sunnîn, and it falls into the Mediterranean some eight miles north of Beyrout. At its mouth is the remarkable pass where Egyptian, Assyrian, and Roman conquerors have in succession inscribed records of their deeds. The Adonis springs from a cave beneath a stupendous cliff beside the ruins of Apheca, and through a yawning chasm,

> "Runs purple to the sea, supposed with blood
> Of Thammuz yearly wounded."

The Eleutherus, now Nahr-el-Kebîr, sweeps round the northern end of Lebanon, through the "Entrance of Hamath," and falls into the Mediterranean some 15 miles north of Tripolis.

Historical and political geography.

No country in the world of the same extent has passed through so many political changes and vicissitudes as Syria. Its first colonists were the descendants of Aram, who gave the name of their progenitor to the whole eastern section of the country. This section was soon subdivided into no less than six districts. (1.) Its northern part, between the city of Hamath and the Euphrates, was called Aram-Zobah (1 Sam. xiv. 47; 2 Sam. x. 6, comp. viii. 3). Palmyra appears to have been in this province (2 Chr. viii. 3, 4). South of the former lay *Aram-Dammesek*, so named from Damascus its capital (2 Sam. viii. 5). (3.) A small territory round the base of Hermon was attached to the city of Beth-Maachah, and hence called *Aram-Maachah* (1 Kings xv. 20; Deut. iii. 14; 1 Chr. xix. 6). (4.) Apparently adjoining the latter was another small territory, called *Aram-Beth-Rehob* (comp. Judges xviii. 28; 2 Sam. x. 6). (5.) Josephus states that Uz, the son of Aram, founded the principality of *Trachonitis* (*Antiq.* i. 7), which the Hebrews called *Argob*. It contained many great and strong cities founded by a race of giants (Deut. iii. 13, 14), the remains of which still exist (Porter's *Damascus*, vol. ii.) (6.) Between Trachonitis and Damascus lay a small but very ancient province, colonized by *Jetur*, a son of Ishmael (Gen. xxv. 15), and by the Greeks named *Iturea*.

Mount Lebanon appears from the earliest ages to have been inhabited by several small independent tribes, who were more or less closely connected with their neighbours on the coast, the Phœnicians. The *Arkites* (Gen. x. 17) dwelt in Lebanon, and the ruins of their old capital Arca may still be seen a few miles from Tripolis. The *Giblites* were also "mountaineers" of Lebanon, and they gave their name to a city and province which to this day we can recognize in the Arabic form, *Jebeil*.

Phœnicia was a province so distinct and so remarkable that it will be treated separately in the sequel.

Under the Seleucidæ the various principalities of Syria were for a time united in one kingdom; but during the harassing civil wars of this dynasty a new division took place, and the old city of Damascus was made the capital of a southern kingdom, including Palestine.

The political divisions of Syria in classic ages, as given by Greek and Roman geographers, are far from being definite. Strabo mentions five provinces:—1. *Commagene*, a fertile and comparatively level region, lying along the right bank of the Euphrates; bounded on the N. by Mount Taurus, and on the W. by the range of Amanus. Samosata was its metropolis, and was situated on the Euphrates, which was here spanned by a bridge (Strabo, *Geog.* xvi.) 2. *Seleucis* lay on the S. and S.W. of the former, and embraced the territories annexed to the cities of Seleucia-Pieria, Antioch, Apamea, and Laodicea-ad-Mare. 3. *Coele-Syria.* This province was originally confined, as the name implies, to the great valley between Lebanon and Anti-Lebanon; but in Strabo's time it was already extended almost indefinitely southward and eastward. It included the territory of Chalcis, a city at the western base of Anti-Lebanon, 20 miles south of Heliopolis; the province of Abila, or Abilene, a mountainous region between Hermon and the valley of the Abana (Luke iii. 1); Damascus, with its noble plain; Iturea; Gaulanitis, lying along the east bank of the upper Jordan; Auranitis, the beautiful plateau east of the latter; Trachonitis, already described; and Batanæa, which embraced the mountains called Jebel-Haurân. 4. *Phœnicia* (see below). 5. *Judœa* (see article PALESTINE).

Pliny's divisions are still more numerous than Strabo's; and Ptolemy makes no less than fifteen provinces. In fact, it appears from a careful perusal of ancient authors, that every city as it rose to importance gave its name to a little state round it; but whenever it was eclipsed by a neighbouring rival, its principality was swallowed up. This gave rise to great confusion in the political geography of the country; but the fact sufficiently accounts for that indefiniteness so marked in the works of Strabo, Pliny, and Ptolemy. Ptolemy mentions three small districts not named by Strabo:—1. *The Coast*, from the Syrian Gates to the border of Phœnicia. This included the narrow plain of Issus, and the plain at the mouth of the Orontes, which Strabo calls Pieria. 2. *Palmyrene*, embracing the desert plains, and naked mountains round Palmyra, and extending eastward to the Euphrates. 3. *Laodicea Scabiosa* embraced the southern section of the plain of Hums, and a part of the adjoining ridge of Anti-Lebanon. The site of the old city from which it took its name was identified a few years ago by the writer of this article. The ruins lie upon the bank of the Orontes, 15 miles above Emesa (Hums), and are now called Tell Mindau.

Under the Romans Syria became a province of the empire, and was generally governed by a proconsul. Some portions of it, however, were for a time suffered to remain under the rule of petty princes, who were dependent on the imperial government, and whose dominions were gradually incorporated. There were also a number of cities to which freedom was given; these had their own laws, and administered their own revenues. Both principalities and free cities were financially subject to the Roman government—they were, in fact, employed as instruments for the collection of the imperial revenues. Antioch was the usual residence of the governor, and was the acknowledged capital of the province. The province increased so rapidly in extent and wealth that, in the reign of Hadrian, it was found necessary to divide it into three parts, namely—1. *Syria Major*, with Antioch at first, and afterwards Laodicea as its capital; 2. *Syria Phœnice*, or *Syrophenice* (Mark vii. 26), embracing the territories of Tyre, Damascus, and Palmyra; 3. *Syria Palæstina.* Towards the close of the fourth century another subdivision of Syria took place, which formed the basis of the ecclesiastical government. The sections were as follows:—1. *Syria prima*, with Antioch for its capital, and the greater part of Northern Syria within its borders. 2. *Syria Secunda;* capital city, Apamea. It embraced the rich plain of Hamath, with several large and prosperous towns. 3. *Phœnicia Prima*, including the greater part of the ancient province of Phœnicia, and extending as far inland as Cæsarea Philippi. Its metropolis was Tyre. 4. *Phœnicia Secunda*, also called Phœnicia-ad-Libanum. Damascus was its capital; and Abila, Heliopolis, Laodicea-ad-Libanum, and Palmyra, were subject to its governor. The other sections were *Palæstina Prima*, *Secunda*, and *Tertia.*

Phœnicia.

In the beginning of the seventh century the wild followers of Mohammed captured Syria, and then Damascus became for a time not only the capital of all Syria, but also of an empire that extended from the Indian Ocean to the shores of the Atlantic. The changes and vicissitudes through which Syria passed from that period to the present day belong more to history than geography.

The whole country of Syria and Palestine is at present divided into three pashalics—Damascus, Aleppo, and Sidon. The *Pashalic of Damascus* includes the districts lying east of the Jordan, the Bukâa, and the Orontes as far north as Hamath. Damascus is the residence of the commander-in-chief of all the Sultan's forces in Syria. The *Pashalic of Sidon* includes all Palestine west of the Jordan, all Lebanon, and the coast as far north as Tripolis. Beyrout is the capital, and is at present the most flourishing town in Syria. A governor, with the title of pasha, resides at Jerusalem; but he is subject to the Pasha of Sidon. The *Pashalic of Aleppo* embraces all northern Syria, with a section of Asia-Minor, extending to Aintab and Marash. The following table gives a comprehensive view of the statistics of these pashalics so far as they are known. It must be remembered that the Turks are far behind in statistics:—

	Damascus.	Aleppo.	Sidon.	Total.
Muslems.........	412,000	460,000	424,000	1,296,000
Christians.......	79,100	81,000	281,000	441,100
Jews..............	5,300	10,000	9,000	24,300
Druzes	18,000	Not known	60,000	78,000
Metâwileh	18,900	...	7,000	25,900
Nusairîyeh......	14,500	41,000	Not known	55,500
Total.........	547,800	592,000	781,000	1,920,800

PHŒNICIA.

The best geographers have included Phœnicia in Syria, and, therefore, its physical geography, statistics, and more recent history, have been connected in this article with those of the latter country; but the political state and history of Phœnicia, during the period of its independence, are so distinct and so interesting that the writer has thought it best to give a condensed view of them in this place in a separate form.

Name.

The Semitic and ancient name of Phœnicia was *Chna*, or *Canaan* (כְּנַעַן, Greek, Χνᾶ). This is the only name used by the Phœnicians themselves, and also by the Hebrews (Gen. x. 17–19; Reland, *Pal.* p. 7). It signifies "low region," probably as opposed to the plateau of Aram; and is, therefore, descriptive of the country. (The root is כָּנַע, "to be low.") The word Phœnicia is supposed by some to be derived from the name of a man, said to be a brother of Cadmus; by others from φοίνιξ, "a palm; by others from the purple dye, φοινός; and by others from the Red Sea, whence, according to Herodotus (vii. 89), the Phœnicians came.

Extent and boundaries.

Ancient geographers give widely different accounts of the extent of Phœnicia. Some say it included the whole maritime plain from the Gulf of Issus to Egypt; while others confine it between the rivers Eleutherus and Crocodilon. Some make it run as far eastward as Damascus; while others shut it in by the ridge of Lebanon. This is not much to be wondered at. The Phœnicians would not confine themselves within definite bounds. They went wherever they found an opening for trade, and they contrived to make that spot their home. It is probable that the nucleus of the nation was very small, including only the narrow strip of plain along the western base of Lebanon, between the Promontorium Album and the River Bostrenus. Soon, however, they extended northwards and southwards, building cities wherever they found a little bay or cape to shelter their ships. Sidon and Tyre were the parent cities—the cradles of the world's commerce. The island of Aradus was early occupied; then followed Accho and Dor on the south, Tripolis and Gabala on the north. All these, and many more, were colonized before the time of Herodotus (iii. 5; iv. 38, &c.) About the period of the Roman conquest of Syria (B.C. 64), the limits of Phœnicia were pretty accurately defined. Pliny says it reached from Aradus to the Crocodile river, which falls into the sea a few miles south of Dor, a distance of 140 miles; its breadth did not average more than 2 or 3 miles. Its situation was admirably adapted for the development of its commerce. On the east, the ridge of Lebanon secured it from attack. The great strongholds, Tyre and Sidon, were so placed naturally as to bid defiance to any ordinary foe. The only approaches to them lay along the coast, and these were defended by the difficult passes at the River Lycus and the Promontorium Album. The coast beyond these points was more open. On the west, the Phœnicians had an uninterrupted seaboard, with a number of little rock-girt ports, insignificant indeed as respects modern navigation, but sufficient for the wants of those primitive ages. The plain, though narrow, is rich, and abundantly watered by streams from Lebanon. The mountain-sides above yielded oil, and wine, and "summer fruits," for which they are still famous; besides an unlimited supply of pine, cedar, and oak, for ship-building. The gardens and fields below produced those palm-groves which probably gave the country its name. The palm has almost disappeared, only a few solitary trees appearing here and there; but orchards of oranges and lemons have taken their place round Sidon, Beyrout, and Tripolis. The glory of Phœnicia has passed. A mournful and solitary silence now reigns along the greater part of a coast which once resounded with the din of an enterprising commercial people.

History of Phœnicia.

The early part of Phœnicia's history is, in a great measure, legendary. In the Bible Sidon is said to be a son of Canaan; and the Arvadites and Arkites, two other Phœnician tribes, were of the same family (Gen. x. 17, 18). In the Scriptures, as well as on their own coins and inscriptions, the Phœnicians are always called Canaanites (Judges i. 31; Reland, *Pal.* p. 7). It would seem, however, from the nature of the language, which closely resembles the Hebrew (Gesen. *Monum. Phœn.*), that they were either amalgamated with some Semitic tribe, or had such intimate relations with their neighbours of Aram, as led them to adopt their language. Herodotus says they immigrated from the Red Sea, and Strabo that they came from two islands in the Persian Gulf. There can be no doubt that the whole descendants of Ham migrated from the plains of Assyria; and the route followed by the Canaanites may have been along the shores of the Persian Gulf, up the Red Sea, and, as Justin states (xviii. 3), to the Assyrian Lake, or Dead Sea, and thence finally to the coast at Sidon. But however this may be, it is certain that they were settled on the little plain at the base of Lebanon, at least as early as the time of Abraham (comp. Gen. x. 19; xv. 21), or nearly 2000 years B.C. Herodotus, who made a journey to Tyre for the express purpose of verifying a date, states that the great temple of Hercules in that city had already existed twenty-three centuries. This would throw back the founding of the temple, and of course the city, to about B.C. 2800, or some 450 years before the Flood, according to the common chronology. No scholar, however, who examines in an impartial spirit the confused annals and long-drawn chronological records of Phœnicia or Egypt, will venture to adopt them in preference to that of the Bible.

Sidon was the first capital of Phœnicia. It was emphatically the "Great Zidon" when the Israelites invaded Canaan (B.C. 1450; Josh. xi. 8). It is several times men-

Phœnicia. tioned by Homer, and before his day its manufactures had obtained a world-wide celebrity. In the earliest periods of Grecian history Sidonian ships were well known on the coasts, and Sidonian merchants in the marts of that country, and also of Asia-Minor. Isaiah wrote, more than twenty-five centuries ago, "Tyre is of ancient days . . . . the crowning city, whose merchants are princes" (xxiii. 7–12); and yet he calls her a "daughter of Zidon." The glory of the daughter then excelled that of the mother, and hence we can account for the fact that some later classic authors call Tyre ματέρα Φοινίκων. In fact, from the earliest period of which we have any trustworthy and full history, Tyre was the chief city of the Phœnicians. Here Hiram reigned who aided Solomon in building the Temple and in navigating his fleets. From his days to the time of Pygmalion we have a dry, uninteresting list of the rulers of Tyre. (See Kenrick's *Phœnicia;* Mover's *Die Phönitzier;* Bochart's *Geog. Sac.*) During the reign of Pygmalion the great colony of Carthage was founded by his sister Dido, so well known to the readers of Virgil. Some time after this the friendly relations which had subsisted for several centuries between the Phœnicians and Israelites were broken; and the cruelties perpetrated by the former were the causes of the prophetic curses pronounced upon them by Joel and Ezekiel (Joel iii.; Ezek. xxvi.), and subsequently so fearfully executed. The whole of Phœnicia was overrun by the Assyrian monarch Shalmanezer (Joseph. *Antiq.*, ix. 14), and afterwards by Nebuchadnezzar, when Sidon was captured, and Tyre stood a siege of thirteen years (*Antiq.* x. 11). In the days of Darius both Phœnicia and Palestine were considered provinces of the Assyrian empire, though still enjoying a kind of independence. The Phœnicians had now attained to great eminence, not only as a commercial, but also as a warlike people. Their fleets were constantly employed in the wars between the Persians and Greeks under Darius and Xerxes (Herodot. vii. and viii.) About B.C. 352, the Phœnicians attempted to regain their independence, and resist the power of Persia; but though they made a noble effort to defend Sidon against the hated foe, they were basely betrayed, and then visited by a terrible punishment. Forty thousand of the inhabitants of Sidon are said to have burned their houses over their heads rather than submit to the cruel conquerors.

After the victory of Issus, Alexander the Great marched upon Phœnicia; and, after an obstinate siege, captured the island-city of Tyre. Phœnicia now lost its nationality, and with this much of its enterprising spirit. Situated on the confines of the dominions of the Seleucidæ and the Ptolemies, it was often the theatre of devastating wars. When the Roman empire extended to Western Asia, Phœnicia was annexed to the province of Syria. Tyre, Sidon, and Aradus still continued to prosper; and Beritus rose to fame, not merely as a commercial city, but as a seat of learning. From this period, however, the history of Phœnicia merges into that of Syria.

Literature and art. It was not for their navigation merely, and their commercial enterprise, that the Phœnicians were celebrated. They were generally regarded, in ancient times, as the inventors of those phonetic characters which, to some extent, form the basis of all literature. The earliest specimens of Greek inscriptions bear considerable resemblance in the forms of their letters to the Phœnician; and they are found in some places colonized by the Phœnicians. Their skill in working gold and silver was also widely known. The bowl presented by Menelaus to Telemachus, and the silver vase proposed by Achilles as the reward in the funeral games of Patrocles, were of Phœnician workmanship (Homer, *Od.* iv. 618; *Iliad*, xxiii. 743). The bronze castings and purple robes of Tyre were everywhere prized. Even in the Roman age that city enjoyed the exclusive privilege of manufacturing the royal purple. The dye was obtained from small shell-fish, of the genera *buccinum* and *murex*, found along the rocky coast. Each mollusk yields but a single drop of the fluid dye, which is extracted by a sharp-pointed instrument (Pliny, *Hist. Nat.*, ix.) Glass was also manufactured in Phœnicia at a very early period. It is said to have been accidentally discovered by some merchants, who arrived on the coast near Carmel with a cargo of natron; and having used some pieces of it to keep up their cooking vessel on the fire, it was melted by the heat, and, mingling with the sand, produced glass (Plin. xxxvi.)

Colonies. Colonies were planted by the Phœnicians in almost every maritime country of the known world; in this respect, also, they were the Anglo-Saxons of antiquity. Cyprus was probably their earliest colony beyond the Syrian coast, and traces of their monuments remain on the island to this day. Thence they extended along the shores of Asia-Minor to Rhodes and the isles of Greece. Several towns were founded on the coast of Crete; and they crossed the mouth of the Adriatic, and established themselves in Malta, Sicily, and at Carthage. Cadiz and Tarshish, on the shores of Spain, were early occupied; and it is probable that they reached England, and carried on mining operations in Cornwall. (See Kenrick's *Phœnicia;* Bochart, *Geog. Sac.*)

Religion. Of the religion of the Phœnicians we have no definite or clear account. The fullest is given in Eusebius's *Prepar. Evangel.* Baal and Ashtaroth—representatives of the sun and moon—were their chief deities. To these they dedicated high places and temples in every part of their dominions. The name Baal also was often adopted by kings and great men; it was prefixed to that of other deities, as Baal-Zebub, "God of flies;" Baal-Berith, "God of the covenant;" Baal-Markos, "God of sports;" and it was prefixed to that of places where temples or altars were set up; as Baal-Gad, Baal-Hermon. The worship of these favourite deities was not only carried by the Phœnicians to their various colonies, but was also introduced among neighbouring nations. Jezebel, the daughter of Eth*baal*, promoted it in Israel (1 Kings xvi. 31).

Climate of Syria. There is, perhaps, no country in the world, of the same extent, which possesses a greater variety of temperature and climate than Syria. Perpetual snow crowns the summit of Hermon, while tropical heat scorches the deep valley of the upper Jordan at its base. The high altitudes along the brow of Lebanon are as cool and invigorating during the summer months as the south of England; while the marshy tracts round the waters of Merom, along the banks of the Orontes, near Apamea, and at the western base of Mount Amanus, are almost as hot and debilitating as the plains of Southern India. The whole seaboard, owing to its exposure to the rays of an unclouded sun, and its being sheltered by the mountain-ranges behind, is very sultry, and in some places unhealthy. But there are a few spots, even on the coast, such as Beyrout and Sueidîyah, where the soil is dry and the air pure; and these form excellent winter residences for invalids. The temperature and climate in the various parts of the interior depend on the elevation and the character of the soil. Jerusalem is high and breezy; but the rays of the sun, reflected from the bare white rocks and white soil around, render the heat most oppressive during the day. In Palestine rain very rarely falls from the end of April till the beginning of October; and a little cloud in the sky, as large as a man's hand, would be a wonder. The whole country is thus parched; vegetation, except where streams of water flow, is extinguished; and the air, during the long summer day, becomes so hot, dry, and scorching, as to render travelling unpleasant, if not actually dangerous.

In Lebanon, on the other hand, though the sun may be powerful, the air is fresh and balmy; while the dense foliage of its sublime glens gives a pleasant shade, and its foaming

torrents diffuse an agreeable coolness, even during the mid-day heat. The stalwart frames of the inhabitants of Lebanon are the best certificates of its bracing climate. The way in which the people digest and thrive on rancid oil, raw vegetables, and other abominations, speaks volumes for the peptic character of the mountain-air. The air, except where artificial irrigation is carried to an undue extent, is extremely dry, and malaria is almost unknown.

In Palestine the autumnal rains commence about the latter end of October, or beginning of November; in Lebanon they are a month earlier. They are usually accompanied by thunder and lightning; they continue for two or three days, not constantly, but falling chiefly during the night. For the two succeeding months they fall heavily at intervals. January and February are the coldest months; but along the coast of Syria, and in Palestine, frost is very rarely seen, and the cold is not severe. Snow falls on the higher altitudes along the whole mountain-ridge, on the plains of Coele-Syria and Hamath, and the writer once saw it eight inches deep on the terraced roofs of Damascus. Yet, in the western declivities of Lebanon, the snow seldom whitens the ground at a lower elevation than 2000 feet. Rain falls at intervals during the month of March; in Palestine it is rare in April; and even in Lebanon and Northern Syria the few showers that occur are generally light.

In the valley of the Jordan the barley harvest begins as early as the middle of April, and the wheat a fortnight later. In the hill-country of Judæa reaping commences about the beginning of June, while in Lebanon the grain is seldom ripe before the middle of that month. A pretty accurate index is thus given to the relative temperature of the different districts. It is not easy to ascertain the exact ranges of the thermometer, as much depends on the position of the instrument; and there are neither observatories nor meteorological societies in the country. In Aleppo, according to Russell, the range of the thermometer is very great; sometimes descending below zero, and rising above 100° Fahr. During a residence of nearly ten years in Damascus, the writer never saw the thermometer below 23°, or above 95°.

Inhabitants of Syria.

The inhabitants of Syria and Palestine form a most interesting study. Their dress, their manners and customs, and their language, are all primitive. No European nation, with the exception perhaps of the Spaniards, bears the least resemblance to them. Like Spain, too, the best specimens of humanity are here found among the lower classes. The farther we go from the contaminated atmosphere of government offices, the more successful shall we be in our search after honesty, industry, and genuine patriarchal hospitality—the great, almost the only, unadulterated virtue of the Arab. The people are illiterate, and extremely ignorant of all western inventions; but there is a native dignity in their address and deportment which will both please and astonish those who have seen the awkward vulgarity of the lower classes in some more favoured lands. Whether we enter the tent of the Bedawy or the cottage of the peasant, we are received and welcomed with an ease and courtesy that would not disgrace a palace. The modes of salutation are very formal, some would call them verbose and even tedious. Still there is something pleasing in them after all. The gestures used are graceful, if a little complicated. The touching of the heart, the lips, and the forehead with the right hand, seems to say that each one thus saluted is cherished in the heart, praised with the lips, and esteemed by the intellect. An Arab when eating, whether in the house or by the wayside, however poor and scanty his fare, never fails to invite the visitor or passing wayfarer to join him. And this is not always an empty compliment. In making purchases from an Arab, one finds his politeness almost overpowering. When the price is asked, he replies, "Whatever you please, my lord." When pressed for a more definite answer, he says, "Take it without money." One cannot but remember under such circumstances Abraham's treaty with the sons of Heth for the cave of Machpelah. Our feelings of romance, however, are somewhat damped when we discover that the price ultimately demanded is four or five times the value of the article; and that every form of lying and misrepresentation will be tried to gain a few additional piastres. The only exception to the general politeness of the Arabs in their intercourse with strangers of another faith, is to be found in some bigoted Muslems of the old school, who have for long centuries been accustomed to use the words "infidel," "dog," "Christian," as synonyms.

The modern inhabitants of Syria and Palestine are a mixed race, made up of the descendants of the ancient Syrians who occupied the country in the early days of Christianity; and of the Arabians who came in with the armies of the khalifs and settled in the cities and villages. The number of the latter being comparatively small, the mixture of blood did not visibly change the type of the ancient people. This may be seen by comparing the Christians with the Muslems. The former are undoubtedly of pure Syrian descent, while the latter are more or less mixed, and yet there is no visible distinction between the two save what dress makes. Every observer, however, may at a glance distinguish the Jew, the Turk, or the Armenian, each of whom is of a different race. The whole inhabitants may be best considered under the heads of religious sects. Religion has made most of the real distinctions existing among them; though difference of climate, employment, and mode of life have also had their effects on dress and minor matters. The mountaineer, for example, has his bag-trousers of immense capacity, his stiff embroidered jacket, and his trim turban; while his wife struts about in all the state of her towering silver horn and flowing white veil. The Bedawy of the desert is *sans culottes*, and his raiment consists of a loose calico shirt, over which is occasionally thrown a coarse cloak, and on his head is a gaudy kerchief, bound with a twisted rope of camel's hair. The city gentleman is arrayed in flowing robes, yellow slippers, red over-shoes, and turban of spotless white or embroidered Indian muslin. The peasant of the plain of Damascus looks more active in his gay-coloured spencer and short Turkish trousers. The inhabitants of some of the villages of Palestine and plains of Hamah seem to carry most of their wardrobe on their heads; for the enormous turban is out of all proportion to the scanty shreds that cling round the body.

We may now glance at the several religious sects.

1. *The Muslems.* These are, and have been for many centuries, the lords of the soil, and they constitute the great majority of the community. They are proud, fanatical, and illiterate. They are taught by the faith they hold to look with contempt on all other classes, and to treat them not merely as inferiors, but as slaves. They are in general noble in bearing, polite in address, and profuse in hospitality; but they are regardless of truth, dishonest in dealing, and immoral in conduct. In all large towns the greater proportion, especially among the upper classes, are both physically and mentally feeble, owing to the effects of polygamy, early marriages, and degrading vices; but the peasantry are robust and vigorous, and much might be hoped for from them if they were brought under the influence of liberal institutions, and if they had examples around them of the industry and enterprise of Western Europe. In religion the Muslems of Syria are *Sonnites;* that is, in addition to the written word of the Koran, they recognise the authority of the *Sonna*, a collection of traditional sayings and anecdotes of the prophet, which is a kind of supplement to the Koran, directing the right observance of many things omitted in that book. They are in general very exact in the observance of the outward rites

of their religion; and in Islâm there is little else. Their great feast of *Ramadân* is kept by a vast majority with scrupulous care; but it must be admitted that long abstinence has not the effect of sweetening their temper or improving their morals.

Besides the *Sonnites* or orthodox Muslems, there are three other sects which we must class under the common name, Muslem.

The *Metâwileh* or followers of Aly, son-in-law of Mohammed. His predecessors on the throne, Abu-Bekr, Omar, and Othman, they do not acknowledge as true khalifs. Aly they maintain to be the lawful Imâm, and they hold that the supreme authority, both in things spiritual and temporal, belongs of right to his descendants alone. They reject the *Sonna*, and are allied in faith with the *Shiites* of Persia. They are almost as scrupulous about the "clean" and the "unclean" in their ceremonial observances, and in the ordinary affairs of life, as the Hindoos. They will neither eat nor drink with those of another faith, nor will they use the ordinary drinking or cooking vessels of others. The districts where they chiefly reside are Bâalbek; Belâd Beshârah, on the southern part of Lebanon; and round the village of Hurmul, near the fountain of the Orontes.

The *Nusairîyeh* or *Ansairîyeh*. It is not easy to tell whether this sect is to be classed among Muslems or not. Their religion still remains a secret, notwithstanding all attempts recently made to dive into its mysteries. They are represented by Asseman as holding a faith half Christian and half Mohammedan. They believe in the transmigration of souls, and observe in a singular, if not idolatrous, manner a few of the ceremonies common in the Eastern Church. They are a wild and somewhat savage race, given to plunder, and even bloodshed when their passions are roused or suspicions excited. They inhabit that range of mountains which bears their name, and which extends from the banks of the Orontes at Antioch to the entrance of Hamath.

The *Ismaelîyeh*, who inhabit a few villages on the eastern slopes of the Ansairîyeh Mountains, resemble the former in this, that their religion is a mystery. They were originally a subdivision of the Shiites, and are the feeble remnant of a people too well known in the time of the Crusades, under the name of *Assassins*. They have still their chief seat in the old castle of Masyâd, on the mountains west of Hamath.

2. *The Druzes*. The Druzes form one of the strongest, most united, and most remarkable sects in Syria. Their peculiar doctrines were first propagated in Egypt by the notorious Hâkim, the third of the Fatimite dynasty. This khalif, who gave himself out for a prophet, though he acted more like a madman, taught a system of half materialism, asserting that the Deity resided in Aly. In the year A.D. 1017, a Persian of the sect of Batanis, called Mohammed Ben-Ismail-ed-Derazy, settled in Egypt, and became a devoted follower of Hâkim. He not only asserted the absurd pretensions of the new Egyptian prophet, but he added to his doctrines that of the transmigration of souls, which he had brought with him from his native country; and he carried his fanaticism to such an extent that the people at last rose in a body and drove him out of Egypt. He took refuge in Wady-et-Teim, a narrow valley at the western base of Hermon; and being secretly supplied with money by the Egyptian monarch, propagated his dogmas, and became the founder of the Druzes. His system was enlarged, and in some degree modified by other disciples of Hâkim, especially a Persian called Hamza, whom the Druzes still venerate as the founder of their sect and the author of their law. Hamza tried to gain over the Christians by representing Hâkim as the Messiah whose advent they expected. Such was the origin of the Druze religion. Their tenets, and especially their mode of worship, are still kept strictly secret. A few of their books have found their way to the public libraries of Europe; and it was the good fortune of the writer recently to obtain in Syria copies of their seven standard works, which had been taken by a Christian from one of their khulweh's during the war of 1845. Some of these works are written in a mystic style, unintelligible to ordinary readers. Their Confession of Faith seems to consist of the following propositions:—

(1.) The Unity of God, and his manifestations of himself to man in the persons of seven individuals, the last of whom was Hâkim.

(2.) Five superior spiritual ministers always existing. These have also appeared in the persons of men at various periods. The chief of them were Hamza and Christ.

(3.) The transmigration of souls. The souls of men never pass into animals.

(4.) The belief in a period when their religion shall be triumphant,—Hâkim shall reign, and all others shall be subject to him for ever.

(5.) The seven points of Islâm are set aside, and the following substituted:—1. Veracity (to each other only). 2. Mutual protection and aid. 3. Renunciation of all other religions (implying persecution of all others when practicable). 4. Profession of the unity of Hâkim (as God). 5. Contentment with his works. 6. Submission to his will. 7. Separation from those in error and from demons.

The Druzes are divided into two classes, the "initiated" and the "uninitiated." With the former all the rites and ceremonies remain strictly secret. The holy books are kept under their care. They have some ceremonies, or are supposed to have some, which are less pure and spiritual than those set forth in their creed. They assemble in their chapels (*khulwehs*) every Thursday evening, refusing admission to all others. What they do then and there is unknown. A figure of a calf made of brass or other metal has been found in their places of worship, and is supposed by some to be an idol, but this they deny, and there can be no doubt that their books do not seem to teach or favour idolatry. Their places of worship are always in remote but conspicuous spots, as if to secure privacy and effectually guard against intrusion. On the whole, they seem to be more a political than a religious body. Their secret meetings are for collecting and communicating information, rather than for worship. The initiated are their chief advisers both in peace and war. The whole country in which they reside is divided into districts; each district has its council of initiated assembling weekly; a delegate from each council appears at the meetings of the councils of bordering districts to hear and to detail everything effecting the Druze interests. The rapidity and accuracy with which news is thus propagated is astonishing, and is of vast importance in time of war.

The Druzes are industrious and hospitable when at peace, but in war they are noted for their daring ferocity. They occupy the southern section of the ridge of Lebanon. They also abound in villages on the eastern and western declivities of Hermon and in Jebel-Haurân. There are a few in Damascus, and in one or two villages near it. Their numbers may be estimated at about 80,000.

3. The Christians are divided into several sects, as follows:—

The Greeks. They are called Greeks simply because they profess the Greek faith, and belong to the Greek or Oriental Church. They are Syrians both by birth and descent; and there is not a trace either in their spoken language, or in the language of their ritual, of any national affinity with the people of Greece. Their number has been estimated at about 115,000. The Greek Church in Syria is divided into the two patriarchites of Antioch and Jerusalem. They are nominally indeoendent, but virtually

Syria.

under the control of the Patriarch of Constantinople. The jurisdiction of the Patriarch of Antioch, who usually resides at Damascus, extends from Asia-Minor to Tyre, and includes (in Syria) the eight bishoprics of Beyrout, Tripolis, Akkar, Laodicea, Hamah, Hums, Saidnaya, and Tyre. The patriarchite of Jerusalem includes the whole of Palestine, and the country east of the Jordan. Its sees are Nazareth, Acre, Lydda, Gaza, Sebaste, Nabulus, Philadelphia, and Petra. The Greek Church enjoys the privilege of having its religious services conducted in the language of the people. It is unfortunate, however, that nearly all the higher clergy are foreigners. They all look to Russia as their natural protector; and Russian gold is profusely expended in the decoration of their churches and support of schools. The parish clergy *must* all be married men; and most of them are selected from among the lowest of the people, with no other fitness for the sacred office than that which the ceremony of ordination confers.

The Syrians or *Jacobites*, originally separated from the Eastern Church on account of the Monophysite heresy. Their head is the patriarch, who resides in Mesopotamia. Their number is very small. The village of Sudud, south-east of Hums, on the borders of the desert, is their head-quarters. They are regarded by all the other sects as heretics; and because they are few and poor they are generally despised.

The Maronites. This sect originated during the Monothelitic controversy of the seventh century. A monk called *John Maron* was the apostle of this heresy among them, and they consequently received his name. In the year 1180 they renounced Monothelitism, and submitted to the authority of the Pope, since which time they have been characterised by an almost unparalleled devotedness to the see of Rome. In order to increase Romish influence among them, a college was founded in that city by Gregory XIII. for the education of a select number of their youth. The two celebrated Oriental scholars and writers, J. S. and J. A. Assemanns, were Maronites, trained in this college. It is remarkable, however, that a church so devoted to the papacy should deviate so far from the Latin ritual. Their ecclesiastical language is Syriac; they have their own distinct church establishment; and every candidate for the priesthood is permitted to marry before ordination.

The Maronites are found in small communities in all the large towns from Aleppo to Nazareth; but they are at home in Lebanon. This mountain-range they inhabit more or less throughout its whole extent; but their great stronghold is the district of Kesrawan, east of Beyrout. Their patriarch, who is their spiritual chief, is selected by the bishops, though he receives the robe of investiture from Rome. The Maronites have a strange taste for the cloister. The number of their convents is greater in proportion than that of any other sect in Christendom. Their whole community does not exceed 220,000 souls; and yet they have in Lebanon alone 82 convents, containing above 2000 monks and nuns. The Maronites are brave and industrious; and their native mountains, though steep and rugged, are the garden of Syria.

The Papal Schismatic Churches have sprung from the missionary efforts of Romish priests and Jesuits during the last two centuries. As the object was to gain partisans, more pains were taken to obtain nominal submission to the authority of the Pope than any real change of doctrine or ritual. They still retain their Arabic service, their oriental calendar, their communion in both kinds, and their married clergy. Their spiritual chief takes the pompous title of "Patriarch of Antioch and all the East." The community numbers about 40,000.

4. *The Jews.* A sketch of the inhabitants of Syria and Palestine would not be complete without a notice of the Jews. In one sense they are the most interesting people in the land. For eighteen centuries have they been driven forth from the country of their fathers, and yet they cling to its holy places still. They moisten the stones of Jerusalem with their tears; her very dust is dear to them, and their most earnest wish on earth is that their bodies should mingle with it. The tombs that whiten the side of Olivet tell a tale of mournful bereavement and undying affection unparalleled in the world's history. The Jews of Palestine are all foreigners. They live almost exclusively in the four holy cities, Jerusalem, Hebron, Tiberias, and Safet; and their whole number does not exceed 9000.

Altogether different from these are the Jews of Damascus and Aleppo. They are Arabs in habits and language, in so far at least as religion will permit. Some of them are men of great wealth and corresponding influence. For generations they have been the bankers of the local chiefs, and have often and fearfully realized all the strange fluctuations of Eastern life—now ruling a province, now gracing a pillory; at one time all-powerful favourites, at another disgraced and mutilated outcasts. Their number is about 15,000.

5. *The Turks.* The Turks are few in number, strangers in race and language, hated by every class, wanting in physical power, destitute of moral principle, and yet they are the despots of Syria. Those occupying the higher government situations are all Turks. They obtain their power by bribery, and they exercise it for extortion and oppression. Their character has been ably sketched by Hamilton:—"They are all ignorant and presumptuous, vain and bigoted, proud without any feeling of honour, and cringing without humility; they cannot resist the temptation of money, or the prospective benefit of a lie. In their government and administrative duties they are tyrannical and overbearing, in their religious doctrines dogmatical and intolerant, and in their fiscal measures mercenary and arbitrary. They are as ignorant of their own history as that of other nations; and this is the case even with the better educated, who are in most respects far inferior in character, probity, and honour to the peasants and the lower classes. As long as the Turk is poor, and removed from temptation, he is honest; but no sooner is he appointed to office, or obtains the management of public money, than his uneducated mind is unable to withstand the charm, and he becomes a peculator and a thief. He appropriates to himself whatever he can lay hands on, and oppresses those below him; while, for the sake of securing his ill-gotten plunder, he propitiates his superiors by bribery and adulation. This has undoubtedly led to the demoralizing practice of the Turkish government of selling all places to the highest bidder, allowing him in return to make the most he can out of the unprotected subjects by extortion and taxation." The Turkish rulers of Syria are here drawn to the life. The country has been ruled for centuries by foreign tyrants. who have no interest in either the soil or the people, save that of grasping their whole available wealth. The Turks have only been able to rule by the cruel policy of pitting against each other the various rival sects and parties. The results are patent—poverty, hatred, bigotry, and bloodshed. A few places along the coast have latterly began to show signs of new life, owing mainly to the enterprise of European merchants, and the protection afforded to property by the influence of European consuls. Beyrout shows what Syria might become under a liberal and paternal government. The eastern border affords a marked contrast to the western. Hundreds of towns and villages are there deserted, though not ruined, and every year adds to their number, while tens of thousands of acres of the richest soil are abandoned to the periodical raids of the Bedawin.

Ruins.

Syria, like Palestine, is emphatically a land of ruins. In some of her fairest provinces desolation reigns triumphant.

Syria.

Many of her noblest cities are now heaps of rubbish; others, though not ruined, are deserted. The silent streets and empty houses, and lonely, desolate palaces and temples of the latter, are even more painfully, more terribly impressive than the utter ruin of the former. The writer has seen in the province of Haurân alone nearly one hundred towns and large villages, most of which contain from fifty to five hundred houses each, perfect in every part as if only built yesterday, and yet there is not now, and history tells us there has not been for centuries, a single man to dwell in them. These houses are all of remote antiquity. Their walls, roofs, doors, and window-shutters are of stone, and so massive as almost to bid defiance to time. The names of a few of them are known in history—such as Phæno, Batanæa, Kenath, Salcah, Philippopolis, Beth-Gamul (Porter's *Damascus*, vol. ii.) In northern Syria there are also many deserted cities, some of which are in a wonderful state of preservation. In Jebel Simân, west of Aleppo; in Jebel-el-Ala, on the east bank of the Orontes; and again, around El-Bara, farther southward, these ancient deserted towns are found. (See Porter's *Handbook*, pp. 609, 617, sq.)

Some of the ruins of Syria, in their massive proportions and architectural splendour, rank among the finest in the world. Bâalbek may be said to stand unrivalled, its cyclopean foundations containing stones from 60 to 70 feet long, surmounted by temples finished in the highest style of Grecian art. Palmyra, though less colossal and less pure in style, is still more striking in the vast extent of its ruins. The long colonnades of Apamea, the great tunnels and docks of Seleucia, and the massive fortifications of Tyre and Aradus, cannot fail to excite wonder and admiration. There are, besides, in the ranges of Lebanon and Anti-Lebanon, upwards of fifty temples more or less dilapidated; and there are some huge castles, such as those of Banias, Esh-Shukîf, Hunîn, El-Husn, Aleppo, Damascus, Bozrah, and Salcah, which prove that the old Syrians were masters in the science of military architecture. Of the ancient great cities of Syria no less than nine are now completely desolate—namely, Apamea, Laodicea-ad-Libanum, Seleucia Pieria, Orthosia, Arca, Chalcis, Phaeno, Bozrah, and Salcah; eight have dwindled down to poor and miserable villages—namely, Heliopolis, Palmyra, Tyre, Aradus, Riblah, Gebal, Edrei, and Kenath; Antioch, the capital in the age of Roman splendour; Sydon, the ancient capital of Phœnicia; and Hamath, one of the primeval strongholds of the Canaanites, are now small decaying towns; while Damascus alone, the oldest city of Syria, of the world, still retains its ancient prosperity.

History.

The earliest notices of Syrian history are found in the Bible, which is at once the most ancient and the most authentic of all histories. In the 10th chapter of Genesis there is a brief record of the colonization of the nations of the world by the descendants of Noah. From this it appears that Syria, by the nature of its first settlement, was divided into two sections, which remained distinct for nearly 2000 years. The first section, embracing the whole eastern division of the country, was peopled by the family of Aram, Damascus being the metropolis, and probably the nucleus of the colony. The second, or western division, was colonized by the sons of Canaan—Sidon, Arka, and Arvad—who settled on the coast and in the ridge of Lebanon; and Hamath, who penetrated farther eastward than his brethren. The next event in the history of Syria was the advent of Abraham. A very early tradition represents him as settling for a time at Damascus; and it is corroborated by two facts,—his steward was a native of that city, and not far from Damascus there is still a sacred spot called by the name of the Patriarch. For a period of nearly nine centuries we have no records of Syrian history. In the time of King David (B.C. 1040), Syria is represented as consisting of a number of independent kingdoms, as Zobah, Damascus, Maachah, and Geshur. Against these the Jewish monarch waged war, and, being successful, placed garrisons in their principal cities. After the death of David, Syria regained its independence. Now, however, the kingdom of Damascus attained to such power as to be the recognized head of Syria. Under the warlike dynasty of the Hadads it became the most influential kingdom in Western Asia; and by frequent incursions into the territories of Israel and Judah, and by the pillage of many of its cities and villages, it terribly revenged the victories of David. The watchful care and prophetic power of Elisha saved Israel for a time from the fury of its foe, and brought upon the armies of Benhadad unexpected calamities. About B.C. 892 Damascus was honoured by a visit from the prophet. Benhadad was then sick, and his sufferings not only made him overlook his old enmity to Elisha, but constrained him to consult him as to his recovery. The man who was sent on this errand was Hazael, whose guilty designs the prophet detected and exposed. His reply and subsequent conduct were thoroughly characteristic of the wily and cruel eastern, "Is thy servant a dog that he should do this thing?" he exclaimed; and then turning away, he hastened to Damascus and murdered his master! Thus terminated the dynasty of Hadad, after a rule of more than 160 years. Hazael succeeded to the throne, and proved both a wise monarch and able general. Under him the armies of Syria were victorious to the borders of Egypt. His successors did not inherit his genius, and the power of Syria began to decline. About B.C. 750 Rezin, the last independent ruler of Syria, entered into an alliance with the king of Israel, and waged war against Judah. The latter, in its difficulties, sought aid from the powerful monarch of Assyria, Tiglath-Pileser, who was not slow to give it. He marched at once across the desert, overran Syria, took Damascus, and carried the inhabitants captive to the banks of the Kir. (2 Kings xvi.; Joseph. *Antiq.* ix. 12; Amos i. 4.)

Syria now became a mere dependency of a more powerful empire, and was ruled by foreign satraps. It remained a province of Assyria until, during the struggles of the eastern monarchs, it was seized by Pharaoh-Necho, king of Egypt. A few years afterwards it was captured by Nebuchadnezzar (B.C. 604), and for a period of three centuries continued subject to the Babylonian and Persian administrations.

Immediately after the great battle of Issus (B.C. 333), Syria passed into the hands of a different dynasty and a different race. Alexander the Great became its ruler. He assigned it to the general Laomedon, and Damascus became the seat of his short sway. After the death of Alexander, and the brief but fierce struggle of his lieutenants over the fragments of his gigantic empire, the fortunes of war threw Syria into the power of Seleucus Nicator, the founder of the dynasty of the *Seleucidæ*. This prince built Antioch, and made it the seat of his government. He and his successors on the throne may justly be termed a race of architects. They not only adorned their capital with structures which rivalled in splendour the noblest monuments of Greece; but they founded many other great cities in various parts of the country. Though almost constantly at war, their kingdom was for nearly 200 years one of the most prosperous in the world. From the commencement of the reign of the Seleucidæ, till the year B.C. 114, Antioch remained undisputed capital. At this time the kingdom was rent by the intrigues of Ptolemy Physcon; and Antiochus Cyzicenus, brother of the reigning monarch, established a new sovereignty at Damascus. Just half a century later the Roman army under Pompey overran Syria, abolished the dynasty of the Seleucidæ, and established their head-quarters at Damascus. Syria was immediately annexed to the Roman empire, and placed under the command of Scaurus, Pompey's lieutenant. For many years

after the conquest, the country was the scene of devastating wars, arising partly from the feuds of petty princes, and partly from the rivalries of Roman governors. After the triumph of Augustus, Mesalla Corvinus was appointed prefect, and henceforth the seat of government was fixed at Antioch.

In the year A.D. 105, Cornelius Palma, the governor of Syria under the emperor Trajan, conquered the region east of the Jordan, and the neighbouring kingdom of Aretas. From this time the various provinces of Syria began to recruit under the secure and paternal government of Rome. Temples, theatres, palaces, and public monuments of great extent and splendour, were erected not only in the chief cities, but in every little provincial town; and their remains even yet, after long centuries of desolation, bear ample testimony to the genius, the wealth, and the taste of the old Syrians. Roads also were constructed, bridges were built, and costly harbours formed. The country remained under Roman and Byzantine rule till A.D. 634. The only circumstances that occurred previous to that period, and which are deserving of notice in a brief sketch like the present, are the establishment of Christianity under the first Constantine, and the conquests of the Persians early in the seventh century. Christianity had spread widely over the land before its establishment as the religion of the empire; and the numbers, the wealth, and the taste of the Christians subsequent to that period may still, to some extent, be estimated by the splendid ruins of sacred edifices in the cities, towns, and villages of Syria.

The Arabs, under the generals Khaled and Abu Obeidah, first invaded Syria in A.D. 633; and only five years afterwards the whole country was conquered, and every city in it garrisoned by their troops. In sixteen years more Damascus became the capital of the vast Mohammedan empire. Syria was then densely populated. Her cities scarcely yielded to any in the world in extent, wealth, and architectural magnificence; but under the withering influence of Islamism their grandeur faded, and their wealth was consumed.

In A.D. 750 the dynasty of the Abassides was founded, and the khalifite was removed from Damascus, first to Cufa and then to Baghdad. Henceforth Syria was a province of the Mohammedan empire. From this period till the middle of the tenth century it was subject to the Khalifs of Baghdad, but it then fell into the hands of the Fatimite dynasty of Egypt. Towards the close of the following century the country was invaded by the Seljukian Turks, and formed into a division of their empire. The cruelties perpetrated by these fanatics on the poor Christian pilgrims that thronged yearly to Jerusalem roused the spirit of western Europe, and excited Christian nations to the first Crusade. In a short time the knights of France and England, headed by Godfrey, were winding through the valleys and marching over the plains of Syria. The fierce, undisciplined followers of the false prophet could not withstand their steady valour. The country was subdued, Jerusalem was taken by storm, and the cruelties perpetrated on Christian pilgrims were fearfully avenged.

Godfrey was elected first Christian king of Jerusalem. Bohemund reigned at Antioch; Baldwin, Godfrey's brother, at Edessa; and the Count of Toulouse at Tripolis. Thus was the country divided into Christian principalities, and ruled by the bravest knights of western Europe. Damascus, however, withstood every assault of the Crusaders; and it is still the boast of the proud Muslem, that its sacred precincts have never been polluted by the feet of an infidel since the dav the soldiers of Mohammed first entered it.

About the middle of the twelfth century Nur-ed-Dîn, a Tartar chief, seized Damascus and some neighbouring cities. He ruled his acquired territory with justice and vigour. At the request of the Fatimite Khalif, he attacked and defeated the Crusaders on the borders of Egypt. His successor, Saladin, was by far the most formidable opponent the Crusaders ever encountered. After gaining a decisive victory over their united forces at Hattîn, near Tiberias, he captured Jerusalem (A.D. 1187), and drove the Franks out of almost every town and fortress of Palestine. Soon afterwards Syria was invaded by the shepherd-soldiers of Tartary, under Holagou, the grandson of Gengis Khan. But, after the death of this chief, Bibars, better known in Arabian history as Melek-edh-Dhaher, brought Syria under the rule of Egypt, and pursued the Tartars beyond the Euphrates. His victories were fatal to the declining power of the Crusaders. Their remaining history is one continued tale of misfortunes. At length, in A.D. 1291, Acre was taken, and the Christian knights driven from the shores of Syria.

For more than two centuries after this period the country was the theatre of fierce contests between the hordes of Tartary and the Mamluke rulers of Egypt. Timur, or Tamerlane, invaded Syria in A.D. 1401, and committed the most fearful ravages. Antioch, Emesa, Bâalbek, and Damascus were reduced to ashes, and their unfortunate inhabitants either murdered or sold into slavery.

In the year 1517 Syria was conquered by the Sultan Selim I., and from that time till the present day it has formed part of the Ottoman empire. During this period, though the country has been visited by few striking vicissitudes, it has steadily declined in power, wealth, and population. The greater part of the inhabitants, oppressed by foreign rulers who take no interest in commerce or agriculture, have sunk into helpless and almost hopeless slavery. What little energy and spirit remain are exhausted in private quarrels and party feuds, which are sedulously fostered by their unprincipled rulers. In 1832 Ibrahim Pasha conquered Syria for his father, Mohammed Aly. The iron rule of that wonderful man did much to break down the fanaticism which for ages has been a curse to the people. He promoted industry, he suppressed the robber bands which infested the leading roads, and he drove the Arab tribes from the eastern borders to the interior of their native deserts, and even there he taught them to fear and obey him. Though the whole population groaned under his yoke, yet it may be truly said that he was the only real ruler Syria had for centuries. In the year 1841, through the armed intervention of England, the country was restored to the Porte.

The long history of Syria may thus be divided into six periods; and it is remarkable that, during each period, a distinct section of the human family has had rule over it. During the first period, of about 1450 years, it was independent under its native princes. During the second period, of 417 years, the Babylonian and Persian monarchs held it. During the third period of 268 years, it was subject to the Greek dynasty of the Seleucidæ. During the fourth period, of 699 years, the Romans possessed it. During the fifth period, of 441 years, it was desolated rather than governed by the Saracens or Arabs. It then fell into the hands of the Tartar or Turkish tribes, who still retain it. But their power is rapidly declining. The throne founded by Othman is tottering to its fall; and the sixth period of Syrian history is fast drawing to a close. (J. L. P.)

SYSTYLE. See ARCHITECTURE, *Glossary* to.

SYZRAN, a town of European Russia, government and 78 miles S. of Simbirsk, on a hill at the confluence of the Syzran with the Volga. It is meanly built, and has unpaved streets. There are here ten churches, two of which are of wood; a monastery; an important cattle market; manufactories of soap and leather, and an active trade. Pop. 15,400.

SYZYGY. See ASTRONOMY.

SZALONTA, a market-town of Hungary, in the county of South Bihar, 50 miles S.S.W. of Margitta. It contains a church; and has an active trade in cattle and swine. Pop. 9500.

SZARRAS, a market-town of Hungary, in the county of Bekes, 13 miles N.N.W. of Gyulla, in a plain near the river Körös. It has two churches; a Protestant gymnasium, and a trade in corn and cattle. Pop. 17,000.

SZASZ REGEN, or SAXON REEN, a market-town of the Austrian empire, Transylvania, on the Maros, in the circle and 25 miles S. of Bistritz. Weaving, tanning, and coopering are carried on here; as well as a considerable trade in planks, shingles, and onions. In the vicinity stands the fine ducal palace of Gernyeszeg. Pop. 4140.

SZATHMAR, or SZATHMAR-NEMETI, a free town of Hungary, capital of a county of the same name, on the Samos, 69 miles E.N.E. of Grosswardein, and about 60 E. of Pesth. It consists properly of two towns, Szamos and Nemeti, on opposite sides of the river, but united under the same municipal government. It is for the most part ill built; but contains a number of public buildings. It is the seat of a bishop; has Protestant and Roman Catholics churches; an Episcopal lyceum; theological seminary; Catholic and Protestant gymnasiums, and other schools. Linen cloth, earthenware, and plum brandy are made here; wine and fruit are raised in the vicinity. Pop. 10,552.

SZEGEDIN, a town of the Austrian empire, Hungary, capital of the county of Csongrad, on the right bank of the Theiss, 60 miles W. of Arad, and 89 S.S.E. of Pesth. The river is here crossed by a bridge of boats, leading to the suburb of New Szegedin on the other side. The town is defended by an old fortress, built by the Turks in the beginning of the sixteenth century, containing barracks and a house of correction. There are also six Roman Catholic churches, one of them a fine Gothic building; a handsome Greek church; a Piarist college, with a gymnasium; a school of industry and trade; and a Hungarian national theatre. Cloth, tobacco, soda, and soap are made here; and vessels for the navigation of the Theiss are built. An important trade is carried on; and annual cattle fairs are held. Pop. 50,244.

SZENTA, or ZENTA, a town of Hungary, in the county of Zombor, on the right bank of the Theiss, 10 miles S. of Kis-Kamsa, and 42 E.N.E. of Zombor. It contains two churches; has an important fishery in the river; and an extensive trade in cattle. Szenta is historically memorable for a victory gained over the Turks here by Prince Eugene, September 11, 1696, the anniversary of which is still celebrated here. Pop. 14,985.

SZENTES, a market-town of Hungary, in the county of Csongrad, on the Kurcza, 29 miles N.N.E. of Szegedin. It is well built; and has a town-house, five churches of different sects, a Latin school, and a trade in corn, wine, timber, and cattle. Pop. 22,150.

SZEXARD, or SZEGSZARD, a market-town of Hungary, capital of the county of Tolna, on the Sarvitz, not far from the Danube, 81 miles S.W. of Pesth. It is defended by dykes from the inundations of the Danube, and is generally well-built, having Protestant and Roman Catholic churches, a high school, a large silk mill, and a considerable trade, especially in wine. Pop. 10,500.

SZIGETH, a market-town of Hungary, capital of the county of Marmaros, on the Theiss, 221 miles E.N.E. of Pesth. It has Protestant and Roman Catholic churches; two gymnasiums, and a Piarist college, large salt-works, and a trade in salt. Pop. 6300.

SZOLNOK, a market-town of Hungary, capital of a county of the same, on the Theiss, at its confluence with the Zagyra, in the midst of marshes, 29 miles S. by W. of Heves, and 49 S.E. of Pesth. It has the remains of an old cathedral; a church; an old Turkish mosque, now a chapel; a gymnasium; court of law; and extensive salt-works. There is an active trade in salt, timber, fruit, and fish. Pop. 10,617.
